Results.—Before the days of antisepsis ligation of the subclavian was a very fatal operation. Poland estimated the mortality at 70 per cent. In most cases death was due to secondary hemorrhage. Koenig collected 20 cases of ligation of the first part of the right subclavian, with 19 deaths. Lilienthal believes that the mortality after ligating the first portion on the right side is now only 16 per cent. (quoted by Neff, in "Annals of Surg.," Oct., 1911). According to Joseph D. Bryant, there have been 134 deaths in 250 ligations at various points of the subclavian ("Operative Surgery"). I have twice tied this vessel with success. Gangrene seldom follows ligation of the subclavian. In 42 recoveries after ligation of various points there was 1 case of gangrene of the arm (Poiret's statistics, quoted by Neff, in "Annals of Surg.," Oct., 1911). In Von Bergmann's 90 ligations for gunshot-wounds there was not a case of gangrene of the arm and only 3 of gangrene of the fingers.

The **vertebral artery** was first successfully ligated by Smythe, of New Orleans, in 1864. He had ligated the innominate for aneurysm of the subclavian and at the same time tied the common carotid. Secondary hemorrhage occurred, the blood coming from the brain. He arrested it by tying the vertebral.

Anatomy—This vessel is the largest branch of the subclavian, and is the first branch coming from the first portion of the subclavian. The vertebral artery ascends and enters the foramen in the transverse process of the sixth cervical vertebra (in rare cases the fifth or the seventh), and ascends through foramina in the cervical vertebræ, passes behind the articular process of the atlas and over the posterior arch of this first vertebra, pierces the posterior occipito-atloid ligament, and enters the skull by way of the foramen magnum ("Gray's Anatomy"). It joins its fellow of the opposite side to form the basilar artery. At its point of origin the vertebral artery has in front of it the internal jugular vein and inferior thyroid artery. Near the spine it lies between the longus colli and scalenus anticus muscles, and on the left side has the thoracic duct to the left and in front.

Ligation.—The position of the patient is the same as for ligation of the carotid artery. Alexander thus describes the operation: "An incision 3 or 4 inches long is made in an upward and outward direction along the hollow which exists between the scalenus anticus and the sternomastoid muscles. The incision should begin just outside and on a level with the point where the external jugular vein dips over the edge of the sternomastoid muscle, or, if the vein is invisible, about ½ inch above the clavicle. The external jugular vein is drawn inward with the sternomastoid muscle. The connective tissue now appearing, the wound is opened by a blunt dissector until the scalenus anticus muscle, the phrenic nerve, and the transverse cervical artery are seen. It cannot be too well remembered that the pleura is at the inner side of the wound, while below lies the subclavian artery. It is now only necessary to separate the edges of the scalenus anticus and the longus colli muscles to see the vertebral artery lying in the space between them. The artery is generally completely covered by the vein, which is drawn aside, and the artery is then ligatured" (quoted in Bryant's "Operative Surgery"). When the vessel is cleared and tied, branches of the inferior cervical ganglion are damaged and possibly included in the ligature, and as a consequence the pupil contracts. Jacobson tells us to remember that the phrenic nerve lies

on the scalene muscle, the pleura is internal, the internal jugular, inferior thyroid, and vertebral veins are over the vessel, and the thoracic duct on the left side crosses it from within outward.

Results.—In 36 ligations of the vertebral artery there were 3 deaths (Joseph D. Bryant).

The Inferior Thyroid Artery. **Anatomy.**—The inferior thyroid artery is a branch of the thyroid axis. It ascends the neck, passes back of the carotid sheath and the sympathetic nerve, and reaches the thyroid gland. The recurrent laryngeal nerve lies behind the artery. The phrenic nerve is external to the artery and near to it in the first part of its course (up to the point of origin of the ascending cervical branch). The ascending cervical branch takes origin just before the artery begins to dip behind the carotid. In front of the beginning of the inferior thyroid artery of the left side the thoracic duct crosses. The artery is ligated in the second part of its course (between its distribution and the origin of the above-named branch).

Ligation.—The position of patient and the incision are the same as for the ligation of the common carotid artery in the triangle of necessity (see page 550). After exposing the sternocleidomastoid muscle retract it outward, and then draw outward the common carotid artery and also the internal jugular vein. The inferior thyroid artery will be found a little below the carotid tubercle. It is cleared and ligated. Treves advises ligation close to the level of the carotid, so as to avoid the recurrent laryngeal nerve.

Innominate Artery.—The innominate artery was first ligated by Valentine Mott, of New York, in 1818. It was first successfully ligated by Smyth, of New Orleans, in 1864. Symth's operation was performed for subclavian aneurysm. He tied the common carotid as well as the innominate and at a later seance tied the vertebral artery because of hemorrhage.

Anatomy.—The innominate artery arises from the beginning of the transverse portion of the arch of the aorta, passes to the back of the right sternoclavicular joint, and divides into the common carotid and subclavian vessels. It rests upon the trachea. It has upon its outer side the pleura, the right innominate vein, and the pneumogastric nerve. Upon its inner side are the remnant of the thymus gland and the beginning of the left carotid artery. In front of it are the inferior thyroid veins of the right side, the left innominate vein, the sternohyoid and sternothyroid muscles, the remnant of the thymus gland, and sometimes a branch from the right pneumogastric nerve.

Ligation.—Place the patient supine, with the shoulders a little raised, and the head thrown back. Carry an incision from the upper margin of the sternum for 3 inches along the anterior margin of the sternomastoid. Make another cut of the same length along the upper border of the clavicle to meet the first cut. Dissect up the flap of skin and fascia. Divide the sternal origin and a part of the clavicular portion of the sternocleidomastoid muscle, and cut the sternohyoid and sternothyroid muscles just above their sternal origins (Joseph Bell). Retract the inferior thyroid veins. Divide the dense leaflet of cervical fascia. Find the common carotid artery, and trace back along this vessel until the innominate comes into view. Retract the left innominate vein downward. The needle is passed from without inward to avoid the right innominate vein and right pneumogastric nerve. If the needle is kept close to the artery the pleura and trachea will not be injured.[1]

Results.—Burns, of Memphis, collected 45 cases and added 1 of his own, making 46 cases, with 9 recoveries ("Jour. Am. Med. Assoc.," 1908). To these should be added Percy Sargent's successful case ("Lancet," May 6, 1911), making 47 cases and 10 recoveries. Hamann ("Annals of Surgery," 1914,

[1] See the exceedingly clear and terse account in that excellent book, "A Manual of Surgical Operations," by Joseph Bell.

lix) reported a successful case and collected the records of 53 ligations, 14 of which were successful. There is no note of gangrene in any of these cases. The ligation of this vessel, especially in the elderly may cause serious brain damage by cutting off circulation or by embolism. Brain changes are not so common as after ligation of the common carotid. Burrell's case in 1895 is counted as a success, although death occurred on the one hundred and fourth day. Smyth's case lived ten years. Sargent's case lived seventeen months and then died of pneumonia and pericarditis. He tied the common carotid as well as the innominate. The case of Coppinger, of Dublin, was alive and well two years after operation. Mitchell Banks's case lived over three months. Dr. Sinclair's case was well three months after operation and the pulse had not returned to the wrist ("Brit. Med. Jour., " March 3, 1917).

Region of the Neck.—Anatomy.—The side of the neck is that space beween the median line in front and the anterior edge of the trapezius muscle behind, which space is limited below by the clavicle and above by the body of the jaw and an imaginary line running from the angle of the jaw to the mastoid process. The sternocleidomastoid muscle divides this space into an anterior and a posterior triangle, and each of the triangles is subdivided by other structures, the anterior into four spaces and the posterior into two (Fig. 280).

The *anterior triangle* is bounded in front by the median line of the neck, behind by the anterior margin of the sternocleidomastoid muscle, and above by the body of the lower jaw and an imaginary line drawn from the angle of the jaw to the mastoid process. This space is subdivided into four smaller triangles—namely, the inferior carotid, the superior carotid, the submaxillary, and the submental.

The *inferior carotid triangle* is called the "triangle of necessity," because the common carotid artery in this region is ligated, not from choice, but through force of necessity. It is bounded in front by the median line, above by the anterior belly of the omohyoid muscle and the hyoid bone, and below by the anterior edge of the sternomastoid muscle. The floor of this triangle is composed of the longus colli, the scalenus anticus, the rectus capitis anticus major, the sternohyoid, and sternothyroid muscles.

The *superior carotid triangle* is known as the "triangle of election," because, if the carotid artery must be tied, the surgeon, whenever possible, elects or chooses to tie it in this triangle. In this region the carotid is superficial, and there can be tied either the external, the internal, or the common carotid artery, as the surgeon elects. The triangle is bounded behind by the anterior edge of the sternocleidomastoid, above by the posterior belly of the digastric, and below by the anterior belly of the omohyoid muscles. Its floor is composed of the inferior and middle constrictors of the pharynx, the thyrohyoid and hyoglossus muscles.

The *submaxillary triangle* is bounded above by the body of the jaw and an imaginary line drawn from the angle of the jaw to the mastoid process, behind by the posterior belly of the digastric muscle and the stylohyoid muscle, and in front by the anterior belly of the digastric muscle. Its floor is composed of the mylohyoid and hyoglossus muscles.

The *submental triangle* is bounded on either side by the anterior belly of one digastric muscle; its base is the hyoid bone and its floor is the mylohyoid muscle.

The *posterior triangle* is bounded in front by the posterior border of the sternocleidomastoid muscle, behind by the anterior edge of the trapezius muscle, and below by the clavicle. The posterior belly of the omohyoid muscle subdivides it into two smaller spaces, the occipital and subclavian triangles.

The *occipital triangle* is bounded in front by the posterior edge of the sternocleidomastoid muscle, behind by the anterior border of the trapezius muscle, and below by the posterior belly of the omohyoid muscle.

The *subclavian triangle* is bounded above by the posterior belly of the omohyoid muscle, below by the clavicle, and in front by the posterior border of the sternocleidomastoid muscle. Its floor is formed by the first rib and the first serration of the serratus magnus muscle.

Common Carotid Artery.—The common carotid was tied to arrest bleeding by Abernethy in 1798. The man died in thirty hours. It is usually said that this was the first case of ligation of this vessel, a statement which Gross denies ("A System of Surgery"). In 1805 Sir Astley Cooper tied the vessel for carotid aneurysm. The patient died on the nineteenth day. In 1808 he ligated the vessel successfully for aneurysm. The *line* of the common carotid artery is from the sternoclavicular articulation to midway between the angle of the jaw and the mastoid process, the head being turned toward the opposite side.

Anatomy (Pl. 5, Fig. 3).—The right common carotid arises from the innominate opposite the sternoclavicular joint; the left common carotid arises from the arch of the aorta. In the neck the two carotids possess identical relations. The common carotid runs upward and outward from behind the sternoclavicular articulation to a level with the upper border of the thyroid cartilage, at which point it divides into the external and internal carotid. The common carotid is contained in a sheath derived from the cervical fascia. This sheath also contains, in separate compartments, the internal jugular vein on the outer side of the artery and the pneumogastric nerve between the vein and artery, but more deeply placed. The anterior edge of the sternocleidomastoid muscle lies over the artery and is a guide. Low in the neck the common carotid is deep, being covered by skin, superficial fascia, platysma, deep fascia, and the sternocleidomastoid, sternohyoid, and the sternothyroid muscles. Above the omohyoid muscle the vessel is more superficial, being covered by the skin, superficial fascia, platysma, deep fascia, and the anterior edge of the sternocleidomastoid muscle. Upon the sheath (occasionally within it), above the crossing of the omohyoid muscle, lies the descendens noni nerve —the descending branch of the ninth pair of Willis (the hypoglossal). This nerve is a valuable guide to the sheath in the triangle of election.

The *sternomastoid* branch of the superior thyroid artery crosses the carotid artery a little below its bifurcation, and the superior thyroid vein also crosses it in this region; the middle thyroid vein crosses the artery near its middle, and the anterior jugular vein crosses low down. The common carotid rests upon the longus colli and rectus capitis anticus major muscles, the sympathetic nerve lying between the last-named muscle and the vessel, outside the carotid sheath. The recurrent laryngeal nerve passes behind the carotid below the omohyoid muscle, and the inferior thyroid artery passes behind the carotid just above the omohyoid muscle. The common carotid is in relation internally with the trachea, thyroid gland, larynx, and pharynx. To the outer side are the pneumogastric nerve (which is on a posterior plane) and the internal jugular vein. On the left side, low down in the neck, the jugular vein often lies in front, or partly in front, of the artery.

Ligation in the Triangle of Necessity.—In this operation the patient is placed supine, with the shoulders raised, a sand-pillow under the neck, and the head turned to the opposite side, with the chin raised. The operator stands upon the side operated upon. The incision, 3 inches long, at a slight angle to the arterial line, runs from the level of the cricoid cartilage downward and inward toward the sternoclavicular joint, following the inner border of the sternocleidomastoid muscle. The surgeon opens the deep fascia, draws the sternocleidomastoid outward, retracts the sternohyoid and sternothyroid muscles inward, and feels for the carotid tubercle of Chassaignac. This tubercle is the costal process of the sixth cervical vertebra, and lies directly under the artery. The tubercle is found about the point at which the omohyoid crosses the carotid. When the tubercle is found we know the situation of the artery,

and that the triangle of necessity is below, and the triangle of election above, the tubercle. The operator draws the omohyoid muscle upward, opens the sheath of the artery on its inner side, clears the vessel, and passes the needle from without inward to avoid the internal jugular vein, remembering that the pneumogastric nerve is in the same sheath as the artery and vein, posterior and external to the artery. In this operation the inferior thyroid veins are much in the way, the anterior jugular vein crosses low down, and on the left side, at the root of the neck, the internal jugular vein may be in front of the carotid artery. If the incision is not sufficiently wide, partially divide the sternocleidomastoid or the sternohyoid and thyroid muscles. In the triangle of necessity the descendens noni nerve does not serve as a guide to the sheath of the vessels. (See Pl. 5, Fig. 4.)

Ligation in the Triangle of Election (Fig. 281).—The *position* of the patient for this operation is the same as in the preceding one. An incision, 3 inches in length, is made along the anterior edge of the sternocleidomastoid muscle in the line of the artery, the middle of this incision being opposite the cricoid cartilage (Fig. 281). In cutting the superficial fascia the surgeon avoids the external jugular vein, the course of which should be outlined before making the incision. The line of the external jugular is from the angle of the jaw to the middle of the clavicle. The operator opens the deep fascia, retracts the sternocleidomastoid muscle outward, feels for the carotid tubercle, draws the omohyoid muscle downward, finds the descendens noni nerve upon the sheath, opens the sheath at its inner side, and passes the needle from without inward. This incision permits ligation of either the superior thyroid or the external, internal, or common carotid, and if it be extended up a little there can be tied through it the lingual and even the facial and occipital arteries. (See Pl. 5, Fig. 4.)

Results.—In from 20 to 25 per cent. of cases after ligation of the common carotid artery there is cerebral softening or some other intracranial complication. Delbet says that cerebral complications follow in one-fifth of the cases. Jordan says in one-fourth of the cases. Crile does not think they are nearly so frequent. Crile states that of the cases that develop cerebral trouble, one-half die. The direct operative mortality, according to Crile, is only 3 per cent. Some modern operators regard the mortality as much higher than this. I was obliged to tie the common carotid during an operation for tumor of the carotid gland; the patient developed hemiplegia. Occlusion of the artery by a removable metal band is much safer than ligation (page 488).

External Carotid Artery.—Burke ligated the external carotid in 1827 (Treves, from Chelius). The *line* of the external carotid artery is the upper portion of the common carotid line.

Anatomy (Pl. 5, Fig. 3).—The external carotid artery, which is one of the terminal branches of the common carotid, arises on a level with the upper border of the thyroid cartilage and runs to the level of the neck of the condyle of the lower jaw. At its point of origin it is covered only by skin, platysma and fascia, and the edge of the sternomastoid, but as it ascends it passes beneath the digastric and stylohyoid muscles and into the parotid gland. The glossopharyngeal nerve, styloid process, and stylopharyngeus muscle lie between the external and internal carotid arteries. The hypoglossal nerve crosses the vessel just below the digastric muscle, and the facial and lingual veins cross it a little below the nerve. The first branch is the superior thyroid, which arises from the very beginning of the trunk. The lingual arises on a level with the greater cornu of the hyoid bone. The facial and occipital take origin above the lingual. Each of them can be ligated through the incision made for ligation of the external carotid.

Operation.—Place the patient in the same *position* as for ligation of the common carotid. The point of election is between the superior thyroid and

the lingual arteries. Make an incision 3 inches in length at a slight angle to the arterial line, from near the angle of the jaw to opposite the middle of the thyroid cartilage. Cut through the skin, superficial fascia, platysma and deep fascia, and retract the sternocleidomastoid muscle outward. Watch for the digastric muscle, find the hypoglossal nerve, and feel for the greater cornu of the hyoid bone. Open the sheath a little below the hyoid cornu and pass the needle from without inward. Ligation of the external carotid has been neglected because ligation of the common carotid is easier.

Results.—Crile believes the operative mortality to be 2 per cent.

Internal Carotid Artery.—The internal carotid was tied by Keith, of Aberdeen, in 1851 (Ashhurst's "International Encyclopedia of Surgery"). The *line* of the internal carotid is parallel with and ½ inch external to the line of the external carotid.

Anatomy (Pl. 5, Fig. 3).—The internal carotid artery, the other terminal branch of the common carotid, arises on a level with the upper border of the thyroid cartilage and enters the carotid canal. The first inch of the artery is the only point where a ligature is ever applied, this point being covered only by skin, platysma, fascia, and the sternocleidomastoid muscle; higher up the artery is more deeply placed. It rests upon the vertebræ and the rectus capitis anticus major muscle. The internal jugular vein is in the same sheath and external to the artery; the pneumogastric is in the same sheath, between the artery and the vein, but posterior to both. The superior cervical ganglion of the sympathetic lies behind the origin of the internal carotid, and between the ganglion and the artery is the superior laryngeal nerve.

Operation.—In this operation the *position* of the patient is the same as for ligation of the external carotid. The incision is of the same length and direction as that for ligation of the external carotid, and is ½ inch external. The sternocleidomastoid muscle is drawn outward, the external carotid artery is found and drawn inward, the internal carotid is found and cleared, and the needle is passed from without inward. The internal carotid is known by its more external position and by the fact that it gives off no branches.

Results.—There is the same danger of cerebral complications after this operation as after ligation of the common carotid. The operative mortality is probably as great.

Superior Thyroid Artery (Pl. 5, Fig. 3).—This branches off from the external carotid below the level of the greater cornu of the hyoid bone, in the triangle of election. It is primarily superficial, runs first upward and inward, next downward and forward, passes underneath the omohyoid, sternohyoid, and sternothyroid muscles, and reaches the thyroid gland.

Ligation.—The position of the patient and of the surgeon is the same as for ligation of the carotid. The artery may be reached through the incision employed for ligation of the external carotid. Gross made an incision beginning at the edge of the hyoid bone, and running downward and outward to the sternomastoid muscle. The skin and superficial and deep fasciæ are divided, and the artery is found deeply placed in the triangle of election between the carotid sheath and the thyroid gland.

Lingual Artery.—Sir Charles Bell ligated the first part of the lingual artery in 1814. The operation beneath the hyoglossus muscle was devised by Pirogoff in 1836 (Treves's "Manual of Operative Surgery").

Anatomy (Pl. 5, Fig. 3).—The lingual artery arises from the external carotid opposite the greater cornu of the hyoid bone, passes beneath the digastric and stylohyoid muscles, reaches the margin of the hyoglossus muscle, passes under that muscle, and emerges from beneath it to run along the under surface of the tongue. The place of election for ligation is where the artery is beneath the hyoglossus muscle. Its guide is the hypoglossal nerve, which lies upon the muscle, but at a slightly higher level than the artery.

Operation.—In this operation the patient is placed recumbent with the shoulders raised and the face turned away from the side to be operated upon. The surgeon stands upon the affected side. A curved incision is made from a little external to the symphysis of the lower jaw, downward and outward, to just above the greater cornu of the hyoid bone, and upward and outward to just in front of the facial artery at the lower edge of the lower jaw. The skin, the superficial fascia and platysma, and the deep fascia are incised. The submaxillary gland is cleared and retracted well upward. The fascia beneath the gland is divided by a transverse incision. The posterior edge of the mylohyoid muscle and the bellies of the digastric muscle are sought for and identified. One of the digastric tendons is retracted down and out (Treves). The hyoglossus muscle is cleared with a dissector; the hypoglossal nerve and ranine vein are found and drawn a little upward. The hyoglossus muscle is divided transversely a little above the hyoid bone and below the level of the hypoglossal nerve. The artery is found under the muscle and the needle is passed from above downward.

Facial Artery. **Anatomy** (Pl. 5, Fig. 3).—It arises from the external carotid a little above the lingual, runs upward and forward beneath the body of the inferior maxillary bone, passes along a groove in the posterior and upper surface of the submaxillary gland, crosses the body of the lower jaw at the lower anterior edge of the masseter muscle, and passes forward and upward to the angle of the mouth and side of the nose.

Ligation (Pl. 5, Fig. 4).—The facial artery is rarely ligated in the cervical portion, but may be reached through the incision employed for ligation of the external carotid. The vessel may be tied before it crosses the submaxillary gland, the stylohyoid and digastric muscles being drawn aside. The vessel is reached in the facial portion of its course by a 1-inch cut at the anterior edge of the masseter muscle (Fig. 281). Branches of the facial nerve are pushed aside. The needle is passed from behind forward to avoid the vein (Jacobson).

Temporal Artery.—The line of the temporal artery passes "upward over the root of the zygoma, midway between the condyle of the jaw and the tragus" (Jacobson).

Anatomy.—The temporal artery arises from the external carotid behind the condyle of the jaw and in the parotid gland, passes over the zygoma, and divides into two terminal branches.

Ligation.—The patient is placed recumbent and the head is turned to the opposite side. An incision 1 inch in length is made (see Fig. 281), the superficial structures and dense fascia are divided, the vein is retracted backward, and the needle is passed from behind forward.

The **occipital artery** takes origin from the posterior surface of the external carotid, below the digastric muscle and opposite the point of origin of the facial artery. It ascends beneath the digastric and stylohyoid muscles and parotid gland; the hypoglossal nerve hooks around it from behind forward. It crosses the internal carotid artery, the internal jugular vein, the pneumogastric and spinal accessory nerves; passes between the mastoid process of the temporal bone and the atlas; grooves the temporal bone; penetrates the trapezius muscle, and ascends over the occiput.

Ligation.—This vessel can be ligated near its origin through the same incision as is employed to reach the external carotid. The hypoglossal nerve is avoided. To tie back of the mastoid process, place the patient in the same position as for ligation of the carotid. Carry an incision from the tip of the mastoid upward and backward, reaching a point midway between the mastoid and the occipital protuberance (Jacobson). Cut the skin, the fascia, the sternocleidomastoid, the splenius capitis, and possibly a portion of the trachelomastoid muscles. Bring the head toward the operator in order to relax the structures, retract the edges of the wound, and clear the artery where it lies

between the mastoid process and the transverse process of the atlas (Jacobson). An electric forehead light is of great assistance in finding the vessel. Pass the needle away from the vein or veins (there are often several).

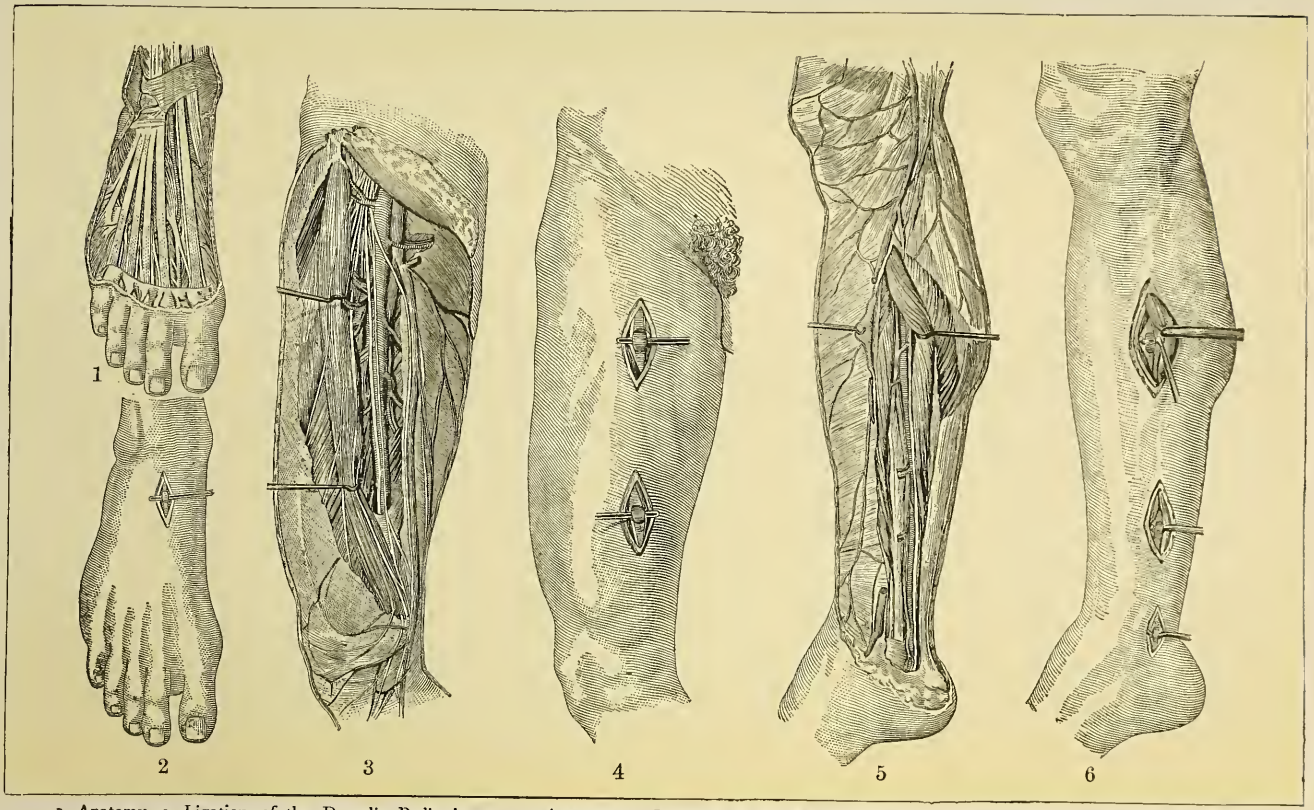
Dorsalis Pedis Artery.—The *line* of the dorsalis pedis artery is from the middle of the front of the ankle-joint to the middle of the base of the first interosseous space.

Anatomy (Pl. 6, Fig. 1).—The dorsalis pedis is a continuation of the anterior tibial artery, and it runs from the bend of the ankle to the proximal extremity of the first interosseous space, where it divides into the dorsalis hallucis and the communicating arteries. The artery rests, from above downward, upon the astragalus, scaphoid, and internal cuneiform bones, and at its point of bifurcation lies between the heads of the first dorsal interosseous muscle. It may lie in some persons a little external to this course. It is held upon the bones by a distinct layer derived from the deep fascia. This artery is covered by skin, by superficial and deep fascia, and by the annular ligament above, and is sometimes partly overlaid by the extensor proprius pollicis muscle, and is crossed, just before its bifurcation, by the innermost tendon of the extensor brevis muscle. The inner tendon of the extensor communis digitorum is to the outer side of the vessel; the tendon of the extensor proprius pollicis is to the inner side, and is a guide. The artery is ligated in the dorsal triangle of the foot—a space which is bounded above by the lower edge of the annular ligament, externally by the inner tendon of the extensor brevis, and internally by the tendon of the extensor proprius pollicis. The artery has venæ comites; the anterior tibial nerve lies, as a rule, to its inner side, but may be found upon the artery or to its outer side, and the inner division of the musculocutaneous nerve is external to the vessel in the superficial parts.

Operation (Pl. 6, Fig. 2).—In this operation the patient is placed supine with the leg and foot extended. Heath flexes the leg partly and rests the sole of the foot directly upon the table. The surgeon stands below the extremity and cuts from above downward. Make an incision 2 inches in length along the arterial line, beginning opposite the lower edge of the annular ligament and running along by the tendon of the extensor proprius pollicis; cut through the skin and superficial and deep fascia; have the toes extended; retract the tendon of the extensor proprius pollicis inward, and the tendon of the extensor communis digitorum outward; clear the artery, find the nerve, try to separate the venæ comites, and pass the needle from the nerve.

Anterior Tibial Artery.—To locate the *line* of the anterior tibial mark a point midway between the head of the fibula and the tuberosity of the tibia, drop 1 inch, and draw a line from the second point to the middle of the front of the ankle-joint.

Anatomy.—The anterior tibial artery is one of the terminal branches of the popliteal. It arises opposite the lower border of the popliteus muscle, passes forward between the two heads of the posterior tibial muscle, comes to the front of the leg through an opening in the interosseous membrane, and runs down to the middle of the front of the ankle-joint. In the upper two-thirds of its course it rests upon the interosseous membrane, to which it is fastened by firm fascia; in the lower third it lies first upon the front of the tibia and then upon the anterior ligament of the ankle-joint. For its upper two-thirds the artery has the tibialis anticus muscle just external to it; at the junction of the middle and lower thirds the extensor proprius pollicis comes from the outside and lies either upon the artery or to its inner side for the rest of its course. Externally in its upper third is the extensor communis digitorum; in the middle third is the extensor proprius pollicis; in the lower third, the proprius pollicis having crossed to the inner side, the extensor communis digitorum again becomes the outer boundary. The artery is covered by skin and by superficial and deep fascia. In its upper third it is deeply placed between



1, Anatomy, 2, Ligation, of the Dorsalis Pedis Artery. 3, Anatomy, 4, Ligation, of the Femoral Artery. 5, Anatomy, 6, Ligation, of the Posterior Tibial Artery. (From Bernard.)

the muscles; in its middle third it is less overlaid by muscle; in its lower third it is superficial except where it is crossed by the extensor proprius and where it is covered by the annular ligament. The artery has venæ comites. In the lower three-fourths of its course it is accompanied by the anterior tibial nerve, which in its course in the upper third of the leg is external to the artery; in the middle third it is external and a little in front of the artery; and in the lower third it is external to or upon the artery (Pl. 5, Fig. 5).

Operations.—The ligations of the anterior tibial (Pl. 5, Fig. 6) are: (1) of the lower third; (2) of the middle third; (3) of the upper third. In all these ligations the patient is placed recumbent with the leg extended, and the surgeon stands to the outer side of the extremity, cutting from above downward on the right side and from below upward on the left side.

Ligation of the Lower Third.—Make an incision 3 inches long in the line of the artery and over the annular ligament. This incision is external to the tibialis anticus muscle and ½ inch from the outer border of the tibia (Barker). Divide the skin and fascia, retract the tendon of the tibialis anticus inward, and the tendon of the extensor proprius pollicis outward, along with the tendons of the extensor communis. Flex the ankle-joint to relax the tendons and clear the artery. Draw the nerve external and pass the ligature from without inward. In order to recognize the muscles in this as in other ligations, rely largely upon the finger while the muscles are being moved.

Ligation of the Middle Third.—In this operation the procedure is similar to the above. Remember that the nerve lies in front of the vessel and that the extensor proprius pollicis muscle is external. The nerve is retracted outward and the needle is passed from the nerve. A good rule for detecting the artery is to find the outer edge of the tibia and by this locate the interosseous membrane, and then, by passing out along this membrane, discover the artery.

Ligation of the Upper Third.—Make an incision 3 inches long in the arterial line. On opening the deep fascia, do not rely on the eye for finding the muscular interspace, as often the latter cannot be seen, and neither a white nor a yellow line is reliable. Place the index-finger deep in the wound and have the tibialis anticus and extensor communis digitorum muscles successively rendered tense by an assistant. In opening the interspace use the handle of the knife. Relax the muscles, retract the tibialis anticus inward and draw the extensor communis digitorum outward. Find the interosseous membrane where it is attached to the edge of the tibia, and the artery will be found upon this membrane, between the tibia and the nerve. Clear the vessel and pass the ligature from without inward to avoid the nerve.

Posterior Tibial Artery.—The *line* of the posterior tibial is from the middle of the popliteal space to a point midway between the tip of the inner malleolus and the point of the heel (Pl. 6, Figs. 5, 6).

Anatomy.—The posterior tibial is the larger of the two terminal branches of the popliteal. It arises opposite the lower border of the popliteus muscle, passes down between the deep and superficial flexor muscles to midway between the tip of the malleolus and the point of the heel, and divides into the external and internal plantar vessels. In the upper third of its course it is very deeply placed midway between the tibia and fibula; in its middle third it is less deep, having passed inward; and in its lower third it is superficial. At the ankle the artery is beneath the annular ligament. From above downward the posterior tibial artery rests upon the posterior tibial muscle, the flexor longus digitorum muscle, the posterior surface of the tibia, and the internal lateral ligament of the ankle-joint. For the first inch or two of the course of the artery the posterior tibial nerve is to the inner side; the nerve then crosses to the outer side, and remains in that relative position throughout the rest of the course of the artery. When the knee is partly flexed and the leg is laid upon its outer surface the artery is between the operator and the nerve, and the nerve is between the artery and

the table. Back of the malleolus, in the first compartment, lies the posterior tibial muscle; in the next compartment is the flexor longus digitorum muscle; in the next compartment are the artery and nerve; and in the most posterior is the flexor longus pollicis muscle.

Operations.—*Ligation Back of the Malleolus.*—In this operation the patient is placed recumbent, with the thigh abducted and the leg flexed and resting upon its outer surface. The surgeon stands to the outer side. Make a 2-inch semilunar incision corresponding in its curve to the malleolus and ½ inch posterior to its margin (Fig. 282). Cut down to the annular ligament, incise the ligament, and find the artery and venæ comites. Clear the vessel and pass the needle from behind forward (to avoid the nerve, which is here posterior and external). Do not make the preliminary incision nearer the malleolus than ½ inch, as the sheath of the tibialis posticus muscle will then surely be opened. In closing the wound, suture the ligament by buried sutures of catgut before closing the superficial parts (Pl. 6, Fig. 6).

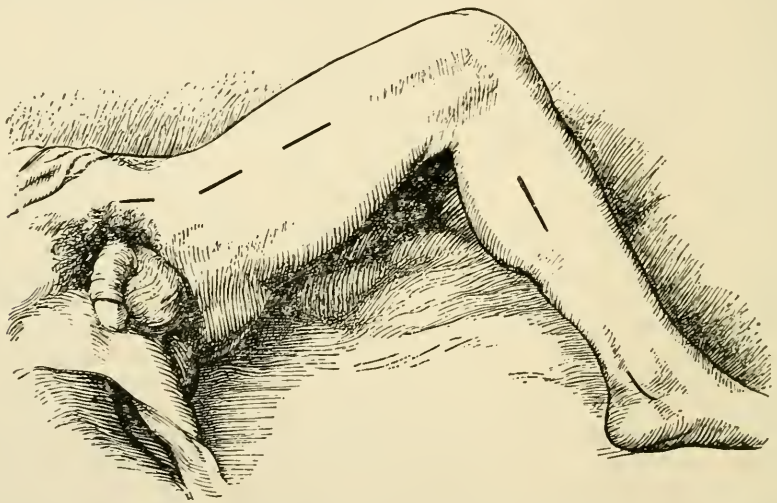


Fig. 282.—The lines indicate the incision to be made for the ligature of the common femoral, of the femoral in Scarpa's triangle and in Hunter's canal, and of the posterior tibial in the calf and behind the malleolus (MacCormac).

Ligation in the Middle of the Leg.—In this operation the patient is placed in the same position as for the ligation back of the malleolus. Feel for the inner border of the tibia, and make an incision 4 inches long 1 inch behind the osseous border, parallel with it, and extending through skin and superficial and deep fascia (Fig. 282). Draw the gastrocnemius muscle outward. Incise the soleus muscle, but not the fascia beneath the soleus; cut this fascia, after dropping the handle of the knife so that the blade is at right angles with the plane of the tibia. Clear the artery; pass the needle from without inward (Pl. 6, Fig. 6).

The **popliteal artery** is almost never ligated in continuity. It can be tied at the upper portion of the popliteal space, at the lower portion of the popliteal space, or at the inner side of the thigh.

Anatomy (Fig. 283).—The popliteal artery is the continuation of the femoral, and runs from the opening in the adductor magnus muscle to the lower margin of the popliteus muscle. This vessel runs downward and outward behind the knee-joint and in the popliteal space. The ham, or popliteal space, is a lozenge-shaped space, which above the joint is bounded on the outer side by the biceps muscle, and on the inner side by the semitendinosus, semimembranosus, gracilis, and sartorius muscles, while below the joint it is bounded externally by the

plantaris and outer head of the gastrocnemius muscles, and internally by the inner head of the gastrocnemius muscle. The floor of this space is formed by the surface of the femur, the posterior ligament of the knee-joint, the head of the tibia, and the popliteus fascia. The internal popliteal nerve passes down the middle of the popliteal space; it is superficial to the vessels in the upper half of the space, and is external to them; it is internal to the vessels in the lower half of the space. The external popliteal nerve is in the outer side of the space. The popliteal vein is between the nerve and the artery. Above the knee-joint it is to the outer side of the artery, but below the knee-joint it is to the inner side. The artery lies deeply in the space.

Ligation in Upper Third.—Place the patient prone. The surgeon stands to the outer side of the limb and makes a vertical incision 3 inches in length along the outer margin of the semimembranosus muscle, exposes the popliteal nerve, retracts the muscle inward and the nerve outward, exposes the artery, separates it from the other structures, and passes the needle from without inward (Fig. 284).

Ligation in Lower Third.—Make a 3-inch vertical incision between the heads of the gastrocnemius muscle. Avoid the external saphenous vein and nerve,

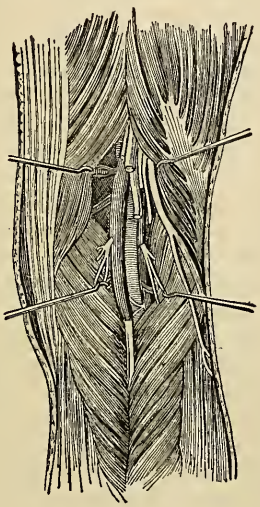

Fig. 283.—Anatomy of popliteal artery (Bernard and Huette).

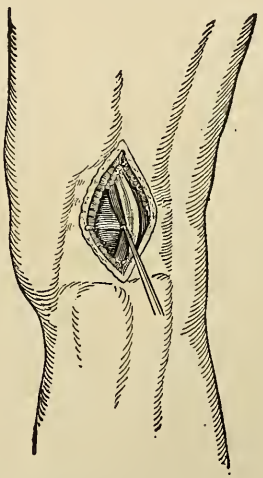

Fig. 284.—Ligation of popliteal artery in its upper third (Bernard and Huette).

and retract them with the popliteal nerve. Separate the artery from the vein and pass the needle from within outward.

Femoral Artery.—The *line* of the femoral artery is from midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur, the thigh being abducted and resting upon its outer surface (Pl. 6, Fig. 3).

Anatomy.—The femoral artery is the continuation of the external iliac trunk; it extends from the lower border of Poupart's ligament to the opening in the adductor magnus muscle, and hence occupies the upper two-thirds of the thigh. The artery for its first 5 inches is superficial, lying in Scarpa's triangle, a space which is bounded externally by the sartorius muscle and internally by the adductor longus, its base being Poupart's ligament and its floor being composed of the psoas, iliacus, pectineus, and adductor longus muscles, and often the adductor brevis. The artery enters the triangle as the common femoral, but after a 2-inch course it divides into the profunda (which

passes deeply) and the superficial femoral. The latter vessel is the one alluded to in this section.

At the base of Scarpa's triangle the vein is internal, the artery is between, and the nerve is external (V. A. N.). At the apex of the triangle the vein is internal and a little posterior. At the apex of the triangle the superficial femoral passes under the sartorius muscle and enters into Hunter's canal, which occupies the middle third of the thigh and which terminates at an opening in the adductor magnus muscle. Hunter's canal is bounded externally by the vastus internus muscle, internally by the adductors longus and magnus, and its roof is fascia which stretches from the adductor longus to the vastus internus. In Hunter's canal the vein is behind the artery in the upper part, but external to it in the lower part, and is firmly attached to the artery. There may be two veins. Inside Hunter's canal, but outside the femoral sheath, is the long saphenous nerve, which crosses the artery from without inward.

A way to remember the relation of the femoral vein to the femoral artery is to recall the fact that the relation of the vein to the artery is always contrary to the relation of the sartorius muscle to the artery: when the sartorius muscle is external to the artery the vein is internal, as at the base of Scarpa's triangle; when the sartorius muscle is crossing in front toward the inside of the artery, the vein is passing at the back to the outside, as at the apex of Scarpa's triangle; when the muscle is over the artery the vein is back of it, as in the upper third of Hunter's canal; and when the muscle is to the inside of the artery the vein is to the outside, as in the lower two-thirds of Hunter's canal. In a ligation at the apex of Scarpa's triangle the inner edge of the sartorius is the guide. In a ligation in Hunter's canal the long saphenous nerve is the guide.

Operations.—*Ligation of the Superficial Femoral at the Apex of Scarpa's Triangle.*—In this operation the *position* of the patient is supine, with the thigh and leg partly flexed, and the thigh abducted, everted, and rested upon its outer surface on a pillow. The operator stands to the outer side of the extremity. From a point corresponding to the middle of Scarpa's triangle, and 2½ inches below Poupart's ligament, make a 3-inch incision in the arterial line (Fig. 282). Cut the skin and superficial fascia. The saphenous vein will not be seen unless the incision is internal to the arterial line; if this vein is seen, draw it inward. Open the fascia lata, find the inner border of the sartorius muscle, and draw it outward. The fibers of this muscle run downward and inward, thus distinguishing it from the adductor longus, whose fibers run downward and outward. Open the common sheath for the artery and vein, and then incise the individual arterial sheath. Clear the artery and pass the ligature from within outward (Pl. 6, Fig. 4).

Ligation of the Superficial Femoral in Hunter's Canal.—This operation was first performed for aneurysm by John Hunter in 1785. In this operation the *position* of the patient is the same as in the ligation at the apex of Scarpa's triangle. Make a 3-inch incision in the middle third of the thigh, parallel with the arterial line and ½ inch internal to it (Barker)(Fig. 282). Incise the skin and superficial fascia, look out for the internal saphenous vein, open the fascia lata, find the sartorius muscle, and retract it inward, thus exposing the roof of Hunter's canal, which is to be opened for 1 inch or more. Within the canal is seen the long saphenous nerve, usually upon the sheath. Open the sheath of the artery, clear the vessel, and pass the needle from without inward.

Results: Ligation at the apex of Scarpa's triangle is a method for treating popliteal aneurysm. It is a very successful procedure. I have performed it 4 times with success and have assisted other operators in 3 successful cases. Syme successfully ligated the femoral about its middle 23 consecutive times, and in Guy's hospital the same operation was done 24 times, with 1 death ("Practice of Surgery," by Thomas D. Bryant). The common femoral and the deep femoral are seldom ligated except for hemorrhage.

Iliac Arteries.—The *line* of the common and external iliac arteries is from a point ½ inch below and ½ inch to the left of the umbilicus to midway between the anterior-superior spine of the ilium and the pubic symphysis. The upper third of this line represents the common iliac, and the lower two-thirds the external iliac (Pl. 3, Fig. 4).

Anatomy.—The common iliac arteries arise from the aorta opposite the left side and lower border of the fourth lumbar vertebra, and extend to the upper margin of the right and left sacro-iliac joints, where they each bifurcate into an external and an internal iliac. The common iliac arteries lie upon the fifth lumbar vertebra, are covered with peritoneum, and are crossed by the ureters. In women the ovarian arteries cross the common iliacs. Each common iliac vein lies to the right side of its associated artery. The right common iliac artery has in front of it, besides the peritoneum and ureter (in women also the ovarian artery), the ileum, branches of the superior mesenteric artery and branches of the sympathetic nerve. The left common iliac artery has in front of it, in addition to structures common to both sides (ureter, ovarian artery, sympathetic branches), branches of the inferior mesenteric artery and the sigmoid flexure with its mesocolon. The internal iliac artery runs from the sacro-iliac joint to the upper margin of the great sacrosciatic foramen. It is very rarely ligated (only for gluteal aneurysm, for uncontrollable hemorrhage from the gluteal or sciatic arteries, or to produce atrophy of the prostate gland). The external iliac artery runs from the sacro-iliac joint along the pelvic brim, upon the inner edge of the psoas muscle, to Poupart's ligament. The external iliac vein is internal to the artery. On the right side, high up, it passes behind the artery. The external iliac artery has in front of it peritoneum and subserous tissue (Abernethy's fascia). The ileum crosses the right, and the sigmoid flexure crosses the left, external iliac artery. The genital branch of the genitocrural nerve crosses the artery low down, and the circumflex iliac vein crosses it just before it terminates in the femoral. The spermatic vessels and the vas deferens in the male, and the ovarian vessels in the female, lie upon the artery near its termination. Sometimes the ureter crosses the vessel near its point of origin.

Ligation of the Iliac Arteries after Abdominal Section.—The best method for ligating the common, the internal, and sometimes the external iliac is by abdominal section. The patient is placed in the Trendelenburg position. The abdomen is opened in the midline below the umbilicus or in the semilunar line of the diseased side. The median incision is to be preferred in order that the deep epigastric artery may not be injured. This artery is a very important anastomotic branch. The intestines are lifted toward the diaphragm, and are held up by gauze pads. The edges of the incision are retracted. The vessel to be tied is located and the point for ligation is selected. The posterior layer of the peritoneum is opened over the selected point, the vessel is cleared, and the threaded Dupuytren's aneurysm needle is passed in a direction away from the vein. In ligating either common iliac pass the needle from right to left. In ligating the external iliac pass the ligature from within outward. It is not necessary to suture the posterior layer of peritoneum. The abdomen is closed without a drain. In these operations be sure to push the ureter out of the way. This operation has been performed by Dennis, Hearn, Marmaduke Shield, Tee, Mitchell Banks, the author, and others.

Results: Bryant ("Operative Surgery") alludes to 5 reported cases of transperitoneal ligation of the common iliac artery, with 1 death.

Ligation of the Common Iliac Artery by the Extraperitoneal Method.—The common iliac artery was tied unsuccessfully by Dr. Wm. Gibson in 1812. It was first successfully ligated by Valentine Mott in 1827. The patient is placed recumbent or in the Trendelenburg position. The body is then turned a little to the opposite side and the thighs are partly flexed. Bryant says there are

two linear guides for this artery. *Crampton's line* is drawn from "the apex of the cartilage of the last rib downward and a little forward nearly to the crest of the ilium, then carried forward parallel with it to a little below the anterior-superior spine" ("Operative Surgery," by Joseph D. Bryant). *McKee's line* is "drawn from the tip of the cartilage of the eleventh rib to a point 1½ inches within the anterior-superior spine, then curved downward, forward, and inward, and terminating abruptly above the internal abdominal ring" (Ibid.).

The incision can be begun just external to the internal abdominal ring and be curved upward and outward as in ligation of the external iliac, but

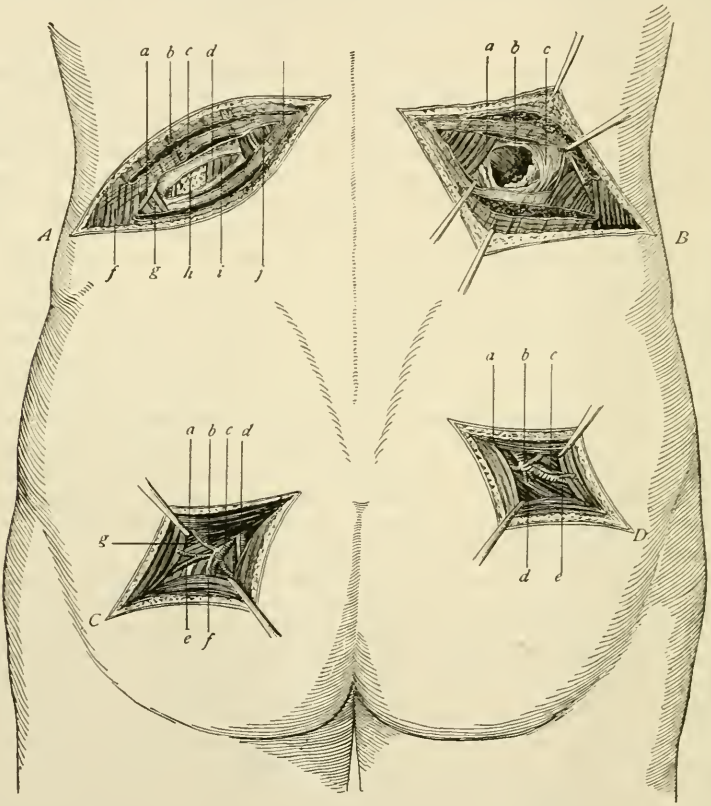

FIG. 285.—*A*, Nephrotomy: *a*, last dorsal n.; *b*, latissimus dorsal m.; *c*, serratus post. inferior m.; *d*, middle layer of lumbar fascia; *e*, outer layer; *f*, ext. oblique m.; *g*, int. oblique m.; *h*, perinephritic (extraperitoneal) fat; *i*, quadratus lumborum m.; *j*, erector spinæ m. *B*, Nephrotomy: *a*, first lumbar n.; *b*, kidney; *c*, transversalis fascia. *C*, Ligature of the sciatic and internal pudic arteries, and exposure of the great sciatic, small sciatic, and internal pudic nerves; *a*, gluteus maximus m.; *b*, inf. gluteal n.; *c*, sciatic a.; *d*, int. pudic a. and n.; *e*, great sciatic n.; *f*, small sciatic n.; *g*, pyriformis m. *D*, Ligature of the gluteal artery and exposure of the superior gluteal nerve: *a*, gluteus maximus m.; *b*, gluteal a.; *c*, superior gluteal n.; *d*, pyriformis m.; *e*, gluteus medius m. (Kocher).

Crampton's incision gives more room. The superficial tissues are divided down to the transversalis fascia, this structure is nicked and divided, and the exposed and unopened peritoneum is rolled upward and inward. The muscular guide is the inner border of the psoas magnus muscle. By its side an artery is felt. If the sacrovertebral prominence is above the vessel touched, the artery is the external iliac; otherwise it is the common iliac. If the ex-

ternal iliac is the vessel first exposed, follow it up to find the common trunk. When the common iliac is found, separate the fatty tissue about it and pass the ligature from the right toward the left in order to avoid the associated vein.

Results: Jos. D. Bryant tells us that this vessel has been ligated by the extraperitoneal method 69 times, with only 16 recoveries, but it is to be remembered that many of these operations were in pre-antiseptic days. The artery has been tied 80 times, with 56 deaths (70 per cent.).

Twenty-one of these operations were done since 1880; there were 10 deaths (mortality of nearly 48 per cent.). In these 21 cases gangrene occurred 7 times. (See Wm. J. Gillette, in "Annals of Surgery," July, 1908.) Halsted estimates the mortality of ligation at 46 per cent. In the days before asepsis it was over 80 per cent. Tee ("Lancet-Clinic," 1915, cxiii) says there are only on record 18 cases in which gangrene did not occur, 16 were performed for aneurysm, 2 for hemorrhage. Gradual occlusion by a metal band is safer than ligation. Halsted prefers ligation of this vessel to ligation of the external iliac, holding the larger an artery and the nearer it is to the heart the less is the danger of gangrene. Tee (Ibid.) reports a successful case. The man was well two years after operation.

Extraperitoneal Ligation of the Internal Iliac Artery.—This operation was first performed by Stevens, of Vera Cruz, in 1812 ("Practice of Surgery," by Thomas Bryant). The incision and the method of exposing the vessel are identical with like steps in the ligation of the common iliac.

Results: Of 26 ligations of this vessel recorded, 18 were fatal, but only a few of the cases were done antiseptically (Joseph D. Bryant's "Operative Surgery").

Ligation of the External Iliac by Abernethy's Extraperitoneal Method (Pl. 3, Fig. 4).—The external iliac artery was first ligated by Abernethy in 1796. The operation failed, but he did the first successful operation in 1806. The patient is placed recumbent with the thighs extended during the first incisions; but in the later stages of the operation the thighs are flexed a little to relax the abdominal structures. The operator stands to the outer side. The surgeon will find the artery by the side of the psoas muscle. Mark a point 1 inch above and 1 inch external to the middle of Poupart's ligament, and another point 1 inch above and 1 inch internal to the anterior-superior iliac spine (Barker). Join these two points by a curved incision 4 inches long and convex downward. Cut the skin, the fat, the two oblique muscles, and the transversalis muscle; open the transversalis fascia, separate the peritoneum toward the vessels, and draw it inward by a broad retractor, and look for the artery along the pelvic brim. The anterior crural nerve is seen to the outer side of the artery, the external iliac vein is to the inner side of the artery, and the genitocrural nerve is upon the artery. Clear the artery near its middle and pass the ligature from within outward. In Sir Astley Cooper's method of ligation the inguinal canal is opened; in Abernethy's method the inguinal canal is not opened.

The Gluteal Artery.—This vessel is a continuation of the posterior division of the internal iliac. It emerges from the great sacrosciatic foramen at the upper border of the pyriformis muscle. It rests upon the gluteus minimus, divides into three branches, and is covered by the gluteus maximus muscle. The superior gluteal nerve lies inferior to the artery (Fig. 285). The artery was first ligated by John Bell of Edinburgh (see his "Principles of Surgery," 1801.)

Ligation.—The patient should be prone. The surgeon stands to the outer side. The incision corresponds to a line drawn from the posterior-superior iliac spine to the upper border of the great trochanter (Fig. 286). Divide the skin, fascia, gluteus maximus muscle, and the fascia over the gluteus medius muscle, and retract the gluteus medius upward. Feel for the great sacro-

sciatic foramen, and at this point the artery is found above the pyriformis muscle. Clear the vessel and pass the needle from below upward (Kocher's "Operative Surgery"). There is practically no mortality from this operation.

The Sciatic Artery.—This artery is the larger of the terminal branches of the anterior division of the internal iliac artery. It passes to the lower portion of the great sacrosciatic foramen, lying back of the internal pudic artery, and resting upon the sacral plexus of nerves and pyriformis muscle (Gray). It leaves the pelvis between the pyriformis and coccygeus muscles, and passes downward between the ischial tuberosity and great trochanter. It is covered by the glutæus maximus muscle, rests upon the gemelli, internal obturator, and quadratus femoris muscles, has the great sciatic nerve external to it, and the small sciatic nerve external and posterior (Fig. 285).

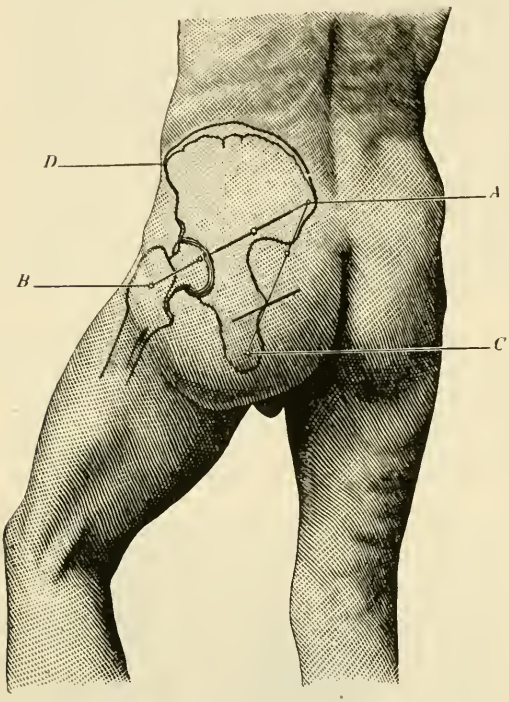

Fig. 286.—Position and direction of the superficial incisions which must be made in order to secure the gluteal artery and the sciatic and pudic arteries: *A*, Posterior superior iliac spine; *B*, great trochanter; *C*, tuberosity of the ischium; *D*, anterior-superior iliac spine; *A–B*, iliotrochanteric line, divided into thirds. This line corresponds in direction with the fibers of the gluteus maximus muscle. The incision to reach the gluteal artery is indicated by the darker portion of the line. Its center is at the junction of the upper and middle thirds of the iliotrochanteric line, and exactly corresponds with the point of emergence of the gluteal artery from the great sciatic notch. *A–C*, ilio-ischiatic line. The incision to reach the sciatic artery and internal pudic is indicated by the lower dark line. It is also to be made in the direction of the fibers of the gluteus maximus muscle. The center of the wound corresponds to the junction of the lower with the middle third of the ilio-ischiatic line (MacCormac).

Ligation.—The patient lies prone. The surgeon stands to the outer side. The incision "corresponds to the middle two-thirds of a line extending from the posterior inferior iliac spine to the base of the great trochanter."[1] MacCormac advises the incision shown in Fig. 286. Divide the skin, fat, fascia, and the glutæus maximus muscle. Find the artery at the lower border of the pyriformis muscle and trace it to its point of emergence from the pelvis. Pass the ligature from without inward. There is practically no mortality from this operation.

Internal Pudic Artery.—This artery is one of the terminal branches of the anterior trunk of the internal iliac. It passes to the lower margin of the great sacrosciatic foramen, and leaves the pelvis between the pyriformis and coccygeus muscles, crosses the ischial spine, and again enters the pelvis by the lesser sacrosciatic foramen. The vessel is accompanied by the internal pudic nerve (Fig. 285).

Ligation.—The position of the patient and the incision are the same as for ligation of the sciatic artery (Fig. 286). The artery is found below the ischial spine. Pass the needle from below upward to avoid the nerve. There is practically no mortality from this operation.

[1] Kocher's "Operative Surgery," by Stiles.

Ligation of the Abdominal Aorta.—This operation was first performed by Sir Astley Cooper in 1817. The patient lived but a few hours. The aorta has been ligated twenty times and there have been twenty deaths. Nine of these cases were aseptic operations. The patient of Monteiro, of Rio Janeiro, lived for ten days. The circulation was entirely restored in the limbs, and the man died from hemorrhage resulting from the ulceration produced by a septic ligature. Keen's case lived for forty-eight days after ligation just below the diaphragm. The urinary secretion was plentiful and the circulation in the lower extremities was restored, death resulting from cutting through of the ligature. Robert T. Morris performed distal ligation below an aneurysm. He encircled the aorta with a soft-rubber catheter and clamped it with forceps. Twenty-two hours after operation the aneurysm began to shrink, and in three hours more had apparently disappeared. Twenty-seven hours after operation the clamp and catheter were removed. The patient died of septicemia fifty-three hours after operation. The necropsy disclosed gangrene of a bit of intestine which had been in contact with the forceps, but the dissecting aneurysm was filled with solid clot, the aorta was patent, and the circulation in the extremities was re-established ("Amer. Jour. of Med. Sciences," Sept., 1900). These cases prove that under certain circumstances the operation is feasible, and in desperate cases it must be considered as a possible means of treatment. Halsted and Matas prefer a metal band to the ligature (see page 488). Gradual occlusion and partial occlusion of the aorta are much safer than sudden closure.

Murray's Operation.—This procedure aims to avoid opening the peritoneum. An incision is made from just below the tip of the tenth rib to a point 1 inch internal to the anterior superior iliac spine. The peritoneum is separated from the abdominal wall until the vessel is reached. Cooper's operation by abdominal section is the preferable procedure.

Operation by Abdominal Section (Cooper's Operation); Instruments Required.—Those used in any ligation, with the addition of an aneurysm needle with a large curve and a very long handle. With an ordinary instrument it is extremely difficult to pass the ligature. It would be a great advantage to use an instrument which, after being passed under the vessel, could have a central eyed shaft projected, as is the center shaft of a Bellocq cannula. Floss silk is probably the best ligature material.

If the patient is much exhausted, an assistant should infuse salt solution in a vein during the operation. In Keen's case there was profound shock, but the moment the ligature was tightened it passed away.

The patient should be placed upon his back. The surgeon stands to the right of the patient and opens the abdomen in the median line, a little above the level of the aneurysm. The intestines are packed aside, the posterior layer of the peritoneum is divided, the surface of the aorta over a small area is cleared of nerves, the plexuses being separated with a blunt dissector.

The needle is passed from right to left. A double ligature of floss silk should be passed and the ends should be tied with a stay-knot. The wound is closed and dressed.

It has been suggested—I think by Wyeth—that it might be wise to tighten the ligature only partially at first, completing the occlusion of the artery after a day or two. Such a procedure would certainly give a better chance for the collaterals to dilate and restore circulation in the legs (see page 488).

Unfortunately, in an aneurysm, the vessel will usually be extensively diseased, and ligation will be out of the question. If, however, a normal region is found, the chance of success in a case of aneurysm will be greater than in a case of hemorrhage from a branch of the aorta, because, in a case of aneurysm, the probabilities are that the collaterals are somewhat distended before a ligature is applied.

Operation upon the Thoracic Aorta.—Tuffier endeavored to suture the sac of an aneurysm so as to reduce its lumen ("Bull. et mém de la soc. de chir.," 1907, xiv). Krummel operated upon a ruptured aneurysm of the lower part of the thoracic aorta. He sutured the sac. The circulation in the legs was restored but the patient died ("Deutsche med. Woch.," 1914, xl).

XX. DISEASES AND INJURIES OF BONES AND JOINTS

Diseases of the Bones

Atrophy of bone is a diminution in the amount of bony matter without change in osseous structure. It arises from want of use (as seen in the wasting of the bone of a stump) or from pressure (as seen in the destruction of the sternum by an aneurysm of the aorta). *Eccentric* atrophy is the thinning of a long bone from within, the outer surface being perhaps unchanged. It is usually a senile change. *Concentric* atrophy means a thinning of the outer surface of the shaft, causing a lessened diameter. It is usually linked with eccentric atrophy.

Hypertrophy of bone may be due to increased blood-supply (as seen in chronic epiphyseal inflammation), the bone growing much more than does its fellow. It may arise from excessive use or from strain (as seen in the increased size of the fibula when the tibia is congenitally absent).

Osteogenesis Imperfecta (*Idiopathic Fragilitas Ossium*).—In this condition fractures occur without known injury, and frequently unite with great deformity because they escaped recognition and were not splinted. The long bones are most apt to suffer. The condition is congenital and some cases are hereditary. The bones of the skull may ossify partly or may remain membranous. The victims of this defect seldom reach maturity. It has been thought by some observers that adrenal disease is the cause.

Achondroplasia.—This is a congenital condition in which the epiphyses of the long bones ossify prematurely, the growth of the limbs being interfered with gravely. A victim of this condition has a body of normal size but very short limbs. The skull is seldom involved. It is thought that the state bears some relation to cretinism. In the condition known as *hereditary deforming chondrodysplasia* irregularly shaped, symmetrical, hyperostoses form about the epiphyseal lines. The ankles, knees, hips, wrists, elbows, shoulders, cranium and other bones may be involved (Ehrenfried, in "Jour. Am. Med. Assoc.," Feb. 17, 1917). Growth becomes very much stunted, great joint disability may be caused, pain may arise from pressure upon nerves, and lack of development of a bone (for instance the ulna) may cause marked deformity (Ehrenfried, Ibid.).

Tumors of Bone (*See Tumors*).—Bones give origin to both innocent and malignant tumors. Myeloid sarcoma takes origin in the endosteum and expands the bone. The fasciculated sarcoma is a periosteal growth. Besides these growths there may develop an osteoma, chondroma, and secondary deposits of cancer and sarcoma. A bone may become cystic. Gummata are frequently met with.

Cysts and Cystomata of Bone.—One variety of cyst is found in the jaws (dentigerous cysts, see page 412). The other variety occurs usually in the medullary canal of long bones and very seldom in short bones and flat bones. "It differs from the dentigerous cyst in the absence of a connective-tissue capsule. The fluid is usually hemorrhagic. Islands of cartilage may be found in the bone capsule" (Bloodgood, in "Progressive Medicine," Dec. 1, 1907). The condition known as *fibrous osteitis* is prone to cause cyst formation. Fibrous osteitis is a very chronic inflammatory condition in which medullar substance is replaced by connective tissue. It may lead to

the formation of a cyst or of cysts. It arises particularly in children and is most commonly found in the femur, tibia and humerus. It may escape recognition until fracture occurs. In 1910 Bloodgood collected reports of 89 cases of bone cyst and 69 of them were related to fibrous osteitis.

Barrie ("Surgery, Gynecology, and Obstetrics," 1914, xix) has presented strong evidence to prove that a basis for various solitary lesions in the long bones is *hemorrhagic osteomyelitis*.

If the condition retains throughout its course hemorrhagic granulation tissue he calls it chronic hemorrhagic osteomyelitis and places in this group giant-cell sarcoma which he regards as a regenerating inflammation. If fibrous tissue appears and cystic formation begins he names the condition chronic fibrocystic osteomyelitis.

A bone-cyst slowly expands and thins the shaft of the bone, and in some cases fracture of the bone is the first evidence of the trouble. Fracture may be caused by very trivial force. Union takes place after fracture, but the enlargement remains. The *x*-ray picture does not enable us to make the diagnosis, because it exactly resembles the picture of any medullary growth possessed of a bony capsule and producing osseous absorption.

Many bone-cysts are produced by softening of solid neoplasms (giant-cell sarcoma, myxoma, medullary fibroma, chondroma). Occasionally cysts form in osteomalacia and osteitis deformans, the condition arising from softening. Hydatid cysts and dermoid cysts are sometimes encountered. A true cystoma of bone, except in one of the jaws, is a surgical rarity. In the jaws cystomata are not very uncommon. The diagnosis of a bone cyst is confirmed by exploratory incision. A solitary cyst is treated by curetment and packing or by filling the curetted cavity with Mosetig-Moorhof bone-wax (page 574).

Multiple cysts may be treated by resection and bone-grafting (Tyler, in "Med. Herald," 1914, xxxiii).

Syphilis of Bone.—Secondary syphilis may attack the bones (see page 376). Tertiary syphilitic lesions are considered on page 379.

Actinomycosis of bone is most usual in the jaw, but may attack the orbit, ribs, sternum, or limbs (see page 356). Actinomycosis of bone may arise secondarily after infection of superficial parts by the streptothrix. In the jaw the fungus obtains entrance to the interior of the bone through a tooth socket. In some cases of bone actinomycosis the fungus reaches the bone by the blood. Actinomycosis leads to the production of granulation tissue, the bone is expanded and becomes carious, and a quantity of new bone is sometimes produced. In vertebral actinomycosis, although the condition resembles tuberculosis, angular deformity does not occur.

Tuberculosis of bone (*tuberculous osteomyelitis*) tends especially to appear in the cancellous ends of long bones. In about one-fifth of the cases it is primary, that is, only one focus can be found. In such cases the point of entry shows no lesion, or the lesion at that point may have healed. In some cases the bacilli enter through the tissue. The blood or lymph carries the bacteria to the region where they lodge and develop.

Healthy marrow is almost immune to infection, it has such a high degree of resistance (Fraser, "Jour. Am. Med. Assoc.," Jan. 2, 1915).

The bacilli grow readily in diseased marrow. The common disease which precedes infection is gelatinous degeneration, the result of endarteritis, and endarteritis can be produced by the toxemia of distant tuberculosis (Fraser, Ibid.). Such a blood-vessel ruptures easily giving rise to hemorrhage and in that area of extravasation bacteria are prone to lodge. Trauma may be an exciting cause. It ruptures the diseased blood-vessels. Long after apparent healing the disease process may awaken into activity and trauma is often the cause of the awakening. In one of König's cases trouble began anew after

sixty years. The disease is especially apt to attack the epiphysis and spread to the joint, although in some cases it spreads to the shaft. In exceptional cases it begins on the diaphyseal side of the epiphysis. Primary tuberculosis is rare in the shafts of long bones, but is not uncommon in the shafts of short bones. When the shaft of a short bone is distended by a tuberculous process the condition is called *spina ventosa*. In a bone focus the original tubercle necroses, other tubercles form and necrose, the separate areas unite and a bone cavity forms. This cavity is surrounded by granulation tissue and the cavity contains tuberculous granulations, necrotic tubercles and perhaps bone sequestra. This cavity is the result of rarefying osteitis and no new bone forms unless there is a sequestrum or are sequestra. A sequestrum causes irritation and irritation leads to bone formation. The sequestra in tuberculous osteomyelitis are not completely loose, but are still attached at some point. The bone may sclerose from the action of osteoblasts, osteoclasts may soften the bone by removing the lime salts or the bone may become "worm-eaten." Sclerotic bone means a healing process. Softened bone means a spreading process. A sequestrum in tuberculous osteomyelitis is usually wedge shaped, the base being toward the joint. A sequestrum is due, König thinks, to the obstruction of a terminal artery by a tuberculous embolus or by the intra-arterial growth of bacilli ("Die Tuberculose der Menschlichen Gelenke, swiel der Brustwand und des Schaedels"). In a certain number of cases tuberculosis infiltrates a spongy bone with great rapidity because of rapid caseation. This condition is known as *infiltrating progressive bone tuberculosis*.

The vertebræ are the most common seats of bone tuberculosis. Next in order come the lower end of the femur, the cranium and face, the hip, the sternum and ribs, foot, humerus, pelvis, tibia and fibula, ulna, radius and scapula.

Primary tuberculosis of the patella is very seldom seen. According to Murphy this immunity is due to the fact that the patella is a sesamoid bone without any epiphyseal loop circulation ("Surgery, Gynecology, and Obstetrics," vi, 1908). See tuberculous arthritis, page 705.

Thickening of the periosteum and beneath the periosteum is one of the first signs of osseous tuberculosis. This results from hyperemia and connective tissue or even new bone may form. I do not mean that the periosteum is attacked primarily. It is not. The initial lesion is osteomyelitis and the periosteal thickening is only a sign of the deeper lesion. If bone production should be marked we would question the diagnosis of uncomplicated tuberculosis and would suspect tuberculosis with syphilis or syphilis alone.

Caries sicca (Volkmann's caries) is a condition without suppuration, in which the joint cavity is obliterated and in which the articular extremity of the bone undergoes "sclerosis and concentric atrophy" (Senn, in "Tuberculosis of Bones and Joints"). It is most common in the shoulder-joint and is a form reasonably curable by conservative means.

Osteitis, Periostitis and Osteoperiostitis.—It is not wise to consider alone acute inflammation of medulla, bone, or periosteum. Acute periostitis almost always is soon accompanied by at least some degree of osteomyelitis and acute inflammation about the epiphysis is soon followed by inflammation of bone, medulla and periosteum, that is by acute osteomyelitis. **Osteitis, or inflammation of bone,** may be due to traumatism, to a constitutional malady or diathesis, to the extension of inflammation from some other structure, to certain fevers, to cold, to phosphorus or mercury, to infection, or to working in pearl button factories. In inflammation of bone the exudate and leukocytes pass into the Haversian canals, spaces, and canaliculi. The bone corpuscles proliferate and the bone undergoes thinning (rarefaction), not because of pressure, but because of absorption by voracious leukocytes and osteoclasts. This process of rarefaction enlarges all the bony spaces, and by destroying septa throws many of the spaces into one. If the surface of a bone inflames, the periosteum will be separated more or less by exudation, and the bone will be

covered with little pits or erosions made by the leukocytes. Inflamed bone is so soft that it can be readily cut with a knife.

Pearl workers' osteitis may arise in those who polish mother of pearl. It occurs particularly in youths before fusion of the epiphyses. It arises in the diaphysis near the epiphysis. The bones of the limbs are most apt to suffer, but the bones of the face or chest may be attacked. The attack begins with pain and moderately elevated temperature and the fever may persist for several weeks. The condition may apparently get well and yet begin again when the patient returns to work. The lesions are often symmetrical and always multiple (Broca). It is a condensing osteitis and undergoes spontaneous cure if the patient gives up the occupation (Deturk, in "Archives Générales de Chirurgie," Nov., 1908). It is thought to be due to dust entering the lungs and reaching vessels in the bone. The dust is composed of carbonate of lime and konchiolin.

Osteitis may terminate in *resolution* or it may terminate in *sclerosis*, the mass of proliferating cells being converted first into fibrous tissue and next into dense bone which contains a very few small cancellous spaces. If the exudation is under the periosteum, the bone will be thickened at this point, bone stalactites marking the points of passage of the vessels. Osteitis may terminate in *suppuration*, this condition being often called *caries*. In tuberculous osteitis caseation of the inflammatory products is very apt to arise (*tuberculous caries*, the *strumous caries* of our predecessors). Acute osteitis may terminate in *necrosis*, the inflammatory exudate compressing the vessels in their bony canals, a portion of the bone being, in consequence, deprived of nutritive material. The portion cut off from nutritive fluid dies *en masse* (necrosis). Osteitis is usually associated with more or less periostitis. A simple acute periostitis without involvement of the bone may arise from traumatism or strain; but in all severe cases of periostitis, in all chronic cases, in all cases due to syphilis, rheumatism, measles, scarlatina, or enteric fever the bone is involved at the same time or subsequently. In syphilitic states gummatous degeneration frequently ensues.

Symptoms of Osteitis and Osteoperiostitis.—As a chronic process, *osteitis* is most commonly found in the femur. The history may exhibit a record of an antecedent injury or chilling of the body. Pain is severe, boring or aching in character, deep seated, worse at night, and aggravated by a dependent position of the part. The symptoms closely resemble those of periostitis, with which disease it is almost sure to be linked. Tenderness exists on percussion, and sometimes on pressure. Subperiosteal swelling, fusiform in shape, is noted; cutaneous edema and discoloration are observed if a superficial bone is inflamed. In syphilis atrophic osteitis may attack the cranial bones and produce softening or even perforation, or osteophytic osteitis may arise, exostoses being formed. *Osteoperiostitis* may be acute or chronic, circumscribed or diffused, and may terminate in resolution, organization, or suppuration. It arises from cold, blows, wounds, strains, the spread of adjacent inflammation, specific febrile maladies, pyogenic infection, syphilis, rheumatism, or tuberculosis. The symptoms are pain (which is worse at night and which is aggravated by motion, pressure, or a dependent position), swelling, edema, and discoloration of the soft parts. Pain in the syphilitic form is not so severe as in other varieties. *Acute diffuse osteoperiostitis* has been called *acute necrosis*. It is very improbable that a violent, diffuse, pyogenic inflammation can attack the periosteum without the bone and medulla becoming involved, in fact it is always described as a pyogenic inflammation of bone and periosteum commonest in boys about the age of puberty. The condition is really acute osteomyelitis (page 575). In *simple acute periostitis* a swelling is felt upon the osseous surface. The swelling is firmly fixed and is very tender, but the bone itself is not enlarged. There is some local heat, discoloration, often fever, and the patient complains of an aching pain, which is worse at night.

Periostitis due to strain demands some special attention. Sir James Paget, years ago, pointed out that muscular exertion might cause periostitis. C. T. Dent has written a valuable article upon this subject.[1]

It is common to hear football players complain of some swelling of the knee-joint. Examination finds tenderness over the tubercle of the tibia with slight swelling of the joint. Dent points out that pain is felt on straightening the leg, not on rotating it. The same observer states that omnibus drivers suffer from periostitis of the fibula, due to pressing forcibly against the footboard; those who ride may develop periostitis of the adductor insertion (riders' bone); the victims of flat-foot may labor under periostitis of the inner tuberosity of the os calcis; bar-keepers, from working a beer-pump, may get periostitis of the scapula, pain being marked on contracting the biceps; a housemaid may develop periostitis at the points of bony origin of the great pectoral from the chest, the condition being due to sweeping and scrubbing.[2]

Treatment of Osteitis and Osteoperiostitis.—In syphilitic forms the local treatment consists in rest, elevation of the part, the application of iodin and mercurial ointment, and bandaging. Specific treatment is given by the stomach or hypodermatically. Operation is rarely justifiable. In other forms, if the case be recent and severe, put the patient to bed, place the limb in a splint and elevate it, employ cold, apply a bandage, and give salines and iodid of potassium internally. Later use ichthyol inunctions locally and apply a hot-water bag. Morphin is administered for pain. If these means fail, order counterirritation by iodin and blue ointment or blisters, and apply heat locally. In severe cases take a tenotome and slit the periosteum subcutaneously to relieve tension; this procedure often quickly relieves the pain. Some cases demand longitudinal osteotomy, which is performed by taking Hey's saw and dividing the bone longitudinally into the medullary canal. If pus forms, drain at once.

Diffuse osteoperiostitis requires early and free incisions through the periosteum, antiseptic irrigation, drainage, rest and elevation of the limb, and strong supporting and stimulating treatment. Amputation is sometimes demanded, as when the patient grows weaker and weaker even after incision, and when a joint is seriously involved. If the necrosis affects the entire shaft, which separates from its epiphyses, and new bone has not yet formed from the periosteum, make a subperiosteal resection of the shaft.

Chronic periostitis is usually syphilitic. A *node* is a chronic inflammation of the deep periosteal layers. Nodes occurring early in the secondary stage remain soft and soon pass away under treatment, but those occurring two years or more after infection are apt to cause a bony deposit. A node may soften, leaving a sinus, at the bottom of which is a piece of dead bone. Gumma of the periosteum is one form of node which is apt to produce caries or necrosis.

Osteoplastic periostitis accompanies chronic osteitis and causes the deposit of new bone, which undergoes sclerosis. The chief *symptom* is aching pain, which is worse when the patient is warm in bed, and is aggravated by damp and wet. A hard swelling is found at the seat of pain (often over the tibia, ulna, clavicle, or sternum). The soft parts are uninflamed and move freely unless softening or suppuration has occurred. Tenderness is manifest.

Treatment of Chronic Periostitis and Osteoplastic Periostitis.—For the nodes of early syphilis administer mercury by the plan usually followed in secondary syphilis; for the nodes of late syphilis give mercury and large advancing doses of iodid of potassium. Blisters, blue ointment, and iodin are applied to the skin over the area of periostitis in both forms, and subcutaneous division of the periosteum is of value. If suppuration occurs, incise antiseptically and drain.

[1] "Practitioner," Oct., 1897. [2] Ibid.

Chronic Abscess of Bone, or Brodie's Abscess.—This condition is sometimes due primarily to tuberculous infection, symptoms being absent for a longer or shorter time and arising because of secondary infection with staphylococci. It is always chronic, never acute. A very acute inflammation, such as is induced by virulent pyogenic organisms, causes acute necrosis rather than an acute abscess. After typhoid fever an area of suppuration may slowly form in the head of a long bone, due to action of typhoid bacilli. Non-virulent staphylococci may be responsible, and the condition may follow long after a staphylococcus osteomyelitis. In 84 per cent. of cases of Brodie's abscess this is the history (Alexis Thomson). The same author says the latent period between the osteomyelitis and the abscess varies from one to fifty-seven years. Chronic abscess of bone was first described by Sir Benjamin Brodie, and is often called *Brodie's abscess*. It occurs in the cancellous structure of the ends of bones—usually in the head of the tibia, sometimes in the femur (Fig. 287) or humerus. It seldom occurs in the shaft of a long bone. A tuberculous abscess of bone may follow a slight injury, which constitutes a point of least resistance. Bacteria lodge and multiply; bone rarefaction leads to the formation of a cavity, the inflammatory products caseate, suppuration arises, and the surrounding bone thickens and hardens because of growth from the periosteum. The abscess is apt to break and often breaks into a joint, as the joint surface is not covered by periosteum and no barrier of bone is there formed. Brodie's abscess may induce necrosis.

Fig. 287.—Chronic abscess in the great trochanter ("American Text-Book of Surgery").

Alexis Thomson thus describes Brodie's abscess ("Edinburg Med. Jour.," April, 1906):

In the first or quiescent stage there is a cavity filled with serum and lined with a membrane like the periosteum of young bones. The outer layer of the membrane is forming new bone of a spongy nature, "further away the old bone is sclerosed and the medullary canal obliterated."

When the mature stage or abscess stage arises the lining membrane is converted into granulation tissue, and the cavity becomes filled with staphylococcus pus. The outer layer of granulations erodes the bone and the abscess progressively enlarges. As the bone is eroded within, new bone is formed by the periosteum and the bone enlarges. If pus formation is more rapid than bone erosion there is tension and pain, but if bone erosion is sufficiently rapid to prevent tension there is little or no pain. Finally, the abscess perforates the bony shell "on the periosteal surface or into an adjacent joint."

Symptoms.—There are attacks of boring pain, worse at night and aggravated by motion and pressure and a dependent position. The pain is intermittent, may be absent for many days at a time, and is in many cases thought to be rheumatic. The tenderness is marked, even when there is an intermission in the spontaneous pain. The patient is apt to believe the pain is in the joint but examination demonstrates that the tenderness is in the bone. If the head of the tibia or the great trochanter is the seat of disease, percussion over that region develops pain most certainly. At times pain in the bone becomes excruciating and tenderness acute. There is more or less loss of function in the limb and in far advanced cases the bone is enlarged. There may be thickening of the bone and soft parts, edema and discoloration of the skin over the seat of trouble,

and attack after attack of synovitis in the nearest joint. Irregular fever and sweats are usually noted, but there may be no fever. The harrassing pain causes sleeplessness, exhaustion, and emaciation. When the pus breaks through the bone, abscess develops in the soft parts. If this abscess bursts or is opened pain ceases (Thomson). The *x*-rays aid greatly in making the diagnosis.

Treatment.—In treating bone-abscess, trephine the bone at the point of greatest tenderness, and if the abscess is missed, follow the advice of Holmes and perforate the wall of bone with the trephine, opening in several directions, to discover the pus. It is often easy to open into the abscess with a chisel or gouge. After opening the cavity scrape its walls, remove dead bone, thoroughly dry with gauze, touch with pure carbolic acid, and pack with iodoform gauze. If the abscess opens into a joint, trephine the bone, and also open, irrigate, and drain the joint.

Caries was a term once used universally to signify suppuration or molecular death of bone. In some cases caries means suppurative osteitis; in others, tuberculous osteitis; in still others, gummatous osteitis. Typhoid fever is occasionally followed by a carious condition of bone. Osteitis is apt to become purulent when the bone is exposed to the air, when rest is not secured, when the health of the individual is below normal, when a foreign body such as a bullet is in the bone, or when tubercle or syphilis exists. The term is seldom used to-day except loosely, and then usually to signify tuberculous disease of bone. When caries arises the softened and granulating bone breaks down and is eventually discharged through a sinus. After drainage is secured, organization, sclerosis, and healing may result. In these cases new bone may form and a cure follow.

Tuberculous or *strumous caries* (*caseous osteitis*), a condition produced by the caseation of the products of a tuberculous osteitis, seldom shows any tendency to self-cure, neither organization nor sclerosis takes place, and new bone seldom forms unless an operation is performed. The interior of bones, especially of the carpus and tarsus, is entirely softened and destroyed and thin shells only are left.

Caries necrotica is a condition in which small but visible portions of soft and dead bone are cast off; *caries sicca* is molecular death of bone without liquefaction or suppuration.

The caseating masses in tuberculous caries contain tubercle bacilli. If a tuberculous collection is evacuated and infection with pus organisms occurs, genuine suppuration takes place, and constitutional infection causes septic fever and may cause death. Pyogenic osteitis may affect any part of any bone; but caseous osteitis (tuberculous caries) tends to arise, especially in cancellous structure (heads of long bones, vertebral bodies, ribs and sternum, and bones of the carpus and tarsus). Tuberculous osteitis of the shaft of a long bone occasionally, but rarely, arises. Tuberculous osteitis is apt to cause tuberculous disease in an adjacent joint. Tuberculous osteitis may be followed by the formation of a cold abscess.

Symptoms.—In the beginning the evidences of caries are usually those of osteitis, but the first sign noted may be a fluctuating swelling due to pus or to caseated tubercle. After a time, at any rate, a fluctuating swelling is discovered. If not opened, the softened mass breaks externally, voids its contents, and leaves a sinus from which flows caseated matter which after a time becomes thin, reddish, and irritating to the skin, contains small portions of gritty bone, and has a foul smell. The opening of the sinus fills up with edematous granulations. A probe carried to the bottom of the sinus finds bone which is sieve-like (worm-eaten), and which on being struck gives a muffled note rather than the clear, sharp note of necrosis; the bone is rough, is bared, and is so soft that the probe can usually be stuck into it. In old cases of caries amyloid disease may arise.

Treatment.—If syphilis exists, give iodid of potassium in advancing doses and a mild mercurial course. If tuberculosis exists, give iodid of iron, arsenic, cod-liver oil, and nourishing foods, and recommend ocean air and living in the open air. Locally, in all cases, insist on rest and at once secure drainage, enlarging the opening, if necessary, and inserting a tube, and even making additional openings; syringe often with antiseptic fluids and dress antiseptically. If the case is seen before spontaneous evacuation has occurred, open under strict antiseptic precautions. When a chronic sinus exists there arises the question of operation. Incomplete operations are worse than useless, for they may be followed by diffuse tuberculosis or pyemia. If the gouge is used, try to remove *all* carious bone. The diseased bone is white, crumbles, and does not bleed; the non-carious bone is pink and vascular. Scrape away all granulations, swab the cavity with pure carbolic acid, and pack it with iodoform gauze. Instead of gouging away bone, there may be used the actual cautery, sulphuric acid, or hydrochloric acid. In severe cases excision is required, and in some rare cases amputation may be necessary. Caries of the spine is considered under Diseases of the Spine.

Necrosis is the death of visible portions of bone from circulatory impediment or the direct action of bacterial toxins. It is analogous to gangrene. One cause of necrosis is traumatism (such as the tearing off of periosteum) which deprives the bone of blood. Inflammation of the periosteum further lessens the nutrition. Acute inflammation in bone causes necrosis, the excessive exudation in the canals and spaces occluding the blood-vessels by pressure. The occlusion of vessels by bacterial thrombi or emboli may lead to necrosis, or the direct action of toxins may first inflame and finally destroy a portion of the bone. A thin shell of bone only may necrose from periosteal separation, or an entire shaft may die from acute pyogenic osteomyelitis or diffuse infective periostitis. Osteomyelitis is the most usual cause of necrosis. Necrosis is most frequently met with in the diaphyses of the long bones, caries in the cancellous tissue of bones. The ribs may become carious, but very rarely become necrotic. A sequestrum may, but does not often, form in a vertebral body, in the cancellous head of a long bone, in the carpus, or in the tarsus. If a sequestrum arises from tuberculous osteomyelitis it is seldom found completely detached, but still retains some vascular connection. In tuberculous osteomyelitis of a long bone the sequestrum is wedge shaped with its base toward the joint, and is due to infarction of terminal arteries. A fragment of dead bone is a foreign body; the healthy bone adjacent to it inflames and softens; granulations form, and this line of granulation, like the line of demarcation of gangrene, tends to separate the dead part from the living, the white dead bone being surrounded by the red zone of granulation tissue. A bit of dead bone is called a *sequestrum*, and Nature tries to cast it off. A superficial sequestrum is known as an *exfoliation*.

Nature's method of casting off a sequestrum is as follows: Suppuration takes place at the line of demarcation, osteitis extends for a considerable distance around this line, the periosteum shares in the inflammation, and new bone forms. A cavity is made within by suppuration, and a box or case is formed without by ossification, the now entirely loosened sequestrum being so encased that it cannot escape. The pus finds its way through the new bone, and there is presented the condition so often seen by the surgeon—namely, a case of new bone known as the *involucrum*, a *cavity* containing pus and the dead fragment or *sequestrum*, and a discharging sinus or *cloaca* (Fig. 288). Nature may eventually cast off the fragment, but the surgeon should not wait for the completion of this slow process.

When a portion of the bone surrounding the medullary canal dies, the condition is called *central necrosis*. In some rare cases necrosis occurs without apparent suppuration, a painless swelling of bone simulating sarcoma.

This condition is known as *quiet necrosis*, and has been described by Sir James Paget and Mr. Morrant Baker. Mercury is an occasional cause of necrosis. The fumes of phosphorus may cause necrosis of the lower jaw in those with decayed teeth. Necrosis may be produced also by frost-bites and burns. Many fevers (measles, typhoid, scarlet fever, etc.) are occasionally followed by necrosis. Syphilis and tuberculosis are occasional causes.

The **symptoms** of necrosis are at first those of osteitis or osteomyelitis. The abscess, when formed, opens itself or is opened by the surgeon, and a sinus or sinuses form in the soft parts, as happens in caries. As a matter of fact, were cases of acute osteomyelitis operated on early, extensive necrosis would be rare. If surgeons followed the rule of removing hopelessly damaged bone at the primary operation for osteomyelitis it would seldom be necessary to do extensive operations for dead bone at a later period. When a sequestrum exists a probe introduced into the sinus strikes upon hard bone with a clear, ringing note, and often finds a sinus or sinuses in the bone. In superficial necrosis the discharge is slight and the probe shows the limitations of the disease. In extensive necrosis the discharge is profuse, much new bone forms, several sinuses appear far apart, and the probe must pass through a considerable thickness of new bone before it finds the bit of dead bone. In a chronic case in which there is an involucrum the surgeon may not operate until the dead bone is separated from the living by a line of demarcation unless there is general sepsis. He may wait until the sequestrum is loose unless the patient is being poisoned during the wait. The tendency of thought is against such long delay as was formerly the custom. In youth dead bone loosens quickly, but in old age slowly. An exfoliation becomes loose sooner than the sequestrum of central necrosis. In diffuse periostitis the necrosed shaft loosens quickly, Necrosed portions of the upper extremity loosen more rapidly than those of the lower. In a young adult two or three months will be required to loosen a necrosed fragment in the lower extremity and from six weeks to two months in the upper. A loose sequestrum may be moved by the probe, and when struck gives a hollow note. In protracted cases of necrosis there is always danger that amyloid disease may arise.

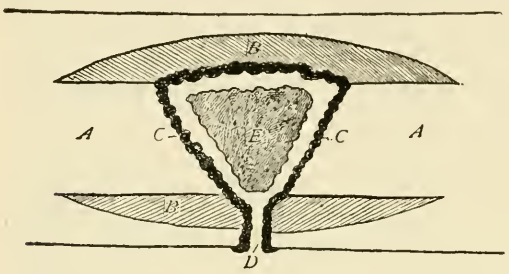

FIG. 288.—Diagram illustrating the formation of a sequestrum: *A*, *A*, Sound bone; *B*, *B*, new bone; *C*, *C*, granulations lining involucrum; *D*, cloaca; *E*, sequestrum.

Quiet necrosis is a rare condition which has led to some deplorable but pardonable mistakes, because it resembles ossifying sarcoma. It follows injury, particularly fracture. The bone enlarges greatly. There is little or no pain and no fever. The diagnosis can only be made by exploratory incision, and it may even be necessary to remove portions for microscopic study before a conclusion can be reached.

Postfebrile necrosis is most usually caused by typhoid fever. The bacilli of typhoid cause chronic osteomyelitis, and this may be followed by necrosis. Scarlet fever, measles, and other febrile processes may also induce necrosis. It is certain that bacilli accumulate in the bones during typhoid fever. They may promptly induce disease; they may remain for long periods apparently inactive and finally pass away; or after a slight strain or injury these organisms may induce bone disease months or even years after the primary infection. *Typhoid bone disease* is often multiple, many bones being involved successively.[1]

[1] Keen's "Surgical Complications of Typhoid Fever."

Not unusually after typhoid fever muscle strain causes periostitis and osteitis, and at such a point necrosis may occur. Either exfoliation or central necrosis may follow typhoid fever. The tibia is involved more often than other bones.

Treatment.—An exfoliation should be removed as soon as it becomes loose, the seat of trouble should be touched with pure carbolic acid, and packing of iodoform gauze should be inserted. The treatment of central necrosis comprises free incisions for drainage, removal of the sequestrum and disinfection, antiseptic dressing, frequent cleansing, rest, nourishing food, stimulants, and tonics. When a sequestrum exists the operation of *sequestrectomy* should be performed. The extremity is drained of blood, an Esmarch band is applied, the bone is exposed by a longitudinal incision, the periosteum is reflected on each side, the involucrum is broken through, and the opening is enlarged with the chisel, gouge, and rongeur. The dead bone should be removed by sequestrum forceps. The medullary cavity on each side of the sequestrum is usually blocked with bone. This bone must be broken through in order that new blood-vessels may form and enter the old cavity. The cavity is to be scraped by a sharp spoon, the lateral edges of the involucrum are cut down until the cavity which formerly contained the sequestrum is very shallow, the wound is irrigated with hot salt solution, dried, painted with pure carbolic acid and then with alcohol, again irrigated with salt solution, and firmly packed with iodoform gauze. Remove the Esmarch band, tie the vessels in the soft parts, suture the wound, and apply dressings. It was long the rule of surgery to remove a sequestrum only when loose, and wait if necessary for it to become loose. This rule has been abandoned in favor of early operation. If possible a sequestrum should be removed before the involucrum has become rigidly ossified. If we wait until the involucrum is rigid we may be sure that the osteogenetic layer of the periosteum has struck work and the bone cavity will have to be filled by artificial means. If we operate from the sixth to the ninth week the osteogenetic layer is hardening but is not rigid, is still active and the cavity will probably heal. The simple removal of a sequestrum—*i.e.*, the operation of *sequestrectomy*—often fails to effect a cure, and even in the most satisfactory cases healing requires a very long time. "The involucrum always contains pyogenic germs that may live in its small foramina and crevices almost indefinitely. For this reason, and on account of the denseness of bony structure, it is well-nigh impossible to disinfect it" (Dr. J. Shelton Horsley, in the "Medical Record," Oct. 20, 1900). Because of the difficulty of curing a case when an involucrum has formed, Dr. Cushing has warmly advocated early operation in osteomyelitis; that is, operation before an involucrum has formed, and when the osteoblasts of the periostum are extremely active. He points out that if an involucrum has formed, the sequestrum and involucrum should be removed after stripping the periosteum from this region. If the periosteum is found not to be infected, it may be stitched together at the gap where the bone has been removed, so that a periosteal cord exists between the two ends of the bone; and the soft parts above this may be closed. If the periosteum is found to be infected, we agree with Cushing that the cavity should be packed with gauze. The cavity that is left by the removal of a sequestrum and the chiseling of the walls of the involucrum, if large, may be filled by various methods more or less satisfactory. In some cases of widespread necrosis due to diffuse infective osteoperiostitis or to osteomyelitis, extensive resection, or even amputation, may be necessary. After removing a sequestrum from a limb devoid of a splint bone always apply splints to the extremity. If the entire shaft of the tibia requires removal the length of the limb may be maintained by implanting the head of the fibula into the head of the tibia. Otherwise extension must be used during repair.

Treatment of Bone-cavities.[1]—Before filling a bone-cavity try to disinfect it. This can be done only relatively. It may be swabbed with pure carbolic acid, followed in one minute by alcohol, or can be mopped with pieces of gauze wet with boiling water. Schede does not pack the bone-cavity, but allows it to fill up with blood-clot after the wound in the soft parts has been closed by sutures. The blood-clot obliterates the dead space in the bone, acts as a support for granulations from the margins, and is slowly eaten by phagocytes. Unfortunately, it is an excellent culture-medium and it often fails of its purpose. Sherman arrests hemorrhage, fills the gap with normal salt solution, and sutures the soft parts without drainage. Some advocate filling the gap with transplanted fat, others with a pedicled flap of muscle. The surgeon may try to fill the cavity by smoothing down the bone edges until the cavity has become a trough, taking flaps of skin from the sides of the wound, separating them freely from the fascia beneath, and holding them within the bone-cavity by inversion sutures or fastening them to the bottom with tacks (*Neuber's operation*). Bayer turns in a fold of skin and periosteum and holds it in place by a roll of gauze sutured firmly upon the wound. Another operation consists in breaking the edges of the involucrum and turning them in. Some surgeons insert decalcified bone-chips. The cavity in the bone is made as sterile as possible and is well dusted with iodoform, the bone-chips are dried and inserted into the cavity, a capillary drain is employed, the periosteum is stitched over the opening, and the soft parts are sutured; but if this cannot be done, iodoform packing is used to keep the chips in place. This method we owe to the genius of Senn. Senn's method often fails because of the impossibility of completely sterilizing the walls of the bone-cavity. Attempts have been made to fill bone-cavities as a dentist fills teeth—with gutta-percha, plaster-of-Paris, copper amalgam, etc., but each of these materials acts as a foreign body in the bone (James E. Moore, on "The Treatment of Bone-cavities," "Jour. Amer. Med. Assoc.," May 20, 1905). Schleich uses formalin-gelatin to fill bone-cavities. The difficulty in every case is the impossibility of completely sterilizing the walls of the cavity. Dressman has advised for this purpose the use of boiling oil, but it is apt to cause superficial necrosis. In some cases the cavity has been healed by the insertion of a Thiersch skin-graft. This method has been advocated by J. P. Lord ("Jour. Amer. Med. Assoc.," May 31, 1902). Von Mosetig-Moorhof's method is one of the best ("Zeitschrift für Chirurgie," lxxi, No. 5). He pours into the cavity a melted material which completely fills the cavity, which will not act as a culture-medium or as a foreign body, which is gradually absorbed, and which "possesses the inhibitory and medicinal properties of iodoform without causing iodoform intoxication" (James E. Moore, Loc. cit.). Mosetig-Moorhof's material consists of 60 parts of iodoform, 40 parts of spermaceti, and 40 parts of oil of sesame. These materials are mixed by heating gradually up to 100° C. On cooling, a solid mass is formed. When the surgeon wishes to use it he heats it up to 50° C. and stirs it while heating (Moore), and pours it into the cavity in the bone. On entering the cavity it at once solidifies. A capillary drain is introduced, the periosteum is sutured with catgut, and the other soft parts are sutured with silkworm-gut. Usually union by first intention is secured. Even if the wound gaps the wax is apt to hold. Mosetig-Moorhof has used this material in 4000 cases without ill effect. Cases of poisoning and at least 1 case of death have been reported (Durvergey, in "Presse Médicale," July 1, 1911). Bismuth paste is preferred by me to the Mosetig-Moorhof wax. Many attempts have been made to fill the defect by *bone-grafting*. The first case of satisfactory transplantation from one of the lower animals with the retention of a vascular attachment was reported by A. W. Morton, in "American Medicine," July 12, 1902. The patient suffered from a compound comminuted fracture of both bones of the right leg. The fracture in the fibula united, but the tibia underwent necrosis,

[1] The views of Macewen and Murphy on repair of bone will be found on pages 136 and 137.

and it was necessary to remove 5 inches of the lower end of the bone. Some days later the periosteum was raised from the ends of the bone and these ends were freshened. The left leg of a dog was amputated just above the tarsus, the bones being sawed so that the ulna was 1 inch longer than the radius. The lower end was partly bared of periosteum, and the ulna of the dog was forced into the cavity of the tibia of the man, and wired to that bone with silver wire. The incision in the man's leg was then sutured, and powerful tendons in each leg of the dog were divided. Each of the dog's other legs was wrapped separately in a plaster-of-Paris bandage, and the entire animal and the leg of the man were than put up in a plaster-of-Paris dressing. Five weeks later the cast was removed, and the bones were sawed and placed in contact with the astragalus. Union took place, and the man was fortunate enough to obtain a useful leg. In some cases a bone defect may be supplied by transference of another bone. Nichols reported 11 cases and insisted on the necessity of preserving the periosteum ("Jour. Amer. Med. Assoc.," Feb. 3, 1904). Huntington has reported a case similar to case No. 2 in Nichols's list. The patient was a boy of seven. A large piece of the entire thickness of the tibia was lost as a result of acute osteomyelitis. There was a gap of 5 inches between the ends of the bone, and the leg was a mere flail. Eight months after the beginning of the osteomyelitis the fibula was sawed opposite the lower end of the upper fragment of the tibia and the upper end of the lower fragment of the fibula was fixed in a cup-shaped depression in the lower end of the upper fragment of the tibia. Six months later union was solid, but in order to improve the weight-bearing power of the limb, nine months after the first operation, the lower end of the upper fragment of fibula was fastened to the upper end of the lower fragment of tibia. The result was excellent. The shortening is only ¾ inch ("Annals of Surgery," Feb., 1905).

Albee's operation of bone-grafting has proved of great value in filling bone defects. In some cases a piece of the tibia may be used in others a rib (see page 782).

Osteomyelitis.—By this term we mean inflammation arising in and about the blood-vessels and attacking the marrow of bone. It may attack the soft tissues and cells in the Haversian canals, in the cancellous spaces, or in the medullary cavity. It may be acute or chronic, localized or diffused. Simple osteomyelitis is not due to bacteria. If localized it usually depends upon a traumatism (fracture, contusion, wrench of an epiphysis). Simple diffuse osteomyelitis may arise in a victim of rickets or osteitis deformans. An acute simple inflammation may cause softening and permit bending. A chronic inflammation causes sclerosis.

Acute infective or **pyogenic osteomyelitis** is an acute and diffuse inflammation of the bone-marrow due to pyogenic organisms. Infection from staphylococci may be limited to a portion of one bone. Streptococcus infection causes widespread involvement of a bone or of several bones. Acute osteomyelitis may be due to mixed infection with bacilli of typhoid and pyogenic organisms, or bacilli of tubercle and pyogenic organisms, a typhoid process or a tuberculous process serving to establish a point of least resistance. The gonococcus and the pneumococcus occasionally produce acute osteomyelitis. In a case of gonorrheal arthritis in which I resected the wrist-joint cultures of gonococci were obtained from the interior of the bone removed.

It was at one time believed that osteomyelitis was due to a specific organism, but Pasteur proved that micrococci are the cause, and Ogston demonstrated pyogenic bacteria in pus obtained from cases of osteomyelitis. In some cases there is pure staphylococcus infection (aureus or albus), both aureus and albus may be present, there may be mixed infection with streptococci and staphylococci, streptococci and several sorts of bacilli, or staphylococci and bacilli. Mixed infections with streptococci are more malignant than staphylococcus

infections. Most cases of osteomyelitis are due to staphylococci. Trauma is a common predisposing cause. It creates an area of tissue damage which captures bacteria from the blood. Ullman was unable to induce experimentally osteomyelitis without first creating by bone injury a point of least resistance. When he applied a ligature to a rabbit's leg for fourteen hours distinct changes were found to occur in the marrow of the bones. These changes consisted chiefly in extravasation and localized hemorrhages. When the marrow was in this condition, if virus were injected into the animal, osteomyelitis resulted, because the bones presented points of least resistance, vulnerable points in which pus cocci lodged and multiplied.

The pyogenic organisms may gain entrance directly by way of a wound (a gunshot-wound, a compound fracture, an amputation). The causative organisms may reach the bone by way of the blood, having entered the blood originally through the lymphatic system or from a focus of suppuration in the skin, the subcutaneous tissue, or a deeper part. Staphylococcus infection commonly depends on cutaneous suppuration.

Pus organisms may pass into the blood from the tonsils or respiratory organs (Kraske); the intestinal canal (Kocher); the genito-urinary tract; or from excoriations, bruises, small wounds, or suppurations in the skin. Certain fevers strongly predispose to the disease by preparing the soil, as it were, for the growth of pyogenic bacteria. Typhus fever, small-pox, malarial fever, scarlet fever, measles, and diphtheria lessen the vital resistance of bone-marrow. Typhoid fever is not unusually followed by chronic osteomyelitis, due solely to typhoid bacilli. If mixed infection with pus organisms occurs, acute osteomyelitis arises. Vital resistance of marrow is lessened by exhausting diseases, overexertion, unhealthy and, especially, putrid food. We know that various infections produce various reactions in marrow, and in this changed marrow vital resistance is probably lessened or even seriously impaired. Longcope made a study of the marrow in 26 fatal cases of enteric fever, and he invariably found numerous lymphoid cells, phagocytes of large size, and multiple foci of distinct necrosis. The cells whose function is to form blood were noted to be undergoing hyperplasia. In persons dead of perforation and general peritonitis there were numerous foci of necrosis, and also widespread degenerative changes in the blood-making cells and pronounced edema and congestion of the marrow ("A Text-Book of Pathology," by Alfred Stengel). When organisms gain entrance directly by a wound (as in a compound fracture), the endosteum, the medulla, and the cancellous tissue inflame and suppurate, and the entire length and thickness of the bone may be involved. The periosteum becomes infiltrated, detached from the bone, and retracted from the edges of the wound in the bone. The soft tissues around the bone may inflame, suppurate, or slough. More or less necrosis inevitably occurs.

Acute pyogenic osteomyelitis without a wound is often called *acute epiphysitis*. Acute epiphysitis is a bad term. The process does not start in the epiphysis. Tuberculosis may start in the epiphysis but not a pyogenic inflammation (Moore, "Annals of Surgery," August, 1916). This condition is most common in infants or children of one or two years of age, but is not uncommon in older children (from ten to seventeen years), and even occurs in adults. It is vastly more common among males than females. The upper end of the tibia and the lower end of the femur are the regions most prone to attack. The hip is seldom attacked. It is most common during the period of active growth of bone. It is frequently preceded by one of the predisposing causes before mentioned (an exanthematous fever, etc.). In some cases a strain or bruise is followed by pyogenic infection, because the damaged tissue extends a hospitable welcome to micro-organisms which are traveling in the body-fluids and pass through the injured area. The most usual antecedent injury is a twist. As Ollier showed, a twist damages the weakest structure, which is the soft, new bone. In at least

half of the cases a history of trauma can be obtained. In some cases there doubtless was trauma, even though we can obtain no history of it. In some cases chilling of the surface of the body is a predisposing cause. In others no predisposing cause is discoverable.

The compact bone suffers secondarily, but is never attacked primarily. New tissue is more susceptible to infection than old tissue, and the disease, as a rule, begins near the epiphyseal line, where new bone is being formed. This point was spoken of by Ollier as "the zone of election of pathological processes." Warren points out that in a growing bone near the epiphyseal cartilage there exists a newly formed spongy tissue, very vascular and connected with the cartilage by a spongy layer of tissue, which is not yet bone, but which does not possess a cartilaginous structure. It is in this portion of the skeleton that the most active changes take place during the period of growth. The medullary substance is very vascular at this point; it is red and without fatty tissue. It communicates with the medullary canal and with the periosteum

Fig. 289.—Fracture of femur after acute osteomyelitis.

Fig. 290.—Osteomyelitis, showing sequestrum formation.

by a number of vascular channels. The epiphyseal cartilage itself is intimately blended with the periosteum. The diaphyseal side of the cartilage produces much more bone than is found in the epiphyseal margin. There is also an active growth of bone in the periosteum, and it is in these regions and in the medullary canal that the inflammatory process originates.[1] The end of the diaphysis is very vascular, but the blood-stream is sluggish because of the large size of the capillary loops ("Practice of Surgery" by Spencer and Gask). The lower end of the femur and the upper end of the tibia are the regions most commonly attacked; but the upper end of the femur and the lower end of the tibia may suffer, and other bones may be attacked, especially the humerus, radius, ulna, and inferior maxilla. The adjacent joint not unusually becomes involved. Though the inflammation begins in the spongy tissue

[1] Warren's "Surgical Pathology."

or medulla, it passes to the canals and spaces of the compact bone. The inflammatory exudate in the canals compresses the vessels and cuts off nutrition from certain areas. Suppuration begins, clots form in the medulla from thrombophlebitis, and the clots in the vessels of the Haversian canals become septic. A small sequestrum forms at the seat of origin of the disease, and the pus about the sequestrum is apt to empty into the medullary canal, causing diffuse osteomyelitis, or into the adjacent joint, causing suppurative inflammation of the articulation.

Marked constitutional symptoms arise from absorption of toxins (suppurative fever), and sometimes true septic infection or even pyemia arises.

Very extensive necrosis may follow osteomyelitis if the patient recovers. Fracture of the bone may occur (Fig. 289). An acute pyogenic osteomyelitis may involve the medulla, may break into the adjacent joint, or may remain localized in the head of a bone and cause an abscess containing fragments of bone or a distinct sequestrum (Fig. 290). The walls of such an abscess are composed of sclerosed bone.

When the medullary canal is involved in a pyogenic inflammation, a part or the whole of the medulla may suffer. The condition may result in central necrosis or in suppurative periostitis and death of the shaft of the bone. The mortality of acute osteomyelitis is high. In the 309 cases collected by Kennedy the mortality was 34 per cent. ("Brit. Med. Jour.," July 20, 1912). The earlier the operation, the less the mortality. Operation within forty-eight hours of the initial chill has a mortality of less than 10 per cent.

Symptoms.—Osteomyelitis secondary to a wound of the bone may occur in a person of any age. If a wound exists—for instance, a compound fracture, —the diagnosis is evident. The constitutional symptoms of septic absorption are positive: there is a profuse, offensive, purulent discharge containing bone-fragments and tissue-sloughs; the periosteum is red, thick, and separated; there are swelling over the bone, great tenderness, and violent boring, gnawing, or aching pain. Osteomyelitis occurring without a wound, the condition often known as acute epiphysitis, occurs in the young, and particularly in children under three years of age.

The symptoms of acute osteomyelitis without a wound of the bone usually come on suddenly and especially at night, and the attack may be so acute as to cause death by systemic poisoning before a diagnosis is arrived at. The disease is generally ushered in by a chill, which is followed by septic febrile temperature. The history will sometimes contain the statement that a blow had been received, that a febrile process had existed, or that the patient had been suddenly chilled after having been overheated (sitting in a draft or in a cellar on a hot day, possibly swimming when very warm, etc.). There is violent aching pain in the bone and acute tenderness near the joint. Within seventy-two hours of the initial chill there will usually be pus in the medullary cavity and a quantity of hopelessly damaged bone if operation has not been performed. The soft parts, which at first are healthy in appearance, after a time discolor, swell, and present distended veins, and may become glossy and edematous because pus is gathered below. The medullary cavity becomes filled with pus. An abscess sometimes reaches the surface and may break spontaneously. The neighboring joint swells, and may become filled with pus; the periosteum and the shaft are involved for a considerable distance; each epiphysis may become affected, the shaft between being comparatively uninvolved, and the epiphyses may separate, displacement and shortening taking place. Extensive necrosis may occur. This disease is often mistaken for rheumatism because of the joint swelling, occasionally for typhoid fever because of the fever, and in some cases for erysipelas because of the redness of the skin. It gives a very grave prognosis. Sometimes an epiphysitis shows milder symptoms and is slower in progress (subacute). These cases are very often mistaken for rheumatism.

But in rheumatism the joint is the part involved from the beginning, while in epiphysitis the joint is involved secondarily after obvious evidence of inflammation well clear of the articulation. Further, the symptoms of rheumatism will be rapidly improved by the use of the alkalis or the salicylates. In the hip osteomyelitis is usually mistaken for inflammation of the joint. Diagnosis cannot be made with certainty without opening the joint.

Treatment.—If osteomyelitis arises secondarily to a wound, apply a tourniquet, sterilize the parts, enlarge the wound, expose and curet the medullary cavity, remove loose fragments of bone, irrigate the medullary cavity with a hot solution of corrosive sublimate or hot salt solution, scrape it with bits of gauze held in the bite of a forceps, paint with pure carbolic acid, pack lightly with iodoform gauze, dress with hot antiseptic fomentations, and secure rest for the parts by splints and bandages. The constitutional treatment is the same as that for septicemia. In some cases amputation is necessary. Acute osteomyelitis without a wound is a most serious condition, rapidly progressive, apt to be quickly fatal, and requiring prompt and radical treatment. Operation should be done as soon as possible after the initial chill. Murphy has insisted upon this for years. Cushing, Le Conte, and others warmly advocate it. I always practise it when possible. Within seventy-two hours, perhaps within forty-eight hours of the initial chill, there will be pus in the medullary cavity and a quantity of bone will be hopelessly damaged. Operation consists in opening the medullary cavity by means of a burr, trephine, or chisel. At such an early stage drainage is all that is necessary, as dead bone has not as yet formed. Very early operation anticipates pus formation. It is not desirable to curet the cavity because the medulla is needed in regeneration. A delay of a very few hours will be responsible for pus and dead bone. When dead bone forms, the medullary cavity must then be freely opened and curetted. The former custom was to pack with iodoform gauze and wait for the formation and loosening of a sequestrum. It is safer and wiser to remove dead bone freely at the primary operation (Le Conte, "Boston Med. and Surg. Jour.," June 1, 1911). When the active symptoms have passed, the pus has drained externally and dead bone has formed the best time to remove the sequestrum will be from the sixth to the ninth week after the attack. At this time the osteogenetic layer of the periosteum is still active. If a needle be pushed through it, it will be found that the involucrum is not yet rigid. Operation done at this stage will probably be followed by healing of the cavity without artificial aids. In any case if the joint is involved it must be drained. In the hip enter the joint by an anterior incision and remove dead bone if there be any, but save all of the neck possible. In all cases employ rest, anodynes, strong supporting treatment, and other remedies advised in septicemia. In a neglected or prolonged case very extensive necrosis occurs and a formidable operation may be

Fig. 291.—Chronic osteomyelitis of the tibia.

required. Even amputation may be necessary. It may be necessary to remove the entire shaft, a bloody and dangerous operation. When dead bone exists and reparative power is not present in the periosteum some method must be employed to fill the bone cavity (page 574).

Chronic osteomyelitis is usually linked with osteitis. Pus may or may not form. There may be only thickening of and pain in the bone. Such a condition can be caused by attenuated bacteria or by bacteria of ordinary power acting on tissue possessed of a very high vital resistance. It may eventuate in osteosclerosis with filling up of the medullary canal, in limited suppuration, in chronic abscess of the cancellous tissue (Brodie's abscess), or in necrosis.

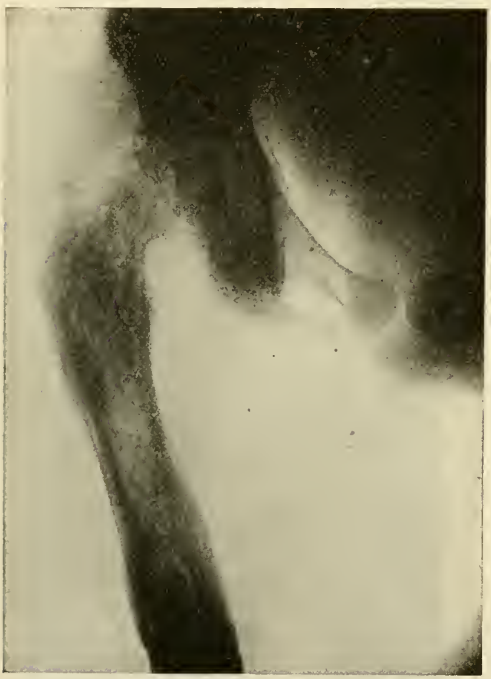

Fig. 292.—Chronic osteomyelitis of the femur.

A tuberculous inflammation is one form of chronic osteomyelitis (see page 275). Syphilis, typhoid fever, etc., may cause it, and it can be caused by glanders, leprosy, and actinomycosis.

The typhoid bacillus under certain conditions is pyogenic. Fränkel taught this some years ago, and Keen proves it in his work on "The Surgery of Typhoid Fever." Osteomyelitis due purely to typhoid bacilli is chronic. When the medulla contains typhoid bacilli pus infection is apt to take place, and if such a mixed infection arises acute osteomyelitis develops. Typhoid osteomyelitis is most apt to arise in the ribs, femur, tibia, humerus, ulna, radius, and metatarsus. It may begin during convalescence or as late as six or seven years after the fever.

In chronic osteomyelitis there are pain, tenderness, and swelling, but no marked constitutional symptoms. In some cases the real trouble is not identified until an abscess forms (see Necrosis). There is a form of chronic osteomyelitis which is nearly always mistaken for rheumatism. J. C. Stewart describes it fully ("N. Y. Med. Jour.," March 25, 1911). It is sometimes preceded by a fever, sometimes by a trivial traumatism, but usually comes on insidiously and endures indefinitely as a chronic condition. Stewart shows that the bone enlarges because of subperiosteal production of new spongy bone. The marrow cavity fills with tissue resembling red marrow. The thick bone is tender at points, there is aching pain, and a trivial rise of temperature toward night.

Treatment.—If an abscess exists, at once evacuate it by incising the soft parts and chiseling the bone. Do not wait for an involucrum to form, but promptly incise, disinfect, and drain. If dead bone is present it must be removed. In the insidious form, so often mistaken for rheumatism, expose and cut through the new bone formation and open the marrow cavity. A case of chronic osteomyelitis may be operated on several times and by different surgeons. The final operation which cures may happen to be the most trivial of all yet to that operation goes all the credit. It is well if possible to make the first operation sufficiently extensive to be thorough.

Osteomalacia, or Mollities Ossium.—In this disease the bones are partly decalcified, and consequently soften and bend. Masses of new uncalcified bone-tissue are formed. Many bones are usually involved, but the bones of the head are not obviously affected. It is commoner beyond than before middle age, though it may occur in infancy, and a case has been reported in which the disease arose at the age of seventy. It is more frequently met with in women than in men, and pregnancy seems to bear more than a casual relation to its production. The disease is particularly apt to arise when pregnancies are rapidly repeated (Marquis, "L'Obstetrique," June, 1910). In osteomalacia the medulla increases in bulk and becomes more fatty, and the osseous matter is absorbed gradually, first from the cancellous tissue and then from the compact tissue. Some observers believe that this curious condition is due to lactic acid in the blood, an abnormal amount of acid having been produced and absorbed because of disorder of the primary assimilation. That there is from some cause, an acidosis in this disease seems reasonably sure (Novak and Poiges, in "Wien. klin. Wochen.," 1913, xxvi). The observers above cited state that normal pregnancy and osteomalacia present like conditions of acidosis and they reach the conclusion that the disease is due to the ovarian changes similar to but more intense than those which occur during pregnancy. It is known that in osteomalacia studies in metabolism show that the body loses calcium and gains sulphur. Volkmann maintained that some inflammatory condition disturbs the blood-supply of the medulla, and von Recklinghausen asserted that arterial hyperemia is responsible. Hönnicke suggests that the disease is due to hypersecretion of the thyroid gland. The probability that the parathyroids play a part in calcium metabolism leads us to suspect them of causal influences. In some cases of osteomalacia tumors of the parathyroids have been found.

Fehling, influenced by finding that improvement may follow removal of the ovaries, set forth the view that the disease is due to overaction of the ovaries, causing reflex dilatation of the blood-vessels of bone. The answer to this theory is the fact that the disease can occur in the male. Some have thought that the disease is of bacterial origin. It is most common in those who dwell in damp or dark habitations. It may arise after a soaking and "taking cold." It is a rare disease in England and America, but is much more common in Germany.

The **symptoms** of osteomalacia are as follows: many points of pain which are often thought to be due to rheumatism; deformities from twisting and bending of bone; sometimes lactic acid and occasionally an excess of calcium salts in the urine. There is no fever early in the case, but later there may be a hectic fever. When the disease comes on after childbirth the iliac bones suffer first. Severe pain arises in the pelvis and back and the pain radiates into the thighs, the pain is worse at night, and is greatly aggravated by pressure or movements. Finally, standing and walking become unbearably painful. The earliest pain may be in the sacrum and be felt only when supine. Pains eventually become generalized throughout the skeleton. Pain in the bony walls of the thorax makes respiration difficult. Great deformity occurs because the partly decalcified bones bend. Many of these patients become fat. Fractures occur from very slight force. In the majority of cases the disease is not cured, but grows progressively worse until the patient dies, after several years, from exhaustion. In some cases the process is arrested and the osteoid tissue is calcified.

Treatment.—In treating osteomalacia in women insist that pregnancy must not occur. In all cases put braces and supports upon distorted limbs to prevent further bending and fracture. Advise hygienic surroundings and nourishing food, and insist on the value of fresh air. Among the medicines that can be used may be mentioned cod-liver oil, lime salts, extract of the pituitary

body, preparations of phosphorus, and bone-marrow. In women the removal of the ovaries sometimes produces great improvement. It has been asserted that the production of anesthesia by means of chloroform may be of benefit.

Acromegaly.—In 1886 Marie reported two cases with acquired and symmetrical enlargement of the face, hands, and feet. He named the condition acromegaly. This curious disease is, in all probability, due to hypersecretion or perverted secretion of the anterior portion of the pituitary body. There is a hypertrophy or a hyperplasisa of this body. As a result of the perverted secretion or accentuated secretory activity there is accelerated growth of the skeleton. It was once thought that tumor was always the cause of acromegaly, but it is now known that whereas tumor may be a cause, many cases occur without tumor. Cases of adiposis dolorosa may show hypophyseal symptoms. Gigantism is probably acromegalic. (For a masterly discussion of this subject see "The Pituitary Body and its Disorders," by Harvey Cushing). Acromegaly is a disease which causes progressive, symmetrical and often great enlargement of both the bones and soft parts of the extremities, and this enlargement is symmetrical. The cranium becomes triangular in shape, with the base below, at the lower jaw. The lower jaw projects in advance of the upper jaw, the nose becomes prominent and thick, the supra-orbital ridges are accentuated (Fig. 293), and the costal cartilages and inner ends of the clavicles become protuberant. Later the larynx, ribs, shoulder-blades, and vertebræ become involved, and the back becomes markedly humped (cervicodorsal hump). The hands and feet are affected in advanced cases. As a rule, the thyroid gland is enlarged, and a postmortem examination may detect a diseased pituitary gland. Severe and uncontrollable headache is sometimes a distressing feature of the disease. In some cases there is marked somnolence. A fireman who suffered from acromegaly would go to sleep almost the moment he sat down. Early there is low assimilation of carbohydrates, often with glycosuria. The disease is not regularly progressive, but exhibits episodes of rapid increase, and periods in which the condition remains stationary or may even retrogress. In a prolonged case signs of pituitary insufficiency are noted, viz.: such high assimilation of carbohydrates that it is difficult or impossible to cause alimentary glycosuria, adiposity, subnormal temperature, and atrophy of the sexual organs. Perhaps such a patient can take 400 gm. of glucose during two hours and yet it will not appear in the urine. Puberty is later. In the male the axillary hair is scanty, the beard is scanty or absent, the facial outline is feminine, the pubic hair is arranged in a triangle with the base above, and the mammary glands are enlarged. Polyuria and polydipsia may be noted. Sexual perversion is not uncommon. The skin is soft like velvet. In both males and females the fingers are short and the skin upon them is thick and furrowed. The nails are very brittle. The *x*-ray shows enlargement of the sella. In all suspected cases an *x*-ray picture should be taken. If a tumor is present or if the gland is hypertrophied the plate will show an enlarged sella turcica. A tumor causes rapid blindness. The disease slowly but surely causes death. Medical treatment is of no avail in cases of pituitary overactivity (*hyperpituitarism*). If there is evidence of hypophyseal insufficiency (*hypopituitarism*) administer hypophyseal extract.

Fig. 293.—Face in acromegaly. Note enlarged superciliary ridge, thickened lips, massive jaw, and general grossness. (Church and Peterson.)

If there is hyperpituitarism it is justifiable to extirpate the gland partially, on the same principle as we partially extirpate the thyroid in a case of exophthalmic goiter. In Cushing's case the operation of partial extirpation of the pituitary body relieved subjective discomforts and modified acromegalic conditions. If there are evidences of tumor of the hypophysis it is justifiable to undertake its removal by operation. This has been accomplished successfully by Hochenegg, Von Eiselsberg, Brochardt, Cushing, Sir Victor Horsley, and others. In the cases of Hochenegg and Cushing not only were pressure symptoms relieved, but acromegalic conditions were greatly benefited.

Leontiasis Ossea or Hyperostosis Cranii (*Virchow's Disease*).—This is a rare condition there being not over 40 cases on record. It begins at puberty as a hypertrophy usually symmetrical and knobby, limited to the facial and cranial bones, and starting, as a rule, in the superior maxillæ. The facial involvement is much greater than the cranials. The soft parts are not involved. I do not say always symmetrical. I operated upon a case involving the facial and cranial bones of one side. The hypertrophy progressively increases, causes difficulty of mastication, and is accompanied by headache. It produces distinct deformity of the jaw like a tumor, whereas acromegaly enlarges all of the proportions of a bone (Fig. 294). The cause is unknown. It is slow in progress, now seeming to cease advancing, now advancing with greater rapidity. The bone changes resemble those of osteitis deformans. The subjective symptoms are due to pressure. There may be nasal obstruction. Violent headache is usual. It may produce blindness, new bone pressing upon the optic nerves. Its course is inexorable and it causes death usually in the fourth decade of life. Treatment is very unsatisfactory. Horsley has obtained some degree of amelioration by operating and removing masses of bone. (See E. D. Telford, in "Med. Chron.," 1914, lix.)

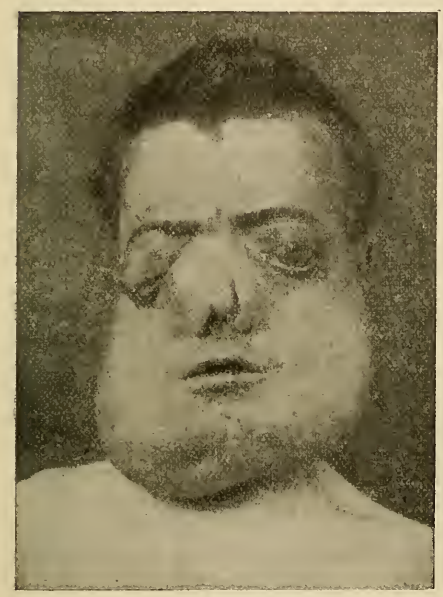

Fig. 294.—Leontiasis ossium.

Fig. 295.—Paget's disease.

Osteitis Deformans (*Paget's Disease*) (Fig. 295).—This disease was first described by Sir James Paget in 1877. Higbee and Ellis state that up to Janu-

ary, 1911, 158 cases have been reported ("Jour. Med. Research," vol. xxiv, No. 1). Packard and Steel were of the opinion that many reported cases were not genuine instances of the disease, some being ordinary osseous tumors, others being cases of enlargement after fracture, and still others being instances of mollities ossium ("Amer. Jour. Med. Sciences," Nov., 1901). Many of the reports are purely clinical. The disease does not appear to be hereditary. Although in 14 instances two or more cases occurred in the same family (DaCosta, Funk, Bergeim and Hawk, in Report of Jeff. Med. College and Hospital for 1915). It is usually associated with widespread arterial sclerosis. Sixty-seven per cent. of reported cases were in males. There is no evidence that gout, rheumatism, or disease of the nervous system plays any part in causation. Lannelongue and Fournier considered the condition parasyphilitic, but there is no real evidence of such origin, in fact a great majority of cases reported during recent years showed a negative Wassermann reaction. Some observers claim to have found organisms in the bone. In two of my cases bacteria could not be demonstrated. It has been asserted that heat or cold may be causal and that the condition has begun after injury of a long bone. A possible cause is disturbance of some internal secretion. The enlarged thyroid in Askanazy's case led him to suggest the theory. In one of my cases the thyroid was atrophied, in two it was obviously enlarged. In two the *x*-ray indicated pituitary enlargement. No parathyroids were found at autopsy in the patient of Higbee and Ellis. These two observers suggest that Paget's disease may be due to absence of parathyroid secretion and the consequent formation of substances which abstract calcium from the bones. In this disease great quantities of new bone are formed, but calcification does not occur. The material undergoes absorption, and the medullary substance of the bone becomes extremely vascular and filled with white blood-cells, and also with giant-cells. The bones lengthen and thicken. The long bones bend and the bones of the skull bulge. An *x*-ray picture shows great thickening of the bones of the skull and perhaps of the jaws. The bending of the long bones has been believed to depend upon the weight of the body acting on uncalcified new bone, but fracture is not particularly apt to occur. It is now maintained that the bending and bulging are active processes, "since the bending is always well marked in those bones which are fixed at both ends by muscles and ligamentous attachments, *e.g.*, the clavicle, radius, and tibia, the accompanying bone (fibula or ulna) acting as the string to the bow" (Gruner, Scrimger, and Foster, in "Archives of Internal Medicine," June, 1912). It is extremely rare before the age of forty, and usually begins between forty and fifty or later, but cases are reported which began between eight and twenty. The enlargement of the bones is usually accompanied by pain in the back and legs, which may be severe. Headache is unusual. Enlargement may be first detected in the cra-

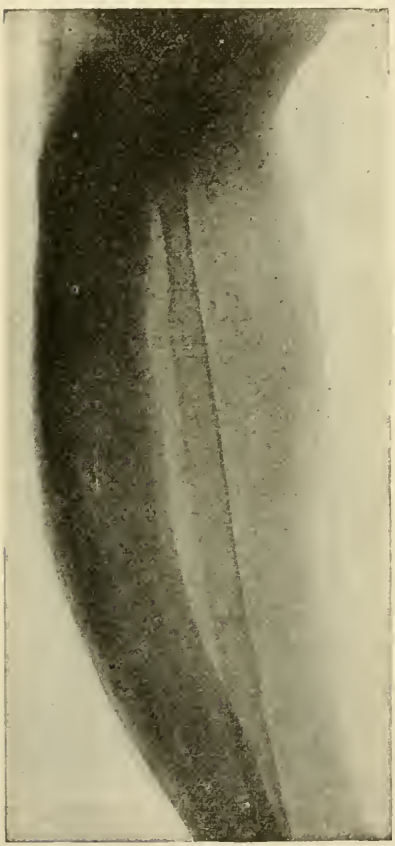

Fig. 296.—Paget's disease.

nium, but is more often first seen in some other bone—for instance, the clavicle, the tibia, the spine, or the radius. The tibia in most cases suffers first, and other bones become involved later. In fact, in some cases the bones of the head do not enlarge at all; but, taking all the reported cases, the skull is affected more frequently than any of the other bones. In some cases the enlargement of the bones seems to be symmetrical; in others it is not. The man finds that at intervals he has to buy a hat of larger size, the forehead is prominent and extremely broad. The posterior part of the head bulges less than the sides and front. In the disease known as leontiasis ossea the chief enlargement is manifested in the face; in Paget's disease there is no enlargement of the bones of the face, or else these bones are trivially involved. In Paget's disease the thickened bones are smooth, in leontiasis ossea these are knobby. Packard and Steele point out that the diagnosis is extremely difficult when but a single bone is involved; but that if two or more bones are involved, we should think of Paget's disease as the condition, especially if we are able to exclude syphilis, cancer, and sarcoma. In mollities ossium the head is not involved at all, and there is not nearly so much thickening of the bone. The two authors before quoted show that in acromegaly the cranium is a triangle with its base below at the lower jaw, the orbital arches being distinctly involved, but that in Paget's disease the involvement is chiefly of the calvarium The patient actually diminishes in height. The chest becomes deformed. There is angular curvature in the dorsocervical region. The lower extremities are usually bent, and the pelvis, as a general thing, is broadened. Paget says: "The most characteristic features are the loss in height, indicated by the low position of the hands, the stooping with round shoulder, the head held forward with the chin raised and the chest sunken toward the pelvis, the abdomen pendulous, the curved lower limbs held apart and usually with one advanced in front of the other and both with knees slightly bent, the ankles overhung by the legs, and the toes turned out. The enlarged cranium, square looking and bossed, may add distinctness to these characteristics, and they are completed in the slow and awkward gait of the patients." In some of the cases there is a tendency to tumor formation. In the 67 cases collected by Packard and Steele, 3 suffered from cancer and 5 from sarcoma. In the 158 cases collected by Higbee and Ellis ("Jour. Med. Research," vol. xxiv, No. 1) there were 14 instances of tumor growth. In some the tumors were in diseased bone, in some they were in normal bone. In Paget's disease there is no particular tendency to fracture.

In a case reported by Gruner, Scrimger, and Foster ("Archives of Internal Medicine," June, 1912) sarcoma appeared in the radius, head of the humerus, and other places. Some cases are associated with goiter. It has been suggested that there is a bacterial cause for Paget's disease. An Italian investigator claimed to have discovered a bacterium and made a serum for use in treatment. In 2 cases I exposed areas of new bone, removed portions, and took cultures. One set of cultures remained sterile. A tube of the other was found contaminated by the skin staphylococcus. In two of my cases metabolism studies were made (DaCosta, Funk, Bergeim and Hawk, Ibid.). Much more calcium and less sulphur were retained than is the case in normal individuals. This is opposite to what is seen in osteomalacia, in which condition the body loses calcium and gains sulphur.

Treatment is practically useless except to the extent of removing surgically some large bony mass. Abbe did this in a man who suffered from a large mass growing from the hard palate. No known remedy diminishes the size of the bones, although iodid of potassium is said occasionally to mitigate pain. Abbe points out that excellent repair takes place after operating upon a bone affected with Paget's disease ("Jour. Am. Med. Assoc.," Feb. 9, 1918).

Osteo=arthropathie Hypertrophiante Pneumique (*Marie's Disease*).—(See page 732.)

Multiple Myeloma.—By this term we mean a new growth in the cancellous tissue of bone which occurs particularly in the ribs, sternum, and vertebræ. It may occur also in the diploë bones of the cranium, in the clavicles, in the bones of the hands and feet, and in the ends of the long bones. The multiplicity is not due to metastasis, but the growths start as separate foci. The nature of the cells in the growths is uncertain. They almost certainly spring from marrow cells. Some consider them myelocytes, some bone-marrow plasma cells. Some of these tumors seem to be truly malignant. Multiple myelomata are related to leukemia, chloromata, etc. (Vance, in "Am. Jour. Med. Sciences," 1916, clii). The effect of the growth is to thin the bones and make them very brittle. This condition was first described by Rustitzky in 1873. About 60 cases have been reported.

The condition begins insidiously, in either sex, during middle age, sometimes in advanced life. It begins usually with attacks of aching in the limbs and weakness. Such attacks may come and go over a considerable period of time. Eventually the back, chest, and ribs become the seats of pain and tenderness. Finally, the pain becomes constant and the patient is confined to bed. In many cases a sternal tumor can be palpated. Spontaneous fractures are apt to occur. Usually Bence-Jones protein is found in the urine. The finding of this protein is not proof of the diagnosis, as it is sometimes found in other bone disorders. Death is due usually to exhaustion. Treatment is futile. (See article by Meyer and Swain, in "Am. Jour. of Med. Sciences," Sept., 1918).

Fractures

Definition.—A fracture is a solution, by sudden force, of the continuity of a bone or of a cartilage. Clinically, under this head are placed epiphyseal separations and the tearing apart of ribs and their cartilages. Blake insists on the difference between a fracture and a wound of a bone. He says: "A bone may be perforated or a portion of it broken off or removed by a missile, and its

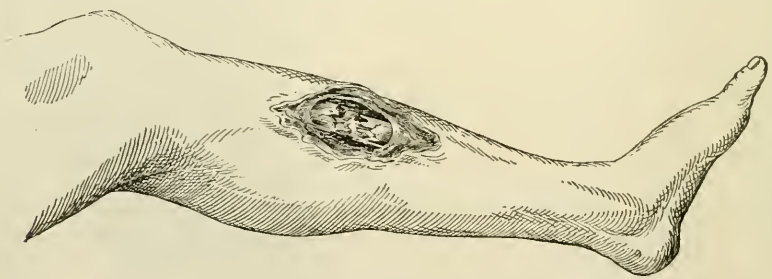

Fig. 297.—Compound comminuted fracture of the tibia.

continuity still remain intact. Such a condition is more often observed in an epiphysis than in a diaphysis. It frequently occurs that a missile penetrates or even perforates an epiphysis without causing a true fracture; but usually, when a diaphysis is perforated, any slight indirect violence is sufficient to break the remaining line" ("Gunshot Fractures of the Extremities," by Lt. Col. Joseph A. Blake, U. S. A.).

Varieties of Fractures.—The varieties of fractures are as follows:

Simple fracture is a subcutaneous fracture, or one in which there is no wound extending from the surface to the seat of bone injury. This corresponds to a contusion of the soft parts.

Compound fracture (Figs. 297 and 307) is an open fracture, or one in which an open wound extends from the surface to the seat of bone injury or in which a wound opens up a passage from the fracture to the surface. This corresponds

to a contused or lacerated wound of the soft parts. The opening may be through the skin; through a mucous membrane, as in some fractures of the base of the skull and pelvis; through the drum of the ear, as in some fractures of the middle fossa of the base of the skull; through the lung, as when a broken rib penetrates that organ; or through the bowel or bladder, as in some fractures of the pelvis.

A *primary compound fracture* is one in which the breach in the soft parts is produced at the time of the accident, either by the direct violence of the injury or by the forcing of a bone or bones through the tissues.

A *secondary compound fracture* is one in which the breach in the soft parts occurs after the accident, either from sloughing of damaged tissues, from ulceration because of the pressure of ill-adjusted fragments, or from the forcing of a bone or bones through the soft parts because of rough handling, neglect, or the tossing of delirium.

Complicated fracture is a fracture plus the complication of a joint injury, arterial or venous damage, or injury to the nerves or soft parts. When a fractured rib injures the lung or when a broken vertebra damages the cord a complicated fracture exists. The term is unfortunate, as it conveys no definite

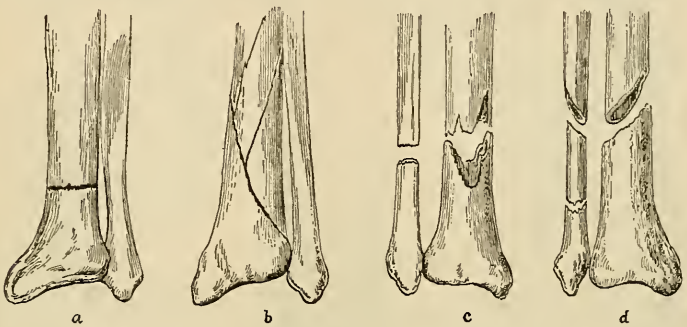

FIG. 298.—Complete fractures: *a*, Transverse; *b*, spiral; *c*, dentated; *d*, oblique or multiple.

meaning, and its use is no more justifiable than it would be to speak of "complicated pneumonia" or "complicated typhoid," for the complication should be named in any case. It must be remembered that damage to the soft parts not sufficiently severe to produce a wound reaching from the surface to the seat of fracture does not make the case a compound fracture, but rather complicates a simple fracture. Remember also that even superficial areas of tissue destruction must be treated antiseptically, otherwise absorption of pyogenic bacteria and their deposition at the seat of injury may cause diffuse osteomyelitis.

Complete fracture is that which extends through the whole thickness of a bone or entirely across it (Fig. 298).

Incomplete fracture is that which extends only partially through the thickness of a bone or only partially across it (Fig. 299).

A *linear*, *hair*, *capillary*, or *fissured fracture*, or a *fissure*, is a crack in a bone with very little separation of the edges. This is an incomplete fracture, but may be associated with a complete break (Fig. 298, *b*).

A *green-stick*, *hickory-stick*, *willow*, or *bent fracture* is a true incomplete break (Fig. 299). The bones most frequently so broken are the radius, ulna, clavicle, and ribs. It arises from indirect force, and it is very rare after the age of sixteen. In rickets green-stick fractures are very common. It is called "green-stick" because the bone breaks like a green stick when forced across the knee, first bending and then breaking on its convex surface. The bone, being compressed between two forces, bends, and the fibers on the outer side of the curve

are pulled apart, while those on the concavity are not broken, but are compressed. In correcting the deformity such fractures are often made complete. The permanent bending of a bone without a break may possibly occur in youth. In children a portion of a bone of the skull may be bent inward, causing depression. In some cases such a depression is permanent; in others it is temporary, the bone returning to its proper level.

Depression-fracture occurs when a portion of the thickness of a bone is driven in by crushing. Fracture by depression is a result of the bending in of a bone (as the parietal), a fragment breaking off from the side toward which the bone is bending. A *depressed fracture* is complete, not incomplete, and by this term is meant an injury in which a fragment of the entire thickness of the bone is driven below the level of the surrounding surface.

Splinter- and Strain-fracture.—The breaking off of a splinter of bone (splinter-fracture) or of an apophysis constitutes a form of incomplete fracture. A strain upon a ligament or a tendon may tear off a shell of bone, and this injury is the "strain-fracture" or "sprain-fracture" of Callender.

Longitudinal fracture is a fracture whose line is for a considerable distance parallel, or nearly so, with the long axis of the bone. Such fractures are common in gunshot injuries (Fig. 300).

Fig. 299.—Green-stick fracture.

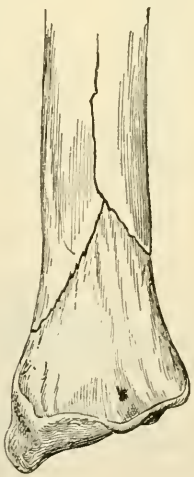

Fig. 300.—Longitudinal and oblique fracture.

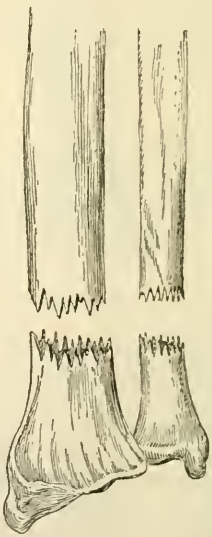

Fig. 301.—Appearances of the ends of fragments.

Oblique fracture is a fracture the direction of which is positively oblique to the long axis of the bone. Most fractures from indirect force are oblique (Fig. 298, *d*).

Transverse fracture is a fracture the direction of which is nearly transverse to the long axis of the bone (no fracture is mathematically transverse) (Fig. 298, *a*). The cause is often, but not invariably, direct force. The *fracture en rave* (radish-fracture, so called because the bone breaks as does a radish) is transverse at the surface, but not within.

Toothed or *dentate fracture* is a form of fracture in which the end of each fragment is irregularly serrated and the fragments are commonly locked together; hence it is difficult to correct the deformity (Fig. 298, *c*, and Fig. 301). Most simple fractures from direct force are serrated.

Wedge-shaped, V-shaped, cuneated, or *cuneiform fracture* ("fracture oblique spiroïde," "fracture en V" of Gosselin, "fracture en coin") is one the lines of which take the shape of a V, which may be entire or may lack the point. It occurs at the articular extremity of a long bone, and a fissure usually arises from its point and enters the joint. If complete, it is a "comminuted fracture."

T-shaped fracture is a fracture which presents a transverse or oblique line and also a longitudinal or vertical line. It occurs at the lower end of either the humerus or femur, the transverse line being above, and the vertical line (intercondyloid) between, the condyles. If complete, it is, in reality, a form of comminuted fracture.

Multiple or *composite fracture* is a condition in which a bone is broken into more than two pieces, the lines of fracture not intercommunicating, or a condition in which two or more bones are broken. Multiple fractures of one bone are divided into double, treble, quadruple, etc. Multiple fractures involving more than one bone are seldom seen, and represent less than 2 per cent. of fracture cases. The reason of their rarity in hospitals

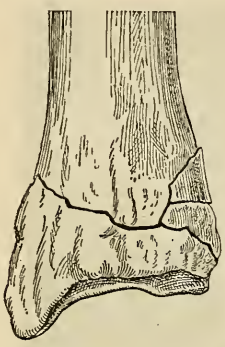

Fig. 302.—Comminuted fracture of the lower extremity of radius.

Fig. 303.—Comminuted fracture of the upper part of femur.

is that they result from severe force and many of the victims die before they can be brought to an institution. The mortality in cases which reach the

Fig. 304.—Impacted fracture of the neck of the femur.

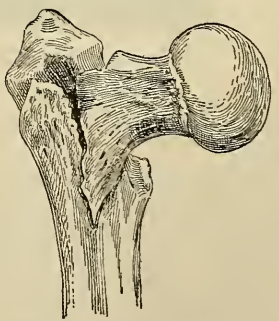

Fig. 305.—Impacted fracture of the neck of the femur.

hospital is large, over 27 per cent. (Astley P. C. Ashhurst, in "Annals of Surgery," August, 1907).

Comminuted fracture is a condition in which a bone is broken into more than two pieces, the lines of fracture intercommunicating (Figs. 302 and 303).

The bone may be broken into many small fragments, there may be much splintering, or the osseous matter may actually be ground up.

Impacted fracture is one in which one fragment is driven into the other and solidly wedged (Figs. 304, 305, and 306).

Fracture with crushing or *penetration* is a fracture in which one fragment is driven into the other, the encasing bone being so splintered that the impacting bone is not firmly held.

Pathological, spontaneous, or *secondary fracture* is one occurring from a very insignificant force acting on a bone rendered brittle by disease.

Ununited fracture is a fracture in which bony union is absent long after the passage of the period normally necessary for its occurrence.

Direct fracture is one occurring at the point at which the force was primarily applied.

Indirect fracture is one occurring at a point distant from the area of primary application of force.

Stellate or *starred fracture* (fracture par irradiation) is one in which several fissures radiate from a center. If the fracture be complete, the condition is, in reality, a form of comminuted fracture.

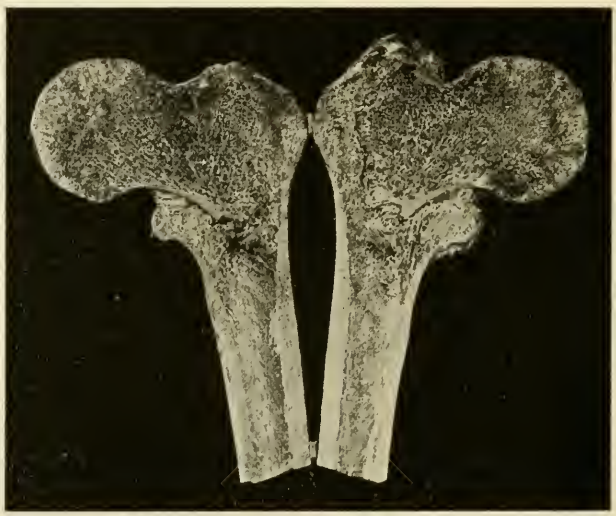

Fig. 306.—Impacted fracture of neck of femur (Conner).

Helicoid, spiral, or *torsion fracture* is a fracture resulting in a long bone from twisting.

Fracture by contrecoup is a fracture of the skull which is on the opposite side of the head to that which was the recipient of the force.

Epiphyseal Separation or Diastasis.—This injury occurs only before the age of twenty-five. In order of frequency, the bones chiefly subject to epiphyseal separation are: the upper end of the humerus, the lower end of the radius, the lower end of the femur, and the lower end of the tibia (John Poland, in the "Practitioner," Sept., 1901). This injury induces deformity, which is often difficult to reduce, and by damaging the cartilage may retard or inhibit a further lengthening of the limb by growth. Occasionally, after damage to an epiphysis suppuration will occur; sometimes thickening takes place. Non-union is very rare. After a sprain of an epiphysis tuberculous disease sometimes develops, but very rarely after a separation.

Intra-uterine fractures are usually due to injuries of the mother's abdomen sustained toward the end of pregnancy. Some hold that they can arise as a consequence of the force of violent uterine contractions. Many so-called "intra-uterine" fractures are wrongly named, as they result from injury during delivery. In sporadic cretinism the bones are fragile and ill-ossified, and many

fractures may occur *in utero*. In the fetal type of fragilitas ossium fractures may occur before, during, or soon after birth.

Designation According to Seat of Fracture.—A fracture may be designated according to its anatomical seat; for instance, fracture of the upper third of the shaft of the femur, fracture of the olecranon process of the ulna, fracture of the middle third of the clavicle, and fracture of the body of the lower jaw. *Intra-articular* fracture is one within or extending into a joint; *intracapsular* fracture is one within the capsule of either the shoulder- or hip-joint; and *extracapsular* fracture is one just without the capsule of either the shoulder- or hip-joint.

Causes of Fracture.—The causes of fracture are: (1) exciting, immediate or direct, and (2) predisposing or indirect.

Exciting causes are: (*a*) external violence and (*b*) muscular action.

External violence is the most usual exciting cause. Two forms are noted: (1) direct violence and (2) indirect force.

Fractures from direct violence occur at the point struck, as when the nasal bones are broken with the fist. In such fractures the soft parts are injured; they may be destroyed at once in part, they may be damaged so severely that a portion sloughs, or they may be damaged so slightly that they do not lose vitality; hence fractures by direct violence may be compound from the start, may become so, or may remain simple. In fractures by direct force discoloration, due to effused blood, usually appears at the point struck soon after the accident. In compound fractures by direct violence the soft-part injury is so great that primary tissue union cannot occur.

Fractures from indirect force do not occur at the point of application of the force, but at a distance from it, the force being transmitted through a bone or a chain of bones, as when the clavicle is broken by a fall upon the extended hand. Such fractures tend to occur in regions of special predilection. If they are not compound, there is no injury of the surface over the fracture. If they become compound by projection of fragments, primary union may still occur. Discoloration over the seat of fracture is usually not present soon after the accident, but may occur later. Discoloration rapidly appears in soft parts at the point where the force was first applied.

Muscular action is rather an unusual cause except in the patella. Fractures thus produced result from sudden or violent muscular contraction. Bones so broken are usually diseased. Violent coughing may fracture the ribs; attempting to kick may fracture the femur; saving one's self from falling backward may fracture the patella; throwing a stone may fracture the humerus; and sudden extension of the forearm may fracture the olecranon process of the ulna.

Predisposing Causes.—There are two classes of predisposing causes, namely: (1) physiological, natural or normal, and (2) pathological or abnormal.

Natural Predisposing Causes.—Under this head is considered the liability to fracture possessed by individual bones because of their shape, structure, function, or position. Those predispositions occasioned by special ages are also considered. In youth epiphyseal separation is commoner than fracture and a fracture is apt to be incomplete. Fractures are commonest between the ages of twenty-five and sixty. From two to four years of age a child is more liable to fracture than later, because he is then learning to walk (Malgaigne). The bones of the old are easily broken, but the normal lack of activity of the aged saves them from more frequent injury. Thus, the predispositions of age are in part due to habits and in part to bony structure. The bones of the young, being elastic, bend considerably before they break; the bones of the old, being brittle and inelastic, break easily, but do not bend. In old age the bones become lighter and more porous, though they do not diminish in size. Absorption takes place from the interior of a bone, particularly at its articular head, the medullary canal increases in size, the cancellous spaces become notably larger, and portions of the remaining bone of the interior show

a fatty change. There is no increase in the amount of mineral salts present, as was long taught. These alterations occur earlier in women than in men.[1] The change of age is a diminution in the amount of bone present, and sometimes a fatty change in a portion of what remains. If the atrophy of bone is other than that normal to senility, it constitutes a pathological predisposing cause of fracture. Normal predisposing causes include the person's weight (which determines the force of a fall), muscular development, habits, sex, occupation, and the season of the year.

Pathological Predisposing Causes.—Hereditary fragility, a form of *fragilitas ossium*, is a condition commonest among women, often existing in generation after generation, and in this condition fractures occur from a very slight force. There exists in these cases bony rarefaction—in fact, a premature senility. *Fragilitas ossium* (*osteopsathyrosis*) may be congenital, may be infantile or may come on later in life. Osteogenesis imperfecta was discussed on page 564. Brittleness may result from senility, wasting diseases, scurvy, scarlatina, bone-cyst, malignant disease of the bone, certain nervous disorders, rickets, osteomalacia, and atrophy due to disuse. Workers in phosphorus are particularly liable to spontaneous fracture of the long bones.

Nervous Diseases.—Bony nutrition is dependent on the spinal cord, and the trophic influence is probably exerted through the posterior nerve-roots. In diseases of the anterior cornua bony growth is much interfered with; in diseases of the posterior columns, as in locomotor ataxia, a true bony atrophy bespeaks trophic disorder. Syringomyelia causes brittleness of the osseous structures, and in paralysis agitans bones are thought to break easily. Trophic changes may occur in the bones of the insane, most commonly when insanity is linked to organic disease. About one-quarter of paretic dements show undue brittleness or unnatural softness of bones.[2] The bones of maniacs are frequently fragile. Fractures among the insane are not necessarily an indication of abuse.

Rickets predisposes to fracture because of altered bone structure and the great liability to falls.

Osteomalacia predisposes to fracture of the long bones, sternum, and ribs.

Atrophy of Bone.—This condition, as has been stated (see above), is normal in senility. It may arise from want of use, as is observed in the bedfast, in the wasted femur of hip-joint disease, and in the bones of a stump. It may arise from pressure, as when an aneurysm compresses the ribs, sternum, or vertebræ. Among other of the pathological predisposing causes are to be mentioned cancer, sarcoma, hydatid and solitary cysts of bone, caries, necrosis, gout, scrofula, syphilis, mollities ossium, and scurvy.

Symptoms of Fractures. *History of an Injury.*—In spontaneous fracture there may be no record of violence; for instance, a bone may break while an individual is turning in bed. In investigating the history, not only seek for a record or for evidences of violence, but try to determine exactly how the accident happened.

A *sound of cracking* is occasionally audible to a bystander at the time of the injury. The patient may have heard it, but very rarely does. A rupture of a tendon or a ligament produces a similar sound.

Pain is usually, but not invariably, present (absent often in rickets). In some fractures the pain is slight, in some there is no pain, in others pain is torturing, and in most it is severe for a time after the injury, but gradually abates unless reinduced by movement. Pain developed at the time of the accident is far less important as a symptom than that which can subsequently be produced by movement. In indirect fracture there is an area of pain at the

[1] Humphrey on "Old Age."
[2] "Manual of Insanity," by Spitzka.

point of application of the force, and another at the seat of fracture. Pain at the seat of fracture can be greatly aggravated by pressure or movement and is rather narrowly localized.

Deformity or *alteration in length or outline* is due in part to swelling and in part to a change in the mutual relation of the fragments (displacement). The deformity due to swelling is no aid to diagnosis, as the same condition occurs in contusion, and often hides some positive symptomatic distortion. The swelling is due first to blood and next to inflammatory products and pressure-edema, and is very great in joint fractures. Swelling due to bleeding is early and rapid. Swelling due to inflammatory exudation is later and gradual. Swelling due to pressure-edema may be rapid. The greater part of the swelling is due to hemorrhage and exudation from the damaged soft parts, a portion of it is due to hemorrhage and exudation from the bone. The swelling is usually in direct ratio to the mobility, the greater the mobility, the greater the swelling. "The swelling in fractures of the skull is inconsiderable, notwithstanding that the total area of bone surface involved is commonly more than in fractures of the leg or arm, and the vascularity greater. The reason for this is the natural immobility of fractures of the skull" (James P. Warbasse, in "Jour. Amer. Med. Assoc.," March 13, 1909). The deformity of displacement may be produced by the violence of the injury (as is the depression in a skull fracture), by the weight of an extremity (as is the falling of the shoulder in a fracture of the clavicle), or by muscular action (as is the pulling upward of the fragment of a fractured olecranon process).

The **varieties of displacement** are: (1) *transverse* or *lateral*, where one fragment goes to the side, front, or back, but does not overlap the other; (2) *angular*, the bony axis at the point of fracture being altered and the fragments forming with each other an angle; (3) *rotary*, one fragment rotating in the bony circumference, the other remaining stationery. As a rule, it is the lower fragment which turns on its long axis, the limb below the level of the break rotating with it; (4) *overlapping* or *overriding*, when the upper level of one fragment is above the lower level of the other fragment. It is usually the lower fragment which is drawn by the muscles above the upper, but in a fracture of the lower extremity the body-weight and sliding down in bed may push the upper below the lower fragment. In overriding the ends are near together and the bones are usually in contact at their periphery. It is obvious that overlapping is associated with transverse displacement, as one fragment must go front, back, or to the side; (5) *penetration* or *impaction* when one fragment is driven into the other, thus producing shortening; (6) *separation of the two fragments* occurs in fracture of the patella, olecranon, os calcis, certain articulations, and in some breaks of the humerus when the arm is not supported.

It is important to remember that a dislocation as well as a fracture may produce displacement, but these two conditions may be differentiated by the observation that the displacement of fracture tends to reappear even after complete reduction, while the displacement of dislocation does not reappear after correction. A displacement is difficult of detection in a flat bone and when one of two parallel bones is broken.

Loss of function may be shown by inability to move the limb because of the break, but it is not always markedly present, though some degree invariably exists. It is slight in "green-stick" and impacted fractures (unless the loss of power arises from pain or nerve injury). A person can walk when the fibula alone is broken, and likewise in some cases of intracapsular fracture of the femur, and can often put the hand on the head in fractured clavicle (Malgaigne). The pain of an injury or the loss of power from nerve traumatism may cause loss of movement in the limb. This symptom is of slight diagnostic value in most fractures.

Extravasation of Blood.—A contusion of the surface accompanied by skin abrasion indicates merely the point of application of direct external violence. If contusion is extensive over a superficial bone, as the tibia or parietal, after a few hours it often simulates fracture by presenting a soft, compressible center surrounded by a ring of hard, condensed tissues and coagulated blood. Direct external violence may merely occasion ecchymosis, and in fracture from indirect force ecchymosis may occur throughout a considerable area. In regard to this symptom, note that even great external violence may occasion no evident contusion or ecchymosis, and in any fracture this symptom may be present or absent. In old people, anemic subjects, fat individuals, alcoholics, and opium-eaters extravastion of blood is frequently marked and persistent. By suggillation is meant an extravasation of blood which slowly invades wide areas of tissue and which appears at the surface after some time only, and then usually as a yellowish discoloration, red hemoglobin having been changed to yellow hematoidin. Linear ecchymosis has been esteemed by some as a sign of fissure, and it is often noted after fracture of the fibula. Linear ecchymosis over the line of the posterior auricular artery was shown by Battle to be a valuable sign of fracture of the posterior fossa of the base of the cranium.

Preternatural mobility is a most important symptom, which is pathognomonic when surely found. The unbroken bone is nowhere mobile in continuity. By preternatural mobility is meant that a bone is mobile in continuity or that there is abnormality in the direction or extent of joint mobility. In some fractures this symptom does not exist (impacted, green-stick, and locked serrated fractures); in others it cannot be found (fractures of tarsus, carpus, vertebral bodies); in others it is difficult to obtain, but at times can be developed (fractures near or into many joints). To develop this symptom try, when the case admits, to grasp the fragments and to move them in opposite directions. In a fracture of the shaft of the femur or humerus fix the upper fragment and carry the knee or elbow in various directions to develop bending at the point of fracture. In fracture of the clavicle push the shoulder downward and inward. In fractures of either bone of the forearm grasp the parallel bone with four fingers of each hand and make pressure on the suspected bone alternately with either thumb, and the same procedure can be used in fractures of the leg. In fracture of the neck of the femur the altered rotation-arc of the great trochanter demonstrates preternatural mobility (Desault). In fracture of the lower end of the radius bend the hand back, and in a break of the lower end of the fibula evert the foot (Maisonneuve). In seeking preternatural mobility remember that the elastic ribs when forced in give a sense of bending, and that the fibula at its middle is "normally flexible" (Dupuytren). Some rachitic bones may be bent.

Crepitus or *crepitation* is both a sensation and a sound, which indicates the grating together of the two rough surfaces of a broken bone. This symptom is of great value, but it is not always present. It is absent in locked serrated fractures, in impacted fractures, in cases where the broken ends cannot be approximated (as in overlapping), is rare when a fractured surface is against the side, and not the broken face, of the other fragment, and is unusual in incomplete fractures. Crepitus is often absent in epiphyseal separation, in softened bones, and in fractures in or near joints, and it may be prevented from occurring by blood-clot, fascia, synovial membrane, periosteum, or muscle between the broken surfaces. The grating found in tenosynovitis must not be mistaken for the crepitus of fracture; the former is diffuse, large, soft, and moist; the latter is limited, small, harsh, and dry. The clicking of an inflamed or eroded joint and the crackling of emphysema must also be separated from bony crepitus. Crepitus of fracture may be present at one moment, but absent the next. It is often not detected during the time swelling is marked, and cannot be discovered after organization

of the callus begins. In but few fractures is it needful to try to hear crepitus with the unaided ear or with a stethoscope upon the part, but in doubtful cases of fractures of ribs and joints this evidence should be sought for.

The above-named symptoms are known as "direct." There are other symptoms known as "circumstantial," such as the flow of blood and cerebrospinal fluid from the ear after some fractures of the middle fossa of the base of the skull; emphysema of the face and epistaxis after fracture of the nasal bones; hemoptysis and emphysema after crushes of the chest; discoloration following the line of the posterior auricular artery after fracture of the posterior fossa of the skull, and subconjunctival ecchymosis after fracture of the anterior fossa of the base of the skull.

Diagnosis.—Examine as soon as practicable after the injury—before the onset of swelling, if possible. Expose the part completely, taking off the clothing, if necessary, by clipping it along the seams. Attentively scrutinize the part and compare it with the corresponding part on the opposite side. If any deformity be present, it must be ascertained that it did not exist before the accident. If the nature of the injury be uncertain, if the patient be very nervous, or if the part be acutely painful, it is better to give ether to diagnosticate, set, and dress. In injuries of the elbow-joint anesthetize before examination, unless an *x*-ray apparatus is accessible to settle the diagnosis, and even then it is usually well to anesthetize in order to facilitate reduction and dressing. In every case of suspected fracture get an *x*-ray picture if possible. A correct diagnosis is of the first importance and on a correct diagnosis proper treatment primarily depends.

A fracture is distinguished from a dislocation by its preternatural mobility, its easily reduced but recurring displacement, and its crepitus, as contrasted with a dislocation's preternatural rigidity, deformity, absence of crepitus, and early strenuous resistance to reduction, with a final tendency to remain in place when once reduced. Further, in dislocation the bone, when rotated, moves as one piece, whereas in fracture it does not so move; in dislocation the bony processes are felt occupying their proper relations to the rest of the same bone, while in fracture some of them present altered relations. In dislocation the head of the bone is found out of its socket, but in fracture it is felt in place. It is important to remember, moreover, that a fracture and a dislocation may occur together, and that the rubbing of a dislocated bone against an articular edge, when the joint has been roughened by inflammation, simulates crepitus.

Great contusion, by inducing extreme tumefaction, may mask characteristic deformity and obscure crepitus. When only a contusion exists, pain is apt to be widespread; but if a fracture has occurred, the pain is accentuated at some narrow spot. In many cases, before he can give a certain opinion, the surgeon must wait some days until the swelling has largely subsided. In such a case it is best to assume in our treatment that a fracture exists until the contrary is known. Combat swelling by rest, the use of evaporating lotions, and moderate compression.

In impaction the diagnosis is difficult. The moderate deformity is concealed by swelling; crepitus and preternatural mobility do not exist unless the fragments are pulled apart, and there is not necessarily much loss of function. A conclusion is reached largely by considering the nature, direction, and extent of the violence, the seat of the pain, and by a careful study of the most minute deformity. It is difficult to recognize fissures. They rarely present any evidence of their existence except a localized pain, and possibly a linear ecchymosis appearing after a few days.

In green-stick fractures the age, the deformity, and possibly crepitus during reduction help in the diagnosis, although in many cases no crepitus is obtained. Epiphyseal separations are diagnosticated by the age, the preternatural mobility, the pain, the swelling, the ecchymosis, the deformity,

the situation of the injury, and the absence of crepitus or the presence only of a soft crepitus. It is important, however, to remember that an epiphyseal separation is sometimes incomplete, and even when it is complete there may be no displacement. In cases without displacement the *x*-rays will not enable us to make a diagnosis. In many cases of complete separation soft crepitus is obtainable, but in not a few cases it is not to be found. In incomplete separation crepitus is absent. If absent in complete separation, probably some tissue is caught in the opened area between the fragments. Fractures are often difficult to recognize when occurring in a group of bones (which are firmly joined by dense ligaments) like those of the carpus and tarsus, or in one of two parallel bones. There is not always a certainty that a fracture exists (see below), and when, after a careful examination, there is still uncertainty, do not prolong the efforts or use great force, but treat the case as a fracture until a cure ensues or the diagnosis becomes apparent.

In a child the diagnosis of fracture is sometimes difficult. Pain may be trivial. Children are liable to a form of fracture in which the periosteum is but slightly torn or is not torn at all, the disability and pain are often slight, and the fracture may be easily overlooked (Cotton and Vose). If after a fall, blow, or twist, a child refuses to use the limb for a considerable time the surgeon should always suspect the existence of a fracture.

In 1895 a method of incalculable value in diagnosticating fracture was given to the surgeon, that is, the use of the force known as the *x*-ray or the Röntgen ray. We can look through a part with a fluoroscope and see the bones as shadows, or we can take a negative of the shadows and print skiagraphs from it. This method is applicable even when the parts are swollen, and even when a limb is clothed or wrapped in dressings. It is possible to obtain a picture of a fractured skull; fractured ribs and vertebræ can be detected; and the process is of the greatest use in detecting fractures of the limbs. It is not infallible. An epiphyseal separation may not be detected, and a slight angling of the plate may give a deceptive appearance of distortion. An *x*-ray picture, to be useful, must be taken by an expert and should be interpreted by a surgeon in association with the *x*-ray expert. It is imperative to employ this method in doubtful cases if an *x*-ray apparatus is accessible. It is advisable to use it in all recognized cases and in all suspected cases.

Complications and Consequences.—Some of the consequences and complications of fractures are—sloughing of the soft parts, thus making the fracture compound; extravasation of blood, causing swelling or even gangrene; rupture of the main artery or vein of the limb; dislocation; edema from pressure of extravasated blood, from inflammatory exudation, from tight bandaging, from thrombosis, or, later, from the pressure of callus; stiffness of joints from synovitis with adhesion, from displaced fragments, or from intra-articular callus; stiffness of tendons from adhesive thecitis or from the pressure of callus; paralysis from traumatic neuritis, the pressure of callus upon nerve-trunks, or from division of a nerve; muscular spasm; painful callus; exuberant callus; embolism; fat-embolism; pulmonary congestion; pulmonary embolism; gangrene; shock; septicemia; pyemia; tetanus; delirium tremens; urinary retention; extensive laceration of the soft parts; rupture of large nerves, and involvement of joints. A fracture may fail to unite, fibrous union or cartilaginous union only being obtained. An epiphyseal separation may arrest the future growth of the limb.

Repair of Fractures. **Simple Fracture.**—In a simple fracture the bone is broken, the medullary contents are lacerated, the periosteum is torn, and the overlying soft parts are damaged to a considerable degree. The periosteum is stripped more or less from each fragment, but it is rarely completely torn through, an untorn portion known as the *periosteal bridge* remaining. The amount of blood effused is usually considerable, and it forms

a decided prominence at the seat of fracture; it gradually gathers because of oozing, and soon clots. This clot lies in the medullary canal, between the fragments, under the periosteum at the ends of the fragments, and in the tissues outside of the periosteum. Very rapidly after the accident the damaged parts inflame (bone, endosteum, periosteum, and the torn periosseous structures). The inflammatory exudate enters into the blood-clot and the leukocytes eat up and destroy the clot. The clot is simply dead material and in no way contributes to repair. The cells of the damaged tissue proliferate and the young proliferating cells (fibroblasts) enter into the spaces in the clot which were eaten out by the leukocytes. Finally, the entire clot is replaced by fibroblasts and much of this cellular mass quickly becomes vascularized (granulation tissue).

The osteoblasts which exist in the deeper layers of the periosteum and, in the tissue of the medulla itself, begin to proliferate actively soon after the fracture has taken place. The fibroblasts have been formed by the proliferation of the ordinary connective-tissue cells, and the proliferating osteoblasts soon enter into and become widely distributed through this mass of fibroblasts. Some observers maintain that the fibroblasts themselves are directly transformed into bone; others deny this, and think that all bone formation comes from

Fig. 307.—Compound fracture.

the osteoblasts. Osteoblasts may form bone directly, or may form cartilage first and then bone. When a fracture takes place, a bridge of periosteum is usually left untorn, and this bridge holds the fragments in contact at some point, just as a strap nailed to a trunk and also to its lid holds these two objects in contact at some point. The new tissue about the periosteal bridge always becomes cartilaginous for a time, but the rest of the callus rarely shows the development of cartilage, and passes directly into bone. If, however, osteoblasts fail to proliferate with sufficient activity, the mass of granulation tissue becomes fibrous tissue; bone is not formed at all, or is very scantily formed, and fibrous union occurs. If the osteoblasts lack activity, but are more active than in the case just cited, they form cartilage extensively—but cartilage only; consequently, cartilaginous union occurs. During the process of the repair of a fracture the ends of the bony fragments are always softened, and some of the bone is absorbed by the osteoclasts. The osteoclasts are really large osteoblasts that have lost the power of producing bone and that furnish a secretion to absorb bone (the elder Senn). After bony union has been accomplished the osteoclasts absorb the superfluous callus. The mass of new tissue around and between the bone-ends is called *callus*. It will be observed that the name is applied successively to fibroblastic tissue, granulation tissue, fibrous tissue, and bone. Warren tells us that callus has no well-defined outline, and "involves not only the bone and periosteum, but also the connective tissue and some of the surrounding muscular tissue." Within a few days

after the injury the inflammatory mass is much firmer than that which follows inflammation involving other structures, and the bone ends have become deeply embedded in a dense mass.

During the second week the callus is greatly strengthened by the formation of dense fibrous tissue in and below the periosteum, of less dense fibrous tissue outside the periosteum, and of cartilage from the periosteal bridge. The newly formed tissue contracts decidedly. During the third week ossification begins at the points farthest from the fracture, and in the course of a short time (from three to six weeks) is complete. The mass of ossified callus, or new bone, is spindle shaped and spongy.

Fig. 308.—Ununited fracture of humerus; unsuccessful wiring.

The terms *intermediate*, *definitive*, or *permanent* callus are used to describe the material which forms between the ends of the broken bone. The names *provisional* or *temporary* callus are given to the material within the canal (central callus) and external to the bone (ensheathing callus). The amount of provisional callus depends directly on the extent of separation and the amount of motion between the fragments. It is Nature's splint, and when the break is not well immobilized a large amount is formed. The greater the amount of motion, short of a degree sufficient to cause non-union, the larger the amount of provisional callus.

The ensheathing callus is after a time largely absorbed, and the central callus in the course of a long time may also be absorbed, with the restoration of the medullary canal, although this latter result is rare. An excessive amount of provisional callus may ossify nearby tendons, may unite parallel bones (radius to ulna, tibia to fibula, a rib to its neighbors), may block a joint just as a stone in the crack of a door will block a door, or may absolutely abolish a joint. Fragments, even if entirely detached, often unite, but they may be surrounded by provisional callus; sometimes they do not cause trouble, but sometimes suppuration takes place. It takes about one year for Nature to remove the temporary callus. The definitive or permanent callus after a time ceases to be porous and becomes very dense bone.

Compound fractures (Fig. 307) without much destruction or bruising of soft parts, if treated antiseptically, soon become simple fractures and unite as such. If the wound is not drained and asepticized and septic inflammation occurs, pus forms, and union by granulation is the best that can be obtained. Compound fractures by direct violence will not heal by first intention because of the loss of vitality of a large area of the soft parts.

Delayed union is usually due to imperfect approximation or unstable fixation of the fragments. Imperfect approximation may result from failure to reduce the fracture (muscle, ligament, or synovial membrane being caught between the bone-fragments); the use of unsuitable splints; too tight application of bandages; pregnancy; and general causes of ill health, for instance, anemia, scurvy, Bright's disease, rickets, or syphilis; disobedience of the patient

or delirium tremens. In delayed union there is pain on passive motion; in non-union there seldom is. In delayed union there is loss of voluntary motion; in non-union there is power of voluntary motion (A. H. Tubby, in "Brit. Med. Jour.," Dec. 7, 1901). In delayed union there is apt to be tenderness on pressure and often a quantity of callus can be palpated. Delayed union is not non-union, but may eventuate in non-union. The exact time requisite for the solidification of a particular fracture cannot be predicted. The average, taken from a large majority of patients, is not true in a minority. For no apparent reason consolidation may require two or three weeks more than the average, but be accomplished at last. Mr. Jones, of Liverpool, well says that ununited fracture is often the result of "surgical impatience," the surgeon frequently examining a part in which union is slow, and that "non-union would

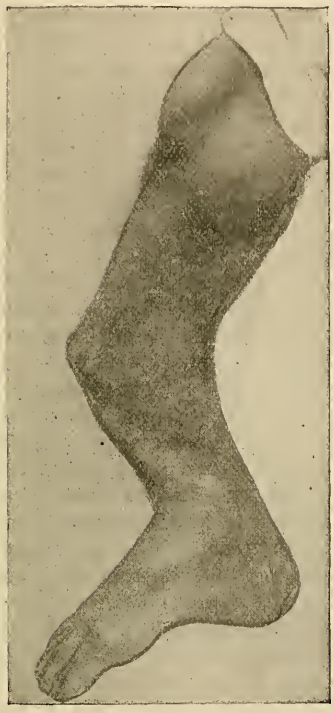

Fig. 309.—Vicious union of fractured bones of the leg. View from inner side of limb.

Fig. 310.—Ununited fracture of the femur.

rarely occur if delayed union obtained proper attention" ("Brit. Med. Jour.," Dec. 7, 1912).

Bending of Callus.—Sometimes apparently sound callus will bend. This is particularly apt to occur in the leg if the bones are not in correct alignment. Failure of correct alignment means great deflection of the weight of the body. I have seen shortening of the femur increase during the third month after a fracture. Mr. Jones, of Liverpool (Ibid.), points out that the surgeon can re-fracture bones by manipulation up to four months after the break. It is obvious that fractures are not soundly united as early as we used to believe, and that a patient must not be allowed to walk too early.

Vicious or **faulty union** is union with great deformity (Fig. 309). This occurs when no treatment has been employed, or when immobilization has been imperfect, or when deformity has not been reduced. It may arise because re-

tentive dressings have been removed by the patient at too early a period, the callus yielding. In many cases it is slight and produces little or no pain or impairment of usefulness. In other cases it is pronounced and produces functional impairment or disastrous pressure on nerves or vessels. Vicious union near a joint always impairs function. If there is pronounced vicious union the bone should be rebroken and set as a fresh fracture. In some recent cases the bone is broken by manual force, and for a number of weeks after a fracture this can be easily accomplished. In older cases osteotomy should be performed.

Non-union of Fractures.—An ununited fracture is a fracture in which union is not effected at all or in which it is not brought about by bone (Figs. 308 and 310). Non-union is especially common in fractures of the upper third of the femur and of the middle third of the humerus. The causes are local and constitutional. The *local causes* are: (1) Want of approximation of fragments; a frequent cause of want of approximation is interposition of soft tissues—viz., muscle, fascia, or periosteum; this is a common cause of non-union, a cause responsible for a decided majority of the cases; if soft tissues are interposed between bone-fragments non-union is almost inevitable; (2) want of rest. As pointed out above, delayed union may result in non-union because of frequent meddlesome examinations. As Sir Robert Jones says, if there is no union at the end of the fifth week do not examine daily, but leave the parts alone for a fortnight at least; (3) want of blood-supply (as seen in the heads of the humerus and femur, or when a nutrient artery is torn, or when a thrombus forms in a vein near the fracture); (4) defective innervation; (5) bone disease; (6) the use of unsuitable splints; (7) tight bandaging. The *constitutional causes* are debility, scurvy, Bright's disease, syphilis, etc. Sometimes union fails without appreciable reason. In an ununited fracture the broken ends of the bone round off and the medullary canal of each fragment becomes closed by bone. The fragments may not be held together by any material, or they may be held by very thin and much-stretched fibrous tissue (*membranous* union), or by strong, thick, fibrous tissue (*ligamentous* or *fibrous* union). When the ends of the bones come together, are held by a fibrous capsule, and move on each other, there exists a *false joint* or *pseudo-arthrosis*. Such a joint may after a time secrete serous fluid for lubrication. In very rare cases a fracture once apparently soundly united may at a later period be obviously ununited, callus having been absorbed or broken. Pain on active motion in the region of a fracture a number of weeks old suggests non-union. If there is also tenderness non-union is highly probable. If, with pain and tenderness, there is marked thickening from callus, non-union is certain ("Brit. Med. Jour.," Dec. 7, 1912).

Treatment of Fractures.—If a man is found in the street with a fracture, further injury must be prevented by applying, after cutting off the clothing over the fracture, some temporary support. If an ambulance or patrol-wagon cannot be obtained, move the patient by hand. If the lower extremity be involved, an improvised stretcher (a board or a shutter) is placed on the ground beside the patient, who is laid on the stretcher, the surgeon lifting the injured limb, and the patient is then carried to the hospital and carefully transferred to a fracture-bed, or, if taken home, to a small ordinary bed, several boards being placed transversely beneath a rather hard but even mattress. The temporary appliances are now removed and a diagnosis is made by the methods before given. Whenever possible have *x*-ray pictures taken (see page 596). After determining the nature of the injury the fragments must be adjusted. This should, if possible, be done at once, because a fracture remaining unreduced may become compound, the fragments may injure important structures, and they are apt to cause intense pain. Reduction is easily effected during shock, as the muscles are in a state of relaxation. Early reduction and fixation largely prevent swelling. If there is very great swelling, reduction may be impossible, and the part must then be supported, moderate

cold, sorbefacients, and gentle pressure being used, ice and tight bandaging, which predispose to gangrene, not being employed. In most cases we can reduce displacement in spite of swelling and cure swelling by the reduction. Set the fracture at the first possible moment. Velpeau's axiom was to reduce fractures at once, regardless of pain, spasm, or inflammation, as reduction is their cure. The longer we wait to reduce a fracture, the greater the amount of force necessary to accomplish it because of progressive infiltration of the soft parts with inflammatory exudate and blood, a process which lessens and finally destroys tissue elasticity. In reduction try to get broken ends in even apposition. In this we may fail, but we must at least strive to obtain a correct alignment. In order to obtain apposition or alignment it may be necessary to make traction by pulleys, and if this is done the patient must be anesthetized (Sir Robert Jones, "Brit. Med. Jour.," Dec. 7, 1912). He says that "end-to-end apposition with an angle of deflection is less satisfactory than slight overlapping in the presence of correct alignment" (Ibid.).

If the patient is very nervous, if the pain is severe, or if rigid muscles antagonize the efforts of the surgeon, reduce the fracture under anesthesia. In some fractures (as those of the clavicle) adjustment is effected by altering the position, and in others (as those of the femur) by extension and counterextension, aided perhaps by pulleys; in some by tenotomy, and in some by kneading, bending, and coaptation. When extension is employed, always endeavor to get a point of counterextension. The extension is to be made on the broken bone (if possible, in the axis of the bone), is to be steady, and neither jerky nor violent. In some cases complete reduction is impossible. This may be due to spasm, to swelling, to the catching of soft parts between the fragments, to the existence of a loose fragment, to locking, or to impaction. An impaction by rotation can generally be released, but it is sometimes undesirable to unlock it. If the fragments cannot be adjusted without violence, retain them in the best attainable position, combat the antagonistic cause, and set them properly as soon as possible or else operate.

After adjusting the fragments maintain them in position by some apparatus. Do not use set splints for each variety of injury. The splints we describe as commonly used are suited to many cases, but in each case a surgeon uses the plan of treatment which in his opinion is suitable to that case. In a given case the routine plan may prove unsuitable. The treatment is to be adjusted to the individual case. The case is never to be forced to an unsuitable routine treatment. All sorts of materials are used for splints; among them may be mentioned wood, felt, pasteboard, plaster of Paris, silicate of sodium, tin (Levis), and aluminum (Elsberg). Avoid pressure over joints or bony prominences and particularly guard against tight or improper bandaging. In fracture of a bone of a limb the circulation in the fingers or toes must be observed as an index of circulation in the limb; hence leave those digits exposed. A retentive apparatus should prevent the redevelopment of deformity, and not be itself productive of pain or harm. For the first few days of treatment of a simple fracture the dressing (if not plaster or silicate) is to be removed every day, to make sure that deformity has not recurred, and if it does recur the fragments must at once be reset. The splints should be padded thoroughly, especially when over joints or bony prominences, and they should, if possible, fix the joints immediately above and below the break. A primary roller should not be used unless plaster is to be employed. By a primary roller is meant a bandage applied to the extremity before splints are placed upon it.

Some years ago Steinmann proposed to obtain extension in fractures by what is called nail extension. A steel wire nail should be driven through the end of the lower fragment. This nail is used as a fixed body on which to set an apparatus for extension. It can also be used to antagonize rotation. The nail is removed in from eighteen to twenty-one days. If it is retained longer

it will produce pressure necrosis (Dyas, in "Surgery, Gynecology, and Obstetrics," 1916, xxiii).

J. C. A. Gerster leaves it in from twenty-eight to thirty-five days ("Jour. Am. Med. Assoc.," 1916, lxvii). Ransohoff devised a tongs, the points of which catch in the femoral condyles (Fig. 311), and Codavilla uses a pin for the same purpose.

There is no doubt that by this method powerful traction can be brought to bear exactly where it is needed. It is said to be safer than treatment by operation. I have never used the method. It seemed to me to possess some of the objections long ago filed against Malgaigne's hooks used for fracture of the patella. Blake, however, tells us that it is the most perfect of methods by which traction can be made upon the femur "because it permits the placing of the limb in an absolutely correct position and acts directly upon the fragment without fixing or injuring the knee. With it a weight of six kilos produces as much effect as fifteen kilos attached by the ordinary adhesive bands. The objection to it is the fear of infection at the site of the pin or tongs, but present experience seems to prove that the tongs at least may be employed with impunity" (Lt. Col. Blake, Ibid.).

Some surgeons at once apply an immovable dressing. This proceeding is safe in simple fractures without much displacement or soft-part injury. This

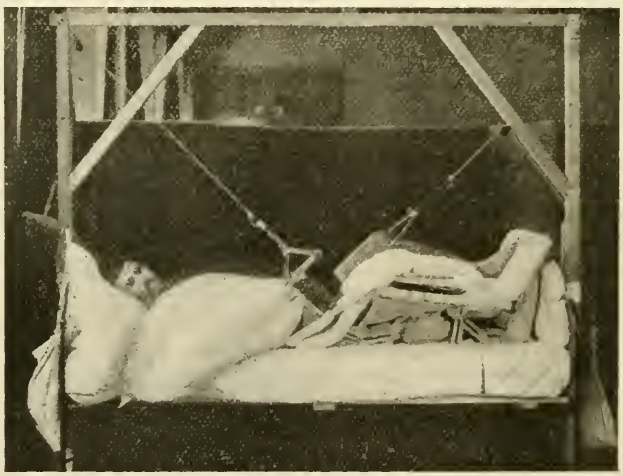

Fig. 311.—Showing the use of Steinmann pins in the treatment of multiple simple fracture of the middle third of femur (Fauntleroy).

dressing is valuable in military practice, for the old and feeble whom we fear to put to bed, for the young who are very restless, and for the insane or the delirious. If, however, there is great deformity, much soft-part injury, or marked swelling, immovable dressings may induce sloughing, edema, gangrene, or faulty union. In the above-named cases use ordinary splints for the first few days; then, if it is desirable, the immovable dressing can be applied. Plaster-of-Paris bandages are used with great care in very young children, as gangrene might result from careless application. It is dangerous to keep old or feeble persons long in bed, as they are prone to develop bed-sores and hypostatic pulmonary congestion. The period for the artificial retention of the fracture varies with the seat of the fracture and the age and condition of the patient. Passive motion is to be made in most fractures in from two to three weeks, though it is sometimes made earlier to prevent ankylosis, and sometimes later because of risk of non-union. Landerer strongly advocates massage, believing that it hastens union and prevents wasting. He applies it as soon as there is no

danger of the callus bending (in from eight to fourteen days). Massage should not be used when great edema points to the possibility of venous thrombosis. The movements might break up a clot and cause fatal embolism.[1] Very early massage may cause fat-embolism. In fracture of the patella wiring is frequently performed, and wiring or plating is frequently practised in fracture of the clavicle, fracture of the tibia, fracture of the upper third of the femur, and other regions. If fragments cannot be approximated or retained by ordinary methods, an incision should be made, approximation effected, and the fragments retained by wire, a clamp, a plate, or a bone ferrule.

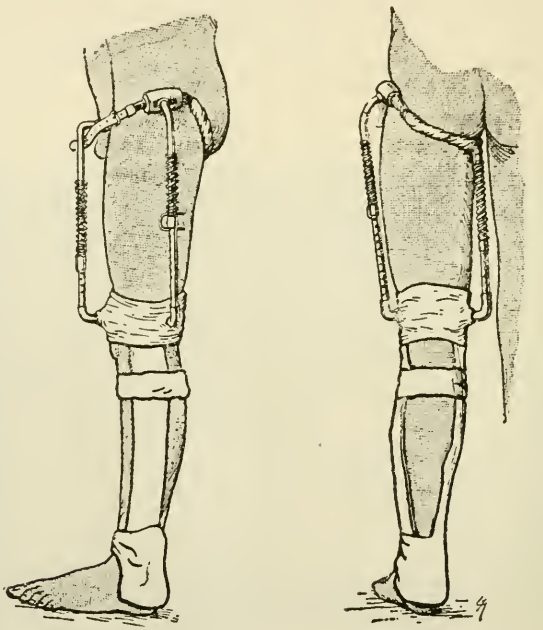
The plan known as the **ambulatory treatment** of fractures of the lower extremities has had warm advocates. The ambulatory splint is an apparatus which enables a man to walk about a few days after receiving a fracture of the leg or thigh. It was devised by Hessing, a carpenter dwelling in a village near Augsburg. Its aim is not only to get the patient about on crutches, but also to cause him to use the limb. It is held that this plan of treatment greatly lessens the patient's sufferings and actually favors union by the stimulation of walking. Bardeleben, in his report to the German Surgical Congress, gave the records of 111 fractures of the lower extremity thus treated (77 simple and 12 compound fractures of the leg, 17 simple and 5 compound fractures of the thigh). The patients were gotten about a few days after the accident, were able to attend to business, had excellent appetites, digested their food perfectly, slept well, and were saved from muscular atrophy. Pilcher has warmly advocated the method. It can be used in fractures as high up as the middle of the femur. The apparatus which we should employ in the ambulatory treatment reaches below the sole of the foot, and is supported firmly above the seat of fracture, the weight of the body being transferred from above the fracture to the firm pad below the sole of the foot on which the patient walks (Figs. 312 and 313). This appliance in a fractured thigh is put on about one week after the infliction of the injury. While the patient sits on the ischial tuberosities extension is made upon the leg. The seat of fracture is encircled by a thin plaster cast. The sole of the other foot is raised by a cork sole. Albers, when treating a fractured thigh, uses plaster of Paris strengthened by bits of wood, running from *below* the sole of the foot to the iliac crest. Krause says in fracture of the ankle carry the dressing to the head of the tibia; in fracture of the leg carry it to the middle of the thigh; in fracture of the lower end of the femur carry it to the pelvis.[2] Bradford warmly advocates the use of Thomas's splint often combined with plaster of Paris. During the last few years surgeons have come to recognize that ambulatory treatment must not be used for all fractures of the lower extremity and is only suited to selected cases. The ambulatory treatment is warmly commended by some military surgeons on the ground that it secures full return of function and also favors union of the bone and healing of the wound (Captain C. Max Page, R. A. M. C.). In fracture of the femur Delbet uses the apparatus shown in Figs. 312, 313. He gets his patients up and has them walking about a few days after the injury.

Prevention and Treatment of Complications.—In every case of fracture of an extremity feel for the pulse between the periphery and the seat of injury in order to be sure the artery is not ruptured. If the soft parts are badly contused, try to prevent sloughing by employing rest and relaxation and by applying heat. If superficial sloughing occurs, treat antiseptically, remembering that even a superficial excoriation can admit bacteria which, carried by the blood or lymph, may infect the bones. If a slough leads down to the fracture, treat the case as a compound fracture. If there be great blood extravasation the danger is gangrene, and after fracture of the lower extremity the foot of the bed may be elevated, or, better, after fracture of the upper or lower limb the

[1] Cerne's case, in "Normandie méd.;" "Bull. med.," 1895, No. 44.
[2] "Centralbl. f. Chir.," vol. xxii, 1895.

extremity, to which splints and bandages are to be loosely applied, is to be raised and surrounded with hot bottles. If a bleb forms, it is to be opened with a clean needle and dressed antiseptically. If gangrene occurs, treat by the usual rules. Frequently after fracture of a bone blebs containing reddish serum form on the skin. The appearance of *blebs* when the circulation is good does not mean gangrene, and is not of any particular consequence. If blebs are distinct symptoms of circulatory impairment, gangrene impends or already exists.

Edema may be due to tight bandaging. If it is due to phlebitis, there is danger of pulmonary or cerebral embolism. In phlebitis elevate the limb, remove all constriction, and employ locally ichthyol ointment; do not use massage, and give stimulants by the mouth. In edema due to weak circulation or



FIGS. 312, 313.—Delbet's apparatus for ambulatory treatment of fractures of the femur (Leriche).

venous relaxation use daily frictions and firm bandaging. If the fracture involves a joint, carefully adjust the fragments, make passive motion early, and inform the patient that he is in danger of a permanently stiff joint.

A *dislocation occurring with a fracture* is reduced at once if possible. To do this, splint the limb and give ether, and try to reduce while the limb is manipulated, using the splint as a handle. Allis is often able to reduce a dislocation accompanied by a fracture. He uses the untorn portion of periosteum as a hinge, pulls upon the lower fragment, and thus draws down the upper fragment and pushes it in place by manipulation. If this fails, it is best to incise and pull the separated end in place by the hook of McBurney and Dowd (Figs. 314–316); but some surgeons say, get the bones in the best possible position, set them, await union, and then treat the unreduced dislocation. A *rupture of the main artery* of the limb presents the symptoms of absent pulse below the rupture, a tumor which may pulsate, and possibly a whirring sound or an aneurys-

mal thrill and bruit. This condition demands that the surgeon should apply an Esmarch bandage, cut down upon the tumor, turn out the clot, and ligate each end of the vessel. *Rupture of the main vein* of a limb causes intense edema and calls for sutures, lateral ligature, or complete ligation. If these measures fail after injury of vein or artery it is seldom successful to ligate higher up. Such a course might succeed in the upper extremity. It would almost certainly fail in the lower. Amputation will probably be necessary. If gangrene appears, amputate at once above the seat of the fracture.

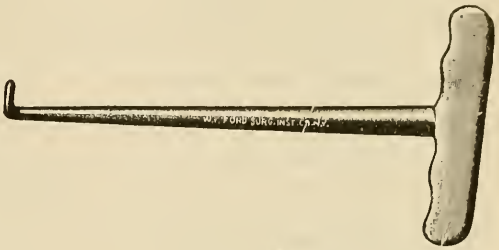


Fig. 314.—Fracture-hook (McBurney and Dowd).

Inflammation is to be treated by compression, rest, moderate cold, and later by 50 per cent. ichthyol ointment. *Muscular spasm* requires morphin internally, firm bandaging, or even tenotomy. Fat-embolism is treated by stimulants and inhalation of oxygen, and possibly artificial respiration. Shock, delirium tremens, urinary retention, etc., are treated according to the ordinary rules of surgery.

Functional Result of Non-operative Treatment.—Union with a good anatomical result means a good functional result in over 90 per cent. of the cases. We used to suppose that a good functional result is usual even with a poor anatomical result, but Jones ("Brit. Med. Jour.," Dec. 7, 1912) shows that we get it in less than 30 per cent. of cases in which the anatomical result is bad.

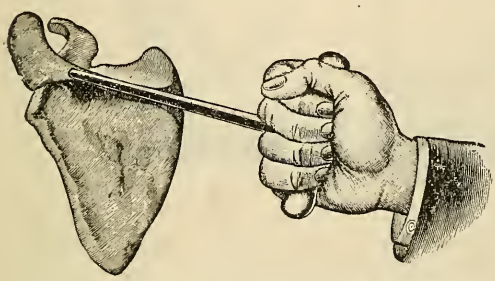

Fig. 315.—Fracture-hook applied at base of acromion process (McBurney and Dowd).

Treatment of Compound Fractures.—In a compound fracture of a limb the first-aid treatment consists in arresting hemorrhage temporarily by the elastic band, painting the wound and the skin about it with iodin, packing the wound and covering the wound with sterile gauze, applying a temporary splint for transportation, and adopting means for combating shock. During transport it may be necessary to administer morphia because of pain. The *x*-rays are of great value in determining the condition of the bones in a crushed part. Thorough examination and satisfactory disinfection require the giving of ether, then the surgeon can determine whether or not amputation is necessary. The question is sometimes determined by the age and general health of the patient. When in doubt and the patient is a healthy young person, give the limb the benefit of the doubt, and wait. It is needless to say that amputation is demanded when the limb is completely crushed or pulpified through its entire thickness. If the artery alone is ruptured, cut down upon it and tie both ends. If the vein alone is torn, suture it, apply a lateral ligature, or, if necessary, tie both ends. If the nerve is severed, suture it. If a joint is opened, drain

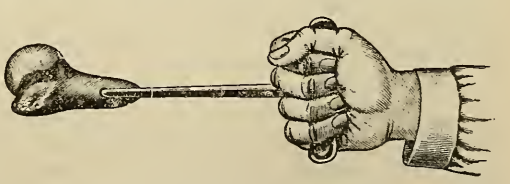

Fig. 316.—Fracture-hook inserted in displaced fragment (McBurney and Dowd).

and asepticize. W. L. Estes ("Jour. Amer. Med. Assoc.," 1914, lxii), from an experience of 800 cases reaches the following important and specific conclusions as to the indications for amputation.

1. If the skin has been so crushed or torn that it is obvious that at least three-fourths of the skin of the periphery and over the fracture will slough—amputate.

2. If the entire periphery of the limb at or near the site of fracture has been subjected to a destructive circular or annular pressure—amputate.

3. If there is much annular laceration of the skin and the muscles are also badly crushed or torn—amputate.

4. If the limb has been subjected to immense pressure (as by a car wheel) and the skin though intact, so completely cut off from nourishment that its doom is sealed, the muscles torn and the bone comminuted—amputate.

5. A nerve trunk can usually be sutured. If the chief blood-vessels are torn across in the usual jagged way either anastomosis or transplant will be useless, and the surgeon should amputate.

6. If the comminution is so extensive that the fragments be free and stripped of periosteum and the condition would demand the sacrifice of 3 inches or more

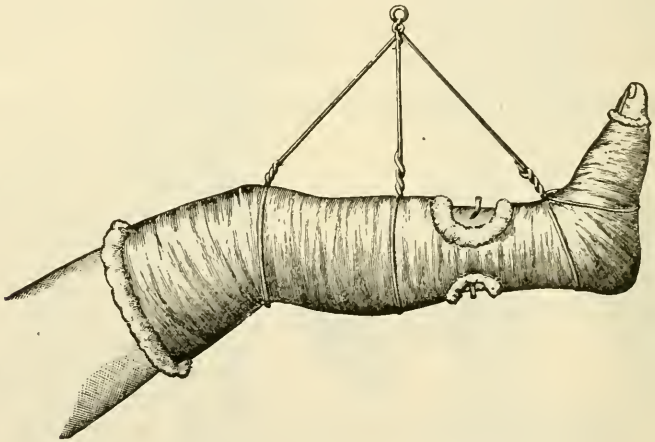

Fig. 317.—Fenestrated plaster-of-Paris dressing. Drainage-tube pulled through limb If Dakin's fluid is used this drainage is not employed.

of the shaft, and if (as is almost sure to be the case) there are extensive lacerations of muscles and skin—amputate.

If an attempt is made to save the limb, be ready at any time to amputate for gangrene, secondary hemorrhage (if religation at original point and compression high up fail), extensive cellulitis, and profuse and prolonged suppuration.[1] When it is determined to try to save the limb, the part must be cleansed thoroughly by the antiseptic method (in no injuries is this more important). If a small portion of bone protrudes, cleanse the skin of the extremity and the protruding bone, push the spicule out a little more, and cut it off. If a large piece of bone is protruded it must not be cut away, but should be thoroughly disinfected, and after the skin wound has been enlarged should be returned into place. Hemorrhage requires a free incision to permit of ligation of bleeding points. In comminuted fractures loose splinters should be removed. Attached splinters covered by periosteum should not be removed. To remove them favors non-union. Personally I seldom use bone plates in compound fractures. All hopelessly lacerated tissue is cut away, the wound is left wide open or is partially sutured and Dakin's fluid is used (page 329). In some cases a counter-opening must be made and the Dakin's fluid used as shown in Fig. 151. If

[1] See Howard Marsh, on "Fractures," in Heath's "Dictionary of Practical Surgery."

circumstances do not admit of using the Carrel-Dakin treatment make a counteropening and pass a drainage-tube through the limb (Fig. 317).

An antiseptic dressing is applied, and the extremity is either subjected to extension or dressed with plaster. The plaster can be applied over a narrow strip of wood, trap-doors or fenestra being cut in the plaster before it sets (the *fenestrated splint*). The wound is then covered with gauze and a bandage.

The bracketed splint is a better dressing than the one just described. After the wound has been dressed with gauze, plaster is at once applied over the ends of brackets (Fig. 318). For fractures of the femur or the bones of the leg we may use a Thomas traction splint or the Balkan frame, sling and weights (Fig. 326). For the leg a Hodgen splint is satisfactory, the knee being slightly bent (Fig. 325). In some fractures of the humerus use suspension and traction. In others use a Thomas splint (Figs. 346 and 348). Some fractures of the forearm are treated by the Thomas splint, others by suspension, traction, and counter-extension. The above methods not only immobilize the fractured bones, but keep the parts aseptic and afford easy access to the wound. If drainage-tubes are used they are usually removed if suppuration does not occur in from forty-eight to seventy-two hours. The wound is treated as any other wound. In some compound fractures it is found difficult or impossible to retain the fragments in apposition by splints or extension (lower end of femur, upper third of femur). In such cases the ends of the bone should be resected and the bones should be fastened together as in a case of ununited fracture, with silver wire, aluminum wire, chromicized catgut, kangaroo-tendon, or the bones should be plated. In a *compound fracture of the patella*, after free incision and disinfection, investigate to determine the gravity of the injury. In an ordinary case in which there are two or three fragments, open the joint, irrigate with saline fluid, drill the fragments, and fasten them with silver wire. Very small fragments should be removed. The wound is partially sutured, Carrel's tubes are inserted, dressings are applied, the limb is immobilized in extension, and Dakin's fluid is used. In a case of severe compound comminuted fracture of the patella, after disinfection, any completely loose piece should be removed and "the remaining portions made smooth with bone forceps and the sharp spoon."[1] The wound is only partially sutured, Carrel's tubes are inserted, dressings are applied, the limb is placed on a straight posterior splint, and Dakin's fluid is used. If a fracture of a rib is compound internally, resect the rib; if it is compound externally, dress antiseptically.

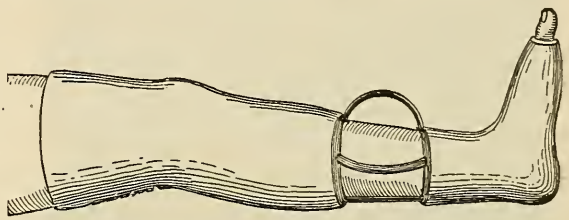

Fig. 318.—Bracketed plaster-of-Paris dressing.

Compound fractures may be followed by gangrene, sloughing, periostitis, septicemia, pyemia, osteomyelitis, necrosis, etc. If cellulitis arises after a compound fracture open freely, remove sloughs and employ Dakin's fluid until suppuration is controlled. Many surgeons have been opposed to suturing after infection of a compound fracture. Some do it. Morison, Good and others, when suppuration has been controlled, proceed as follows: Cleanse the skin about the wound and also the wound. Dry the wound. Cover the wound and fill all pockets and bone cavities with "bipp." Wring out gauze in liquid paraffin, put a quantity of "bipp" in its center and bring the gauze in contact with the entire wound surface. Dressings need changing only in from 5 to 15 days. The infection soon becomes entirely local. Then the skin surfaces are brought toward each other by heavy mattress button sutures of silk, coated with "bipp." In six or seven days much will be gained and then new

[1] Lilienthal's "Imperative Surgery."

sutures are introduced and the skin edges curve nearer together. At each seance "bipp" is introduced into the wound. The skin will require undercutting to prevent inversion. From time to time any loose bone fragments should be removed. (The above is taken from the "International Abstract of Surgery," Nov. 1918, which took it from F. B. Gurd's article in the "Lancet," 1918, cxciv.) Gurd treats sinuses by passive hyperemia. If that fails, he excises the scar, cuts away dead bone, introduces "bipp" and inserts mattress sutures (Ibid.).

Operative Treatment of Recent Fractures.—Many cases are now operated upon immediately (within ten days of the injury). Others are operated upon at a later period than ten days after the injury because non-operative methods fail to obtain or to maintain good position (delayed operation). In some fractures reduction and fixation are only possible by operation.

Skiagraphs have demonstrated that the ordinary non-operative treatment is often followed by permanent displacement. In many cases this does not seriously impair function, in not a few it does. There is much impairment of function after fracture of the patella with wide gaping of the fragments, and after fracture of the femur with repair in a position of marked angulation or decided overlapping.

The most perfect results are obtained by operation, which exposes the fracture and enables the surgeon to correct the deformity and fix solidly the fragments. Practically all surgeons agree that for fracture of the patella, fracture of the olecranon, and fracture of a long bone with incomplete reduction, or in which deformity recurs in spite of splinting, operation gives the best chance for a good functional result. In most fractures of long bones treated conservatively perfect apposition of the fragments is not obtained, although we may think it has been. Bloodgood points out that in fractures near joints there is great difficulty in reduction and little evidence of deformity.

The Special Committee of Inquiry of the British Medical Association in a recent report warmly advocates operation in many cases. Sir Robert Jones, of Liverpool, although believing as a general rule in non-operative treatment, says that if in any case there is sound reason to doubt the successful outcome of non- operative treatment, operation should be performed. He opposes waiting to see what happens because the delay may lose the chance of obtaining a good functional result ("Brit. Med. Jour.," Dec. 7, 1912).

Personally, I follow Sir Robert Jones's rule and operate when I fear that conservative treatment may fail. I operate primarily for:

Fractures that cannot be well reduced or which cannot be kept reduced. Many fractures about joints are of this character.

Fractures in which crepitus cannot be obtained because soft parts are caught between the fragments.

Fracture of the patella.

Fracture of both bones of the leg in the lower third.

Most fractures of the os calcis.

Some cases of Pott's fracture.

Most cases of fracture of the upper third of the femur.

Some fractures of the neck of the femur in the young and middle aged.

Some fractures of the surgical neck of the humerus.

Fractures of the olecranon, especially those in which the upper fragment has rotated.

Some fractures of the elbow-joint.

Some fractures of both bones of the forearm (in order to preserve pronation and supination).

Some fractures of the metacarpus.

Fractures of the zygoma.

Some fractures of the mandible.

Fractures of the clavicle when complete reduction is impossible or when sharp-pointed fragments threaten to pierce the skin or damage important structures.

In compound fractures and in many comminuted fractures operation is necessary. If in any case of fracture an important nerve or blood-vessel has been divided an operation is necessary to arrest hemorrhage, to treat traumatic aneurysm, or to perform nerve-suture.

Most children are manageable by conservative methods and do not do as well as adults after operation. Hence in children I am more conservative than in adults.

Again, do not forget that operation may not give a good functional result. It often fails to do so. If this is not well understood both the surgeon and patient may be disappointed after operation. There is, of course, some risk in the treatment by incision, and it is only justifiable in competent hands and amid proper surroundings. The occasional operator should look to it with less confidence than the daily operator. If infection occurs it will be a catastrophe, and may cause death, hence perfect asepsis is required imperatively. Operation for recent fractures can never be routine treatment and will never be extensively employed outside of a hospital.

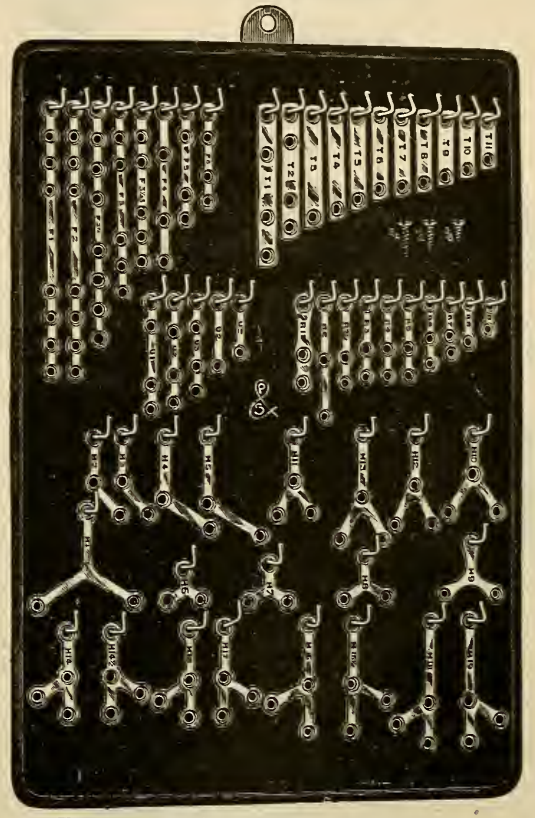

Fig. 319.—Lane's vanadium steel plates.

If operation is determined upon the best period to select, unless some grave complication calls for haste, is from seven to ten days after the accident. An incision is made, the bone is inspected, tissue intervening between the fragments is removed, and the fragments are coaptated and fixed by screws and a perforated plate, by silver wire sutures, bone-ferrules, chromic catgut, nails, some form of clamp or an autogenous bone-graft.

Plates and screws are used by many. Wire used for fracture of a long bone acts as a hinge, and in a wired fracture the alignment is apt to be disturbed. Wire was first used for this purpose in 1775 by Lapeyode and Sicre, of Toulouse (Geo. W. Guthrie, "Amer. Med.," March 7, 1903). It is now seldom used except for the patella, the olecranon, the clavicle, the zygoma, and the anatomical neck of the humerus. I prefer the steel plates of Arbuthnot Lane (Fig. 319) or the silver plates of Halsted. These plates are perforated for screws. The plate is not removed unless it loosens or gives trouble. After operation the extremity must be carefully fixed by splints or plaster of Paris; the circulation must be watched, guarded, and maintained; massage should be used and pas-

sive motion be employed as in a case treated by the non-operative method. If rigid fixation of the fragments is obtained and maintained repair will usually occur with very little callus formation. Too firm approximation may be followed by so little callus formation that there is delayed union or the fracture fails entirely to unite. In some cases the screws cause bone absorption and the plate loosens. Occasionally necrosis occurs. I agree with J. B. Lowman ("Penn. Med. Jour.," 1915, xix) that in some cases plating prevents union. Months after operation the plate may be found to be loose and bent and the break entirely ununited.

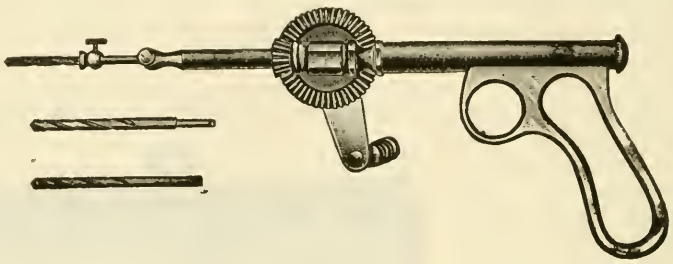

FIG. 320.—Richter's bone-drill (pistol grip).

In one of my cases of fractured femur the plate broke. Bone-grafting is a superior method unless there is a strong tendency on the part of the fragments to bend, rotate, or override. Then a plate should be used. Gallie uses a plate of boiled bone and screws of bone ("Canadian Jour. of Med. and Surg.," 1916, xxxix). It is seldom that a plate requires removal from the humerus or femur. It not unusually requires removal when applied to more superficial bones.

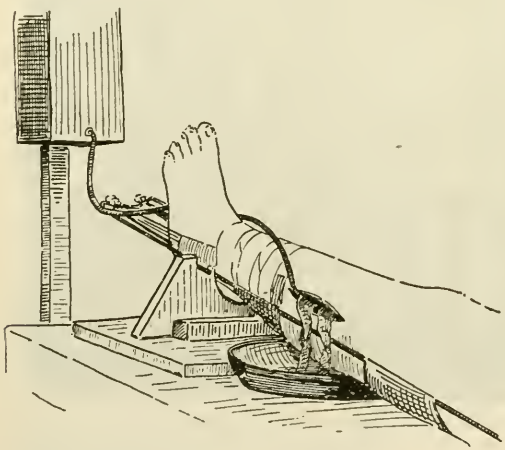

FIG. 321.—Compound fracture of the tibia and fibula. The Thomas splint is supported by a bracket in order to suspend the leg. Continuous irrigation apparatus and bandage drains are in use (Hull).

Treatment of Delayed Union and Ununited Fracture (see page 782).—When delayed union exists, seek for a cause and remove it, treating constitutionally if required, and thoroughly immobilizing the parts by plaster. Orthopedic splints may be of value. Use of the limb while splinted, percussion over the fracture, with a rubber hammer, and rubbing the fragments together, thus in each case producing irritation, have all been recommended. Blistering the skin with iodin or firing it has been employed. Buechner advocates the induction of hyperemia by a constricting band, just as Bier induces congestive hyperemia in treating tuberculous areas. At first the constriction is permitted to remain but a short time, but the period is lengthened every day, until in a few days it remains almost continuously day and night. It is to cause a pinkish-blue flush of skin, but not pain. The limb must be warm to the touch. During the two or three hours daily that the band is off raise the limb to relieve edema. Ten days of this treatment will inaugurate union in some cases. Helferich

of Greifswald devised this method in 1887. In several cases I have thought that it did good. I also administered thyroid extract to these patients. Lannelongue and Menard inject a 1:10 solution of zinc chlorid between the fragments. I have had several successes with this plan. Leaving acupuncture needles in for days is approved by some, and electropuncture is advocated by

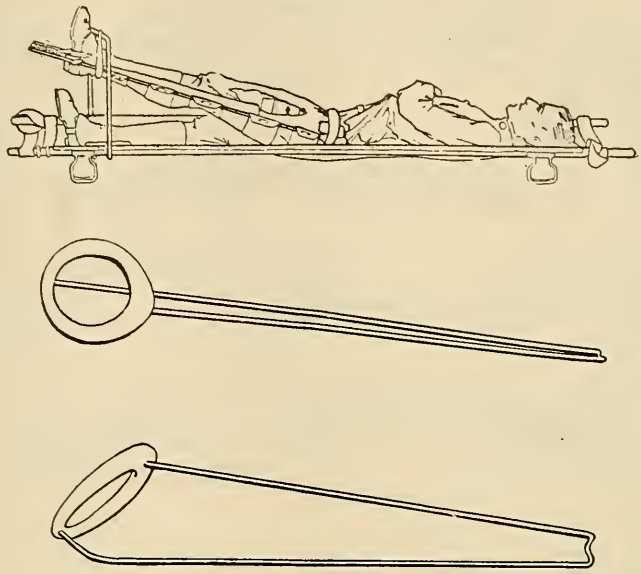

Fig. 322.—Thomas traction leg splint (Osgood).

others. Lisowskaja takes a piece of periosteum from the tibia, cuts it into small bits, puts them into normal salt solution and injects the mixture between the fragments. Kauffer makes a mixture of pulverized bone and sterile petrolatum and injects it between the fragments. If the union be very long delayed,

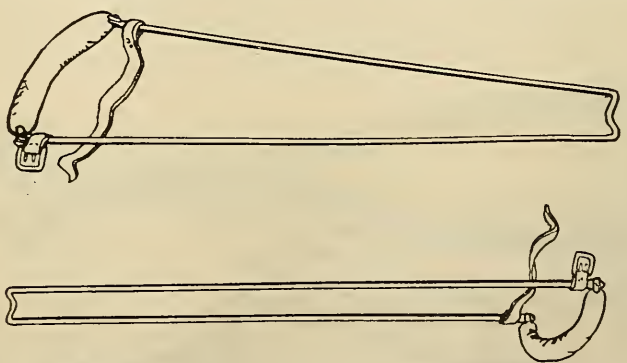

Fig. 323.—Blake-Keller hinged half ring modification of Thomas traction leg splint (Osgood).

forcibly separate the fragments and put up the limb in plaster as we would a fresh break. If these means fail, irritate by subcutaneous drilling or scraping, or, better, by laying open the parts and then drilling and scraping at many places. Cases of ununited fracture must be treated by excision of the bony ends and fibrous tissue, securing the fragments together by periosteal sutures, by pins, by screws and plates, by ivory pegs, by screws, by silver or aluminum bronze wire,

by kangaroo-tendon, by Senn's bone-rings or bone-ferrules, by chromicized catgut or by a bone graft. I have used extensively Halsted's plates of silver and Lane's

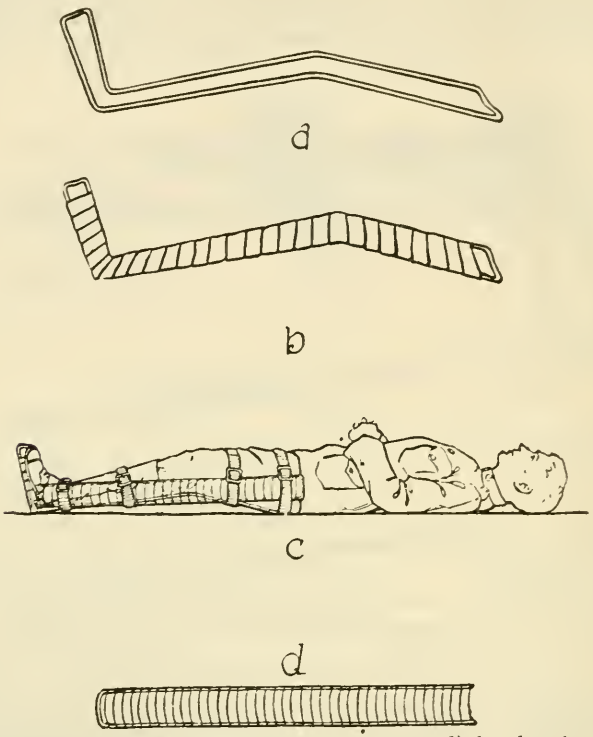

FIG. 324.—Cabot posterior wire splint (*a*) in skeleton, (*b*) bandaged, (*c*) applied with side splints of ladder material; (*d*) ladder splint material (Osgood). This is very useful for transport.

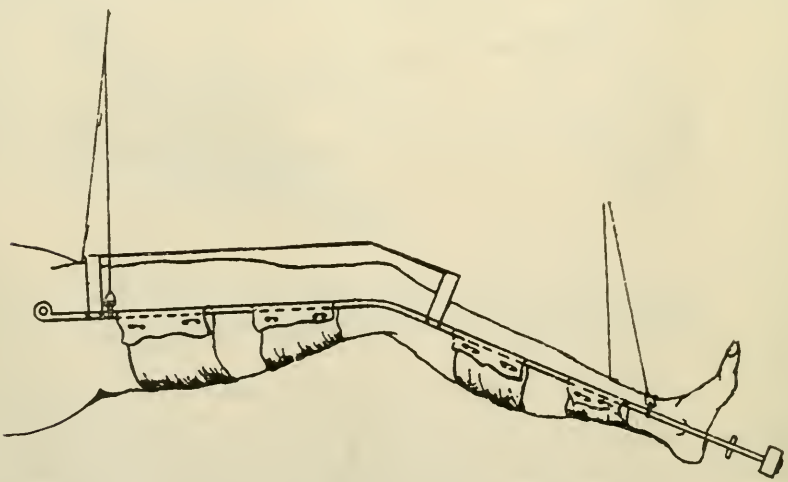

FIG. 325.—Modified Hodgen's splint.

plates of vanadium steel. Delorme makes an incision, removes bone-splinters and fibrous tissue, smooths off one end, forces this into the bored-out medullary

canal of the other fragment, and sutures the periosteum. Gussenbauer's clamp will often give a good result, and was used for years by Billroth. This is a metal bar with two nails set at right angles to the bar. One nail is driven into each fragment. Langenbeck fixed a screw into each fragment and connected the screws by a piece of iron. Parkhill's clamp, which is an improvement on

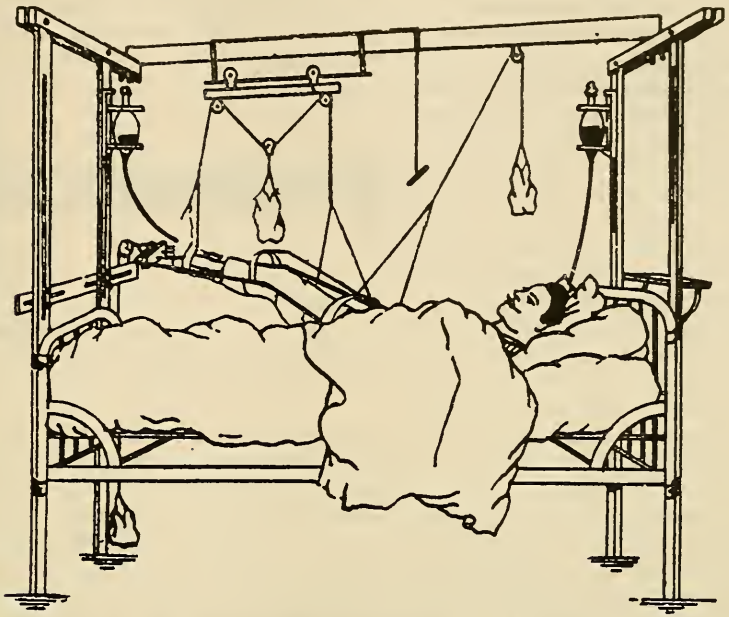

Fig. 326.—Frame for suspension and extension.

Langenbeck's instrument, secures absolute immobility and is a very useful instrument.

Sometimes union fails in spite of a formidable operation. In such cases there is no tendency to bone production. A bone-graft may be partially separated from one of the fragments and interposed between the freshened ends, a bone-graft may be taken from the sound tibia and be interposed (Albee's Method),

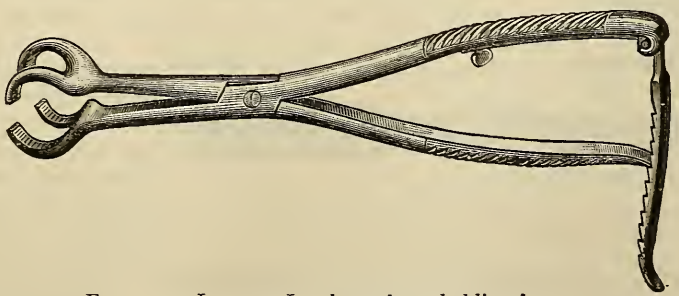

Fig. 327.—Lowman-Lambotte bone-holding forceps.

fresh bone-splinters may be interposed, or a portion of a rib may be used with screws or nails as a clamp. It is always desirable to take the bone-graft from the individual. Such a graft is more powerfully stimulating to bone growth than a graft from another individual or from one of the lower animals. Transplantation from the lower animals has, however, been successfully practised (see page 574). Albee believes that in a recent fracture Lane's plates fulfil

the indications but in an ununited fracture they do not, because in the latter there is lessened osteogenetic activity. The bone-graft fixes the fragments, stimulates osteogenetic activity, furnishes a scaffold for bone growth, and also grows bone itself. For further remarks on operation see page 782.

Treatment of Vicious Union.—If angular deformity results from faulty union, it can be corrected by molding the part into shape while the callus is soft. If the callus has become hard, the bone can be refractured. If faulty union occurs with overriding, an osteotomy can be performed.

Gunshot Fractures.—Of course simple fractures occur in war, but they present nothing peculiar. Compound fractures are extremely common and are frequently fatal. We have already set forth the difference between a bone wound and a gunshot fracture (page 586).

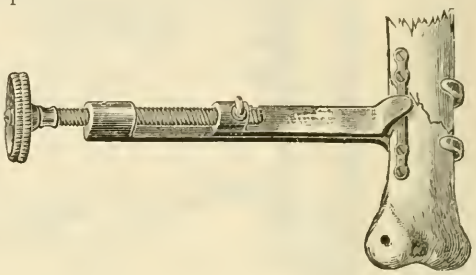

Fig. 328.—Lowman's combination bone and plate holder.

Leriche points out that a missile may fracture a bone (impact), may fracture it and lodge (penetration), may fracture it and pass through (perforation). Gunshot fractures are regarded as certainly infected except some fractures due to rifle or shrapnel bullets, infection being brought about by a contaminated projectile or by a bit of clothing or other foreign body which was carried in. Bits of clothing are particularly apt to be carried in by shell fragments. All sorts of breaks may occur. Comminution is the rule, except in fractures by impact. A rifle bullet striking a point ahead is apt to split a bone, but it may only cause comminution. A rifle bullet striking side on causes comminution like a shell fragment. In fractures due to shell fragments the bone is comminuted extensively and the soft parts are badly damaged and, as Blake and others point out, the tissues for some distance wide of the lacerations are in a state of lowered vitality because of tissue shock. Military surgeons dwell on the frequency with which bone fragments are driven widely before the missile, causing pulpification of muscle and perhaps a huge wound of exit.

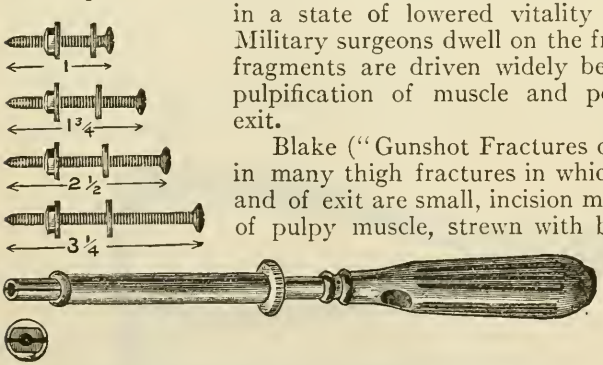

Fig. 329.—Sherman's bone bolts and nut-driver.

Blake ("Gunshot Fractures of Extremities") says that in many thigh fractures in which the wounds of entrance and of exit are small, incision makes evident a great area of pulpy muscle, strewn with bone fragments. In shell wounds the bones and soft parts are damaged more gravely than is commonly seen in the compound fractures of civil life. A great deal of tissue is not quite dead but is on the verge of death. Such tissue serves as a luxurious breeding place for bacteria. Captain Basil Hughes, R. A. M. C., calls attention to the facts that amputation performed through such tissue does not cause pain, and that the use of a rubber tourniquet or the application of a powerful antiseptic causes the death of such decadent tissue ("Brit. Med. Jour.," March 3, 1917).

Bits of clothing and other foreign bodies are apt to be carried into the tissues. Infection is inevitable. Compound fractures are very common from shell wounds. In shell wounds the bones and soft parts are damaged more gravely than is commonly seen in the compound fractures of civil life. A great deal of tissue is not quite dead but is on the verge of death. Such tissue serves as a luxurious breeding place for bacteria.

The wounded man is gravely shocked and is predisposed to infection because of this damaged tissue and his fatigue and exposure. Transportation is a great strain and radical treatment may be long deferred.

Usually at the first-aid station iodin is painted on the parts, an antiseptic dressing is applied, the limb is fixed in an emergency splint and antitetanic serum is given. A large T is written on the forehead with iodin or an anilene pencil to show that antitoxin has been given. A tourniquet is not to be applied. Few persons will bleed to death for want of it. Many would develop gangrene were it used. The patient is then transported to the rear. Attempts at immediate sterilization have not been successful. This is a notable contrast to the South African war in which such treatment proved very serviceable. Radical operation must be done at the first possible moment. In trench warfare it may be possible to apply it at the first dressing station. It may be done at the field hospital, at the evacuation hospital, or in some unfortunates, at the base hospital. The rule should be to do it at the earliest possible minute. The danger of gas gangrene, tetanus, sepsis, is intensified by every minute of delay. During transportation pulmonary embolism may arise, there may be hemorrhage, shock may be aggravated, insecurity of fixation may lead to tearing of the tissue by the bone-ends and to the dissemination of infection (Hughes, Ibid.). Some cases require immediate amputation. Most cases in which tourniquets were in use for a considerable time require amputation (Hughes, Ibid.). The treatment for the average case which does react from shock is, give an anesthetic, shave the skin, clean the parts with gasolene and paint with iodin. Make a free incision, remove foreign bodies, remove bone-fragments which are entirely loose or which are stripped of periosteum and excise freely damaged tissue. The wound is left open. It is not the custom to close compound fractures without drainage. Tubes are inserted, Dakin's fluid is introduced, dressings are applied and the limb is immobilized in the form of splint obtainable and best suited to the case. Suspension with extension is praised by many surgeons (Fig. 326). Some prefer plaster. The special splints are legion. A treatise is necessary to discuss gunshot fractures and that treatise must be written by a military surgeon. Figs. 321, 322, 323, 324, 325, 346, 347, 348, 349, 350, 351 show some of the many apparatuses employed. In fractures through or near the hip-joint the abduction frame of Major Robert Jones is most satisfactory (Fig. 403). In other fractures of the femur and in fractures of the leg the Thomas splint is the appliance preferred by many. The desirable treatment is Carrel's method. In some cases the exigencies of the situation restrict the treatment to free drainage and immobilization.

Special Fractures.—Nasal bones, because of their situation, are often broken. The commonest seat of fracture is through the lower third, where the bones are thin and lack support. The fracture is usually compound externally or through the mucous membrane internally. There may be a transverse fracture or a comminuted fracture. The *cause* is direct violence. Displacement may not occur at all, but when present at once after injury it arises primarily from force, and never from muscular action, no muscle being attached to these bones. If the force is from the front, the nose is flattened; if from the side, it is deflected. Manipulation, blowing the nose, or sneezing, may cause or add to displacement. In a transverse fracture the lower fragment is driven backward so it may drive back the quadrangular cartilage and "the cartilage may be fractured, bent or dislocated from its attachment to the upper border of the muscle, or its lower angle may be torn loose from the membranous portion of the septum, or from its connection with the maxillary bones at the anterior end of the vomer" (Fractures by Roberts and Kelly). Side blows may luxate one or both nasal bones. A blow from in front may luxate one or both bones from the frontal bone. Displacement is soon masked by swelling. Crepitus

can sometimes be elicited by lightly grasping the upper part of the nose with the fingers of one hand and moving it gently below from side to side with the fingers of the other hand. Preternatural mobility is valueless as a sign, because of the natural mobility of the cartilages. Nose-breathing is difficult because of blocking of the nostrils by blood-clot. When deformity is absent, diagnosis, except by the *x*-rays, may be almost impossible.

The complications that may be noted are cerebral concussion, brain symptoms from implication of the frontal bone or cribriform plate of the ethmoid bone, and extension of the fracture to the superior maxillary or lachrymal bones. The vomer or the nasal spine of the frontal may be broken. Emphysema of the root of the nose, the eyelids, and the cheeks is common, and means either a rent in the mucous membrane of Schneider or a crack in the frontal sinus. There may be much discoloration because of subcutaneous hemorrhage. Epistaxis is usual, and is distinguished from the epistaxis produced by fracture of the base of the skull by the facts that the bleeding in the first condition, although profuse, is, as a rule, soon checked, and is not followed by oozing or cerebrospinal fluid,whereas in the second condition it is profuse, continued, and is perhaps followed by a flow of cerebrospinal fluid. Fracture of the bony septum occasionally complicates nasal fractures, and deviation of the cartilaginous septum often takes place. Suppuration may occur and necrosis of bone or cartilage may follow. The prognosis is usually good if reduction is accomplished early. Fixation occurs soon.

Treatment.—Whenever possible nasal fractures should be treated by a rhinologist. After cocainizing the nares a careful inspection should be made by means of a mirror and a light to determine whether or not there is any injury of the septum. This point must be determined in order that the deformity of the septum may be corrected at the same time as the deformity of the nasal bones. When there is no displacement, or when a displacement does not tend to be reproduced after reduction, employ no retentive apparatus of any kind. Order the patient not to blow his nose for ten days and syringe it daily with a solution of bicarbonate of sodium. If deformity be noted, correct it at once, as the bones soon unite in deformity. If the attempts at reduction are very painful, or if the subject be a child, a woman, or a nervous man, give ether to obtain primary anesthesia. Reduction is effected by a grooved director or steel knitting-needle wrapped in iodoform gauze and passed into the nostril; the fragments are lifted with this instrument, and the fingers externally mold them into place. A rubber dilator can be used in reduction. This is pushed into the nose and inflated by air or water. If the septum is deviated and cannot be pushed in place by a metal sound, it must be twisted into place by means of septum forceps. If bleeding is moderate, check it with cold; if severe, by plugging. "For fractures high up with displacement, gauze packing carried well up will be required to retain the elevated bones. For lower deviations the Asch tube will be needed" (Scudder, on "The Treatment of Fracture"). A hollow vulcanite plug is inserted in each nostril and the nose is molded into correct shape over the plug. The patient breathes through the hollow plug. A thread runs from each plug and is fastened to the cheek by adhesive plaster. Once or twice a day the plugs are removed, cleaned, and greased with iodoform ointment. The nose is cleared and the plugs are reinserted. If flattening tends to recur, pass a Mason pin (Fig. 330) just beneath the fragments, through the line of fracture and out the opposite side. Steady the fragments by a piece of rubber externally

FIG. 330.—Mason's pin.

caught on each end of the pin, or with figure-of-8 turns around the ends with silk. Leave the pin in place for five days. The instrument of Mason is a sharp, strong, nickel-plated pin, with a triangular point.

If lateral deformity tends to recur, hold a compress over the fracture or fix a molded-rubber splint over the nose by a piece of rubber plaster 1½ inches broad and long enough to reach well across the face, and use compression for ten days. In neither of the above cases is the nose to be blown, and in both cases it is to be syringed once or twice a day. In fractures rendered compound by tears in the mucous membrane, irrigate with normal salt solution or boric acid solution, holding the head so that the solution will not run into the mouth; plug with iodoform gauze around a small rubber catheter, which instrument permits nose-breathing; carefully remove the gauze daily and syringe. In fractures compound externally cleanse externally, antisepticize with iodin, and dress with a film of cotton soaked in iodoform collodion or compound tincture of benzoin, or apply sterile gauze. Fractures of the bony septum, if showing a tendency to reproduction of deformity, require packing as above explained, or the use of a special splint within the nostrils (Fig. 331), or the application of vulcanite plugs, so made that the patient can breathe through them and threads can be attached to them. Fractures of the nasal cartilages are to be pinned in place. Fractures of the nose are entirely united in from ten to twelve days. If an unreduced fracture unites in deformity osteotomy and refracture is the only resource. If bone and cartilage are involved in a lateral deformity the septum is usually deviated. In such a case a septal deviation should be amended by submucous resection and the cartilage deviation be corrected by intranasal surgery.

Fig. 331.—Jones's nasal splint.

Fractures of the Lachrymal Bone.—The lachrymal bone may be broken when the nasal bones, a superior maxillary bone, or the lateral plate of the ethmoid is fractured, and union is solid in from three to four weeks. The question of how much deformity is to be expected is always uncertain, and in not a few cases obstruction of the nose follows fracture because of damage to the septum.

Treatment.—Treat the chief injury, which is the fracture of the other bone or bones. Maintain the patency of the lachrymal duct by frequently passing a clean probe.

Fractures of the Superior Maxillary Bone.—Although a fragile bone, the superior maxillary is rarely broken except through the alveolar border. It may be broken by transmitted force from blows on the chin, or on the head when the chin is fixed; but direct violence is the usual cause. The walls of the antrum may be crushed in, the palatine process in the nasal process may be broken, transverse fracture may occur, there may be intermaxillary separation, or separation of the alveolar process. The pterygoid processes are seldom broken. Comminution may exist. Fracture of the orbital surface is a not uncommon result of a gunshot wound. If the causal force has been very violent, the line of fracture may extend into the base of the skull. Comminution is the rule, and the injury is often compound. These fractures induce great swelling, pain, asymmetry, and inability to chew. Mobility and crepitus may be detected. Deformity is due to the breaking force, and not to the action of any muscle. When a portion of the alveolar arch is fractured, as may occur in pulling teeth, the small fragment is depressed backward, and there exist irregularity of the teeth (some of which may be loosened) and inability to chew food. Fracture of the nasal process is apt to injure or cause pressure upon the lachrymal duct. When the antrum is broken in there are great sinking over the fracture, depression of the malar bone, and if the mucous membrane has been torn, emphysema. Transverse

fracture of the upper part of the body of the bone may cause no deformity. The force required to break the superior maxillary borne is so great that fractures of other bones almost certainly occur, and concussion of the brain not infrequently exists. Injury of the infra-orbital nerve is not unusual, causing

Fig. 332.—Hard-rubber splint; wire arms and chin-piece held together by metal rods and nuts.

pain, numbness, or an area of anesthesia involving one-half of the upper lip, the ala of the nose, and a triangle whose base is one-half the upper lip and whose apex is the infra-orbital foramen. There is also loss of sensation in the gums and upper teeth of the injured side. Orbital fracture causes subconjunctival ecchymosis. Fractures of the superior maxillary bone occasionally induce fierce hemorrhage from branches of the internal maxillary artery; and if this has happened, be on the watch for secondary hemorrhage (these vessels being in firm canals).

Fig. 333.—Front view of splint (Fig. 332), with mouth closed (Moriarty).

Treatment.—If the fracture does not implicate the alveolus, or if no deformity exists, apply no apparatus, but feed the patient on liquid for four weeks. Reduce deformity, if it exists, by inserting a finger in the mouth. If the antrum is broken in, put the thumb in the mouth and push the malar bone up and back. In certain cases of deformity make an incision at the anterior border of the masseter muscle, insert a tenaculum or aneurysm needle, and pull the bone into place (Hamilton). If the malar bone or malar process is driven into the antrum, Weir tells us to incise the mucous membrane above and external to the canine tooth of the upper jaw, break into the antrum with a bone-gouge, insert a steel sound, lift out the malar bone, and pack the antrum with gauze. Loose teeth are not to be removed; they are pushed back into place and held by wiring them to their firmer neighbors. Hemorrhage is arrested

by cold and pressure. If hemorrhage is dangerously profuse or prolonged, tie the external carotid artery.

If the line of the teeth, notwithstanding the wiring, is not regular, mold on an interdental splint. The usual splint for the upper jaw is the lower jaw held firmly against it by the Gibson, the Barton, or the four-tailed bandage. There is a great amount of dribbling of saliva during the treatment, and a dressing must be used to catch this fluid. Every day remove the bandage and dressing, and wash the face with soap and water. The patient, who is ordered not to talk, is to live on liquid food administered by a nasal tube or by pouring it into the mouth back of the last molar tooth by means of a tube or a feeding-cup. Never pull a tooth to obtain a feeding space; but if a tooth is lost, utilize the vacant space for this purpose. After every meal wash out the mouth with peroxid of hydrogen, followed by chlorate of potassium, boric acid, or normal salt solution, and thus prevent foulness and the digestive disorders it may induce. Dispense with the dressings in four or five weeks, and let the patient gradually return to ordinary diet.

In fractures compound externally do not remove fragments, antisepticize by dichloramin-T, arrest bleeding as far as possible by ligature, by pressure, or by plugging, wire the fragments if feasible, dress with gauze, and wash the mouth with great frequency. Fractures compound internally are treated as simple fractures, except that the mouth is washed more frequently.

FIG. 334.—Hard-rubber splint in position, upper teeth resting upon it (Moriarty).

The **malar bone** is rarely broken alone. Hamilton says no uncomplicated case is on record. The malar is a strong bone resting on a fragile support, and hence it may become a wedge to break other bones and yet itself be unfractured. The *cause* of fracture is violent direct force. A fracture of the orbital surface of this bone causes subconjunctival hemorrhage like that encountered in fracture at the base of the skull, and may produce irritation of the infraorbital nerve. Protrusion of the eye may result either from hemorrhage or from crushing in of the malar bone. There is a hollow below and to the outer side of the orbit. Occasionally the line of fracture is detectable, but mobility and crepitus are very rarely discoverable. Chewing is apt to cause pain, and often the motions of the lower jaw are limited, the coronoid process being pressed upon by a depressed malar bone, an associated fracture of the zygoma, a blood-clot, or swollen tissue (see Scudder, on "Treatment of Fractures").

Treatment.—If no deformity exists, there is practically nothing to be done. If deformity exists, try to correct it as in fractures of the superior maxillary bone. If correction is impossible by ordinary methods and the movements of the lower jaw are impeded by the displaced bone, make a small incision and through this insert an instrument and endeavor to lift the bone into place. As these cases are almost invariably complicated by fracture of the upper jaw, they are treated in the same manner as the latter injury. The union is complete in three weeks.

Fractures of the zygomatic arch are very rare. The *causes* are: (1) direct

violence; (2) indirect force (from depression of the malar), and (3) forcing foreign bodies through the mouth. Direct violence is the usual cause. Direct violence causes inward displacement, and indirect force may cause outward displacement. The usual seat of fracture is at the smallest portion of the process—that is, on the temporal side of the temporomalar suture (Matas). The symptoms are pain, ecchymosis, swelling displacement, and difficulty in moving the jaw (because of injury to the masseter muscle).

Treatment.—In simple fracture give ether and try to push the arch in place. Many surgeons do not make an incision, as depression will do no harm and the functions of the jaw will be restored. Simply dress with a compress, adhesive strips, and the crossed bandage of the angle of the jaw. Union will take place in three weeks. Matas[1] advises operation. An anesthetic is administered and the parts are antisepticized. A long semicircular Hagedorn needle is threaded with silk, is entered 1 inch above the middle of the displaced fragment, is passed well into the temporal fossa, and is made to emerge ½ inch below the arch. The silk is used to pull a silver wire around the fracture, and this wire is employed to pull the bone into position. A firm pad is applied externally and the wire is twisted over the pad. Antiseptic dressings are applied, and on the ninth or tenth day the wire, splint, and dressings are removed permanently. I have employed this plan in 2 cases with perfect satisfaction.

Fractures of the inferior maxillary bone (the *mandible*) may, and usually do, involve the body, although they occasionally occur in the rami. Any part of the body may be fractured, the most usual seat being near the canine tooth or a little external to the symphysis (Pick). A portion of alveolus may be broken off. In fractures of the ramus either the angle, the condyloid neck, or the coronoid process may be broken. In fractures of the body the posterior fragment generally overrides the anterior. Fractures of the lower jaw are often multiple and those of the horizontal portion are almost always compound, because the oral mucous membrane and alveolar periosteum are torn. Fractures of the ramus are seldom compound. A portion of the alveolus may be broken during the extraction of teeth. The *cause* is usually direct violence, as a blow, a kick, a fall or a gunshot wound. Indirect violence (lateral pressure) may fracture the body at or near the symphysis. Fractures near the angle are always due to direct violence. Indirect violence may fracture the neck of the condyle (falls on the chin), and so may direct violence. Fractures of the coronoid process are very rare, and they arise from great direct violence (usually a gunshot wound or some other penetrating force) or by muscular action (violent contraction of the temporal muscle). Comminuted fractures are rare. Multiple fractures are by no means unusual.

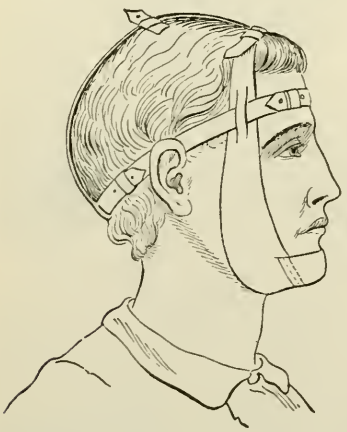

Fig. 335.—Hamilton's bandage.

Symptoms.—In fracture of the body preternatural mobility and crepitus generally exist. The gum over the fracture swells rapidly and decidedly. There is bleeding because of laceration of the gum; saliva dribbles constantly; the patient supports the jaw with the hand; great pain exists (possibly from injury of the nerve), and deformity is present, shown by inequality of the teeth if the fracture is anterior to the masseter, the anterior fragment going downward and backward and the posterior fragment going upward and forward. The downward displacement is due to muscular action (action of the digastric, geniohyoid,

[1] "New Orleans Med. and Surg. Jour.," Sept., 1896.

and geniohyoglossus). The backward displacement is due to the violence. The temporal, internal pterygoid, and masseter muscles draw the posterior fragment upward and to the front. In a fracture of the lower jaw at any point below the orifice of the dental canal the nerve will be more or less injured and examination will discover areas of anesthesia on the skin of the chin, on the side of the cheek, on the inner surface of the lower lip and on the buccal surface of the gum. These areas represent the trajectory of the mental branch of the inferior maxillary nerve (Imbert and Gauthier, in "Paris Médicale," Jan. 20, 1917). Two or three days after fracturing the jaw some of the cervical lymph-glands enlarge. When a fracture of the lower jaw is compound internally, suppuration usually takes place and the odor of decomposition becomes marked. In fracture of the neck of the condyle the jaw is drawn toward the injured side, and the condyle is pulled inward and forward by the action of the external pterygoid muscle. In fracture of the coronoid process the temporal muscle pulls the small fragment upward.

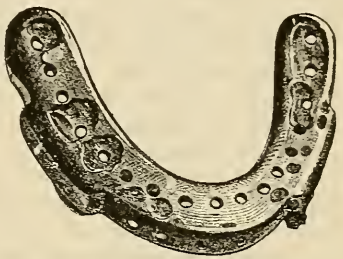

Fig. 336.—Vulcanite splint with boxes vulcanized on each side. If the jaw is fractured in the region of the molars, considerable pressure is required to get the parts in position; therefore it is best to vulcanize on to the sides of the vulcanite splint boxes into which wire arms can be inserted (Pilcher).

The *complications* are: digestive disorders and diarrhea from swallowing foul discharges; loosening of the teeth; lodgment of loosened teeth between the fragments; bleeding (usually only oozing from the gum, but there may be hemorrhage from the inferior dental artery), and suppuration. Necrosis may follow these fractures, an abscess of the neck may develop, or a sinus may form.

Treatment.—The advice and aid of a dental surgeon are invaluable. Correct deformity with great care and be sure to bring the teeth into normal alignment. As a rule, push loose teeth into place and put back detached ones; but occasionally a tooth obstinately prevents perfect approximation, and if it does it must be removed. Remove a tooth if it lies between the fragments, but replace it in its socket after reducing the fracture. Wash the mouth with hot water to clean it and to check bleeding. If bleeding is very severe, compress the carotid artery for a time. The fracture can be dressed with a pad of lint over the chin and Hamilton's four-tailed bandage (Fig. 335). A common plan is to take a splint of pasteboard, felt, or gutta-percha; pad it lightly with cotton, mold it to the part, and hold it in place with a Barton or a Gibson bandage. If apposition of the fragments cannot be maintained by the above methods, fasten the teeth together with wire, wire the fragments together, or have a dentist apply an interdental splint (Figs. 336, 337). Fracture of the lower jaw can often be satisfactorily treated by Angle's bands. These bands are of great value in complicated cases, in which two or more fractures exist. Each band consists of thin metal and a screw and a nut to fit the screw. The band is adjusted around a firm tooth and a nut is applied so as to hold the band tightly. Several bands are placed upon teeth in both jaws. Silver wire of silk is thrown around the pins of the bands so as to catch, and the jaws are thus held firmly together. In some cases holes are drilled in the bones and the fragments are held together by means of silver wire. In some few cases plates and screws are used. The patient is to be fed on liquid food (see Fracture of

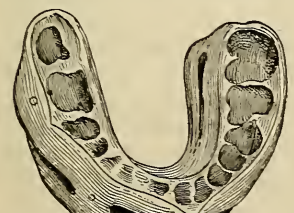

Fig. 337.—Interdental splint.

the Upper Jaw), the mouth is to be washed frequently with peroxid of hydrogen, followed by boric acid solution or normal salt solution, and if bandages are used they should be changed every second day. The union should be complete in five weeks. The best plan of treatment in all cases not operated upon is to send the patient to a skilful dentist and have him apply an interdental splint and direct the treatment. A specialist may succeed in obtaining such fixation that union in good alignment follows when a general surgeon might only secure union in poor alignment. Though these fractures are often compound, they very seldom endanger life.

Fractures of the Hyoid Bone.—These fractures are uncommon injuries, and are caused by hanging, by throttling, by blows, and by falls in which the neck strikes some obstacle. If the bone breaks by throttling, it is its body which fractures (indirect force). Fractures by muscular action are most unusual. The thyroid cartilage, the cricoid cartilage or the trachea may also be broken.

Symptoms.—The symptoms are: A sensation of something breaking; bleeding from the mouth if the mucous membrane be lacerated; pain, which is worse on opening the jaws or on moving the head or tongue; difficulty in swallowing; muffled, hoarse voice or aphonia; swelling, and frequently ecchymosis, of the neck. There are observed occasionally, though rarely, harsh cough and dyspnea, irregularity of bony contour, and crepitus. Always look into the mouth and see if there can be detected ecchymosis or laceration of the mucous membrane or projection of a bony fragment. The displacement is produced by contraction of the middle constrictor of the pharynx. A simple fracture of the hyoid bone is seldom dangerous but if there is laryngeal involvement that condition may destroy life.

Treatment.—For dyspnea, be ready to perform intubation or tracheotomy at a moment's notice. Edema of the glottis is a great danger. Try to restore the fragments with one hand externally and with a finger in the mouth. Put the patient to bed and have him lie back upon a firm rest so that his shoulders are elevated. His head is to be placed between extension and flexion, a pasteboard splint or collar is molded on the neck, and a bandage is applied around the forehead, neck, and shoulders to keep the head immobile. The patient must not utter a word for a week; he must be fed at first by enemata, and then for some time on liquid diet, which is given through a stomach tube early in the case. Endeavor to control the cough by opiates. A fractured hyoid bone requires about four weeks to unite.

Fractures of the tracheal and laryngeal cartilages are caused by direct violence, as hanging, throttling, blows, or kicks. Very seldom is muscular action responsible. The thyroid or cricoid may be broken alone or together. The hyoid bone may be broken with them both or with the thyroid alone. The tracheal cartilages may suffer alone or with the laryngeal cartilages. The arytenoid may break. These injuries are greatly more common among men than women. They are rare in young persons, and are commonest when the cartilages have begun to ossify. They are very grave injuries. The mortality is between 30 and 40 per cent. Death may be caused by edema of the glottis, hemorrhage beneath the mucous membrane or hemorrhage into the air passage causing obstruction to the entrance of air.

The *symptoms*, which are severe, are pain, aggravated by attempts at swallowing or speaking; swelling, ecchymosis it may be, and emphysema of the neck; cough; aphonia; intense dyspnea; and bloody expectoration if the mucous membrane is ruptured. There can be detected inequality of outline (flattening or projection) and perhaps moist crepitus. The usual seat of injury is the thyroid cartilage.

Treatment.—Cases without dyspnea require quiet, avoidance of all talking, feeding with a stomach-tube, the application of compresses and adhesive strips over the fracture, and the use of remedies to quiet cough. The surgeon

must be ready to operate at any moment. In most cases dyspnea exists, due to projection of the fragments or submucous extravasation. When there is dyspnea, emphysema, or spitting of blood, at once practise intubation, or, if unable to do this, open the larynx or trachea below the seat of fracture. If laryngotomy or tracheotomy is performed, try to restore displaced fragments to proper position. If the fragments will not remain reduced, introduce a Trendelenburg cannula or a tracheotomy tube, and pack gauze around it. Take out the packing in four days, and remove the tube as soon as the patient breathes well, when the opening may be allowed to close. In these cases feed with a stomach-tube and keep the patient absolutely quiet. Union takes place in four weeks.

Fractures of the Ribs.—The ribs, owing to their shape, elasticity, and mode of attachment, readily bend and as readily recover shape, and thus withstand considerable force without breaking. Notwithstanding these facts, the situation of the ribs so exposes them that in 16 per cent. of all cases of fractures noted by Gurlt these bones were involved. In children fracture of a rib seldom occurs and is usually incomplete; it is common in adults and the aged, and in them is generally complete. It is more frequent among men than among women. The ribs commonly broken are from the fifth to the ninth, the seventh being the one that most frequently suffers. Fracture of the first rib alone is an excessively rare accident. The eleventh and twelfth ribs are seldom broken. A rib may be broken in several places, and several ribs are often broken at the same time. Fracture of a single rib is not nearly so common as fracture of several ribs. These fractures may be compound, either through the skin or through the pleura. Damage of the lung will result in pneumothorax. Fractures compound by a wound of the skin surface are very rare, except from gunshot wounds.

Causes.—Direct force, as buffer accidents, kicks, blows with heavy instruments, or being jumped on while recumbent, may produce these injuries. A fracture from direct violence occurs at the point struck, and the ends, projecting inward, may damage a viscus. *Indirect* force, as great pressure or blows which exaggerate the natural bony curves, tends to produce fractures near the middle of the ribs or in front of their angles and to force the ends outward. A number of ribs are apt to be broken. Muscular action, as in coughing, sneezing, lifting, or parturition, occasionally, but very rarely, is a cause.

Symptoms.—In connection with the history of the accident the symptoms are: acute localized pain (a stitch) on breathing, increased by pressure over the seat of pain, pressure backward over the sternum, cough, and forcible inspiration or expiration. Respiration is largely diaphragmatic, the patient endeavoring to immobilize the injured side; cough is frequent and is suppressed because of pain. Crepitus is often, but not invariably, found. The surgeon seeks for it, first, by resting the palm of his hand over the seat of pain while the patient takes long breaths; second, by placing a thumb before and one behind the seat of pain and making alternate pressure; third, by auscultation. It should be remembered that incomplete fractures are the rule in children; hence in them do not expect crepitus. Deformity is usually trivial unless several ribs are broken, because shortening cannot occur and the intercostal attachments prevent vertical displacement. Preternatural mobility may occasionally be elicited, when the region is not deeply covered with muscles, by pressing on one side of the supposed break and observing that a part of, and not the entire, rib moves. If air gathers in the subcutaneous tissue and there is no wound of the surface, it is proof of rib fracture with lung damage. In such a case the lung has been penetrated by a fragment, and air has been forced out into the tissues. This condition is recognized by great and growing swelling, which crackles when touched. Such a collection of air is known as *cellular emphysema*. Bloody expectoration suggests lung injury;

bloody expectoration and cellular emphysema, without an external wound, prove injury of the lung. A simple, uncomplicated case of fracture of a rib or ribs in a young person gives a good prognosis.

The *complications* are: additional injury, making the fracture externally or internally compound; laceration of the pleura, pericardium, heart, lung, diaphragm, liver, spleen, or colon; rupture of an intercostal artery; hemothorax; cellular emphysema; pulmonary emphysema; pneumothorax; pyothorax; traumatic pleurisy; pneumonia; bronchitis; congestion or edema of the lungs.

Treatment.—In an uncomplicated case the patient is not kept in bed, as breathing is easier when erect than when recumbent. Angular displacement outward is corrected by direct pressure. Displacement inward is soon corrected as a rule, by the expansion of ordinary respiratory action; but if it is not thus corrected, etherize, the deep breathing of the anesthetic state almost always succeeding. If ether fails, and dangerous symptoms ensue, incise under strict antiseptic precautions, elevate, or sometimes resect a portion of the rib.

After correcting any existing deformity immobilize the injured side. If the patient is a man, shave the chest. Direct the patient to raise his arms above his head, to empty his chest of air by forced expiration, and to keep it empty until a piece of rubber plaster (2 inches wide) is forcibly applied a number of inches below the fracture and from the spine to the sternum. The patient is now allowed to take a breath and is then directed to empty the chest again, another piece of plaster being applied, covering the upper two-thirds of the width of the first strip. This process is continued until the side is strapped well above and well below the fracture (Pl. 7, Fig. 13). Over the plaster light turns of a spiral bandage of muslin are carried, or a figure-of-8 bandage of the chest is applied, the turns crossing over the seat of injury. About once a week the plaster is removed and fresh pieces applied after rubbing the chest with soap liniment, drying, and anointing excoriations with an ointment of oxid of zinc. The dressing is worn for three or four weeks. The patient avoids cold, damp, and drafts. The diet must be nutritious but non-stimulating, and any cough should be treated by opiates and expectorants. A person with this injury who has reached the age of sixty must take stimulant expectorants (ammonii carb., 10 gr., in infus. senegæ, ½ oz., *t. i. d.*) or employ a steam-tent several times a day. The old method of treatment, in which the chest was included in a forcibly applied broad rib-roller, is not to be used except as a temporary expedient; it compresses the entire chest, causes pain and dyspnea, and tends to loosen and slip.

Fracture of the ribs complicated by visceral injury is highly dangerous, and requires confinement to bed. The treatment is that of the visceral injury. If there be bloody expectoration, apply adhesive strips as above indicated, put the patient to bed reclining on a bed-rest, keep him quiet, subdue the circulation, and employ opium, diaphoretics, and expectorants (a good mixture consists of squill, ipecac, ammonium acetate, and chloroform; opium is given separately). Inflammations of the lung or the pleura, fortunately, are apt to be localized, and are treated as ordinary inflammations of these parts. In laceration of an intercostal artery incise and try to ligate; if unable to ligate, resect a rib and apply a ligature. If the signs point to internal bleeding, resect a rib, search for the bleeding point, ligate and drain the pleura. Emphysema usually soon disappears; but if it does not, make many small incisions in the cellular tissue, dress antiseptically, and employ pressure. Pneumothorax, if increasing dangerously, demands tapping with a trocar and if this fails the introduction of a drainage tube. When there arises a sudden attack of dyspnea, which is prone to happen in these cases, and in which the face becomes blue, the heart labors, and suffocation seems imminent, bleed the patient almost to syncope. Empyema calls for operation.

Fractures of the costal cartilages are not common, even in the aged. Such fractures occur either through the cartilages or through their points of junction with the ribs. These injuries generally arise from direct violence, the cartilage of the eighth rib being most prone to suffer. Bennett, of Dublin, has seen over 25 specimens of fracture of the first costal cartilage. Indirect force (such as a blow upon the shoulder) is occasionally the cause, but when it is the cause some other injury besides the fracture of the cartilages is apt to be noticed. Muscular action is a possible cause.

Symptoms.—Displacement is often absent; but if present, it is forward or backward of either fragment, and is due chiefly to the force of the injury, but partly, it may be, to muscular action. When displacement is absent, crepitus will not often be found; in fact, crepitus is usually absent in these injuries. Localized pain, swelling, and ecchymosis are noted. Preternatural mobility may or may not be detected. Union by bone is to be expected.

Treatment.—If displacement exists, try to reduce it. If the fragment is displaced backward, reduce by deep inspirations; if the fragment is displaced forward, reduce by pulling back the shoulders. In this attempt failure is the rule, and the surgeon may then adopt Malgaigne's expedient of applying a truss over the projection for a day or two. Dress and treat the case as if a rib were broken, dispensing with dressings in four weeks.

Fractures of the Sternum.—The sternum may be broken, along with the ribs and spine, from great violence. Fractures of the sternum alone are infrequent, because the bone rests on a spring-bed of ribs. Fractures of the sternum may be simple or compound, complete or incomplete, single or multiple. The most usual injury is a simple transverse fracture at or near the gladiomanubrial junction, at which point dislocation may also occur. Both fracture and separation of the ensiform cartilage are very rare. The sternum may be broken along with the ribs or clavicle.

Causes.—These are: *direct* force, as by a fall of an embankment or of a wall, by a car-crush, or by the passing of a cart-wheel over the body; *indirect* force, as by a fall upon the head, thus driving the chin against the chest; by a fall upon the feet, the buttocks, or the shoulder; by forced flexion or extension of the body over an edge or angle (as may occur during labor-pains).

Symptoms.—In fracture of the sternum displacement is not always present, but when it does occur the lower fragment is apt to pass forward; displacement may, however, be transverse or angular, or there may be overriding. The posterior periosteum, which rarely tears, limits displacement, but some deformity can, as a rule, be detected. The history of the nature of the accident has a valuable bearing upon the question of diagnosis. The position assumed by the patient is with the head and body bent forward, as attempts to straighten up cause much suffering. There is fixed and localized pain, increased by deep respiratory action, by body movements, or by cough. Crepitus is sought for by auscultation and by placing the hand over the injury and directing the patient to make quick respirations. Mobility may become manifest on external pressure, during respiration, or while attempts are being made to bring the body erect. Respiration in these cases is usually much interfered with. It is not important to separate diagnostically diastasis from fracture.

Complications.—Other fractures generally complicate fracture of the sternum, and laceration of the pleura or pericardium and hemorrhage into the anterior mediastinum may exist. Abscess of the mediastinum and necrosis of the sternum may appear as late consequences. The *prognosis* is good in uncomplicated cases.

Treatment.—The deformity attending fracture of the sternum is to be corrected, if possible, by external pressure. If overriding is found, effect reduction by bending the body back over a firm pillow and ordering the patient

to respire deeply; if this method fails, give ether and then bend the body backward. The deformity, after reduction, tends to recur, but the bones unite well even in deformity, and no great harm results. The fragments need not be cut down on or be hooked up unless there be internal injury. After reducing the deformity, cover the front of the chest with adhesive strips extending laterally from one axillary line to the other, and covering a region from above the fracture down to the ensiform cartilage. Place over this covering an anterior figure-of-8 bandage of the chest. In some cases, where deformity recurs after reduction, a circular bandage of the chest is applied and the shoulders are pulled strongly back with a posterior figure-of-8 bandage. The plaster is to be reapplied once a week. Some surgeons treat these cases by means of a large compress held by adhesive plaster and a broad tight roller.

The patient goes promptly to bed, and reposes, erect or semi-erect, on a bed-rest. This position favors easy respiration and antagonizes the tendency to displacement. The diet should be light, nutritious, and non-stimulating. Convalescence is established in four weeks, and the plaster should be permanently removed in five weeks. When the ensiform cartilage is so bent in as to cause intense pain or to injure the stomach, it should be exposed by incision and resected. Edema of the skin and fever, if they appear, indicate pus, in which case an incision should be made at the edge of the sternum and the pus-cavity should be irrigated and drained.

Fractures of the Pelvis.—In some of the indicated fractures serious injury of the pelvic contents is apt to be found.

Fractures of the False Pelvis.—Fractures of this region are seldom dangerous unless comminuted. There may be fracture of the iliac crest or of the anterior superior spine, or the line of fracture may traverse the entire length of the flanged-out ilium, or the bone may be comminuted with the association of grave visceral damage. The anterior superior and posterior superior spines may be broken off.

Causes.—The cause of fracture of the false pelvis is generally violent *direct* force, as the passage of a wagon-wheel, the fall of a wall, the kick of a horse or mule, or the force of car-crushes. Violent contraction of the rectus femoris muscle may tear off the anterior inferior spine of the ilium.

Symptoms.—In fracture of the false pelvis the history of violent force is noted. The patient leans toward the injured side. Pain exists, which is aggravated by movements (particularly by bending forward), by coughing, or by straining to empty the bowels or the bladder. Ecchymosis and swelling are manifest. Crepitus and preternatural mobility are detected by moving the iliac crest. Deformity is very rarely present. A person with fracture of the crest alone or of a spine alone can stand and walk. Cases uncomplicated by visceral injury make good recoveries.

Complications.—The fracture may be, but rarely is, compound, as the parts are well protected by muscles. The colon may be injured when comminution has taken place.

Treatment.—If there are symptoms of injury to the colon, perform laparotomy, search for the injured region, and suture it. In treating an ordinary fracture of the false pelvis the Bradford frame is probably the best apparatus but many surgeons simply put the patient on a fracture-bed, raise the shoulders, and apply a canvas binder about the pelvis, or encase the pelvis in broad pieces of rubber plaster, or employ the belt or girdle. The pressure of the binder, girdle, or plaster must not be so great as to force the fragment of ilium inward. The knees should be bent over two pillows so as to semiflex the legs and thighs, and the knees should be tied together. To restrain thigh movements it may be necessary to encase a restless patient in splints or bind him to sand-bags. If the pelvic binder displaces the fragments or causes pain, abandon it and trust to position. If the fragment cannot be retained in place, wire it. The dressings

can be removed in six weeks, and the patient is allowed to get up in eight weeks. In simple, uncomplicated fracture of the false pelvis the prognosis is good. In compound fractures of the false pelvis asepticize, drain and dress, put on a binder, and direct the same position to be maintained as for simple fractures.

Fractures of the True Pelvis.—The most usual seat of these fractures is through the obturator foramen, the ascending ischial and horizontal pubic rami being broken. A fracture may occur near the symphysis pubis, the symphysis may be separated, a line of fracture may run near to or into the sacro-iliac joint; the same may involve each side of the body of the pubis, and there may be multiple fractures. Fractures of the acetabulum and of the tuberosity of the ischium may occur. Before the seventeenth year the innominate bone may be broken into its three anatomical segments. Fractures of the true pelvis are highly dangerous because of the damage which is apt to be inflicted on the pelvic contents. There may be laceration of the bladder or membranous urethra, injury of the vagina, the rectum, the uterus, or the small gut. The *cause* of pelvic fracture is violent force, direct or indirect. Front force tends to produce direct, and side force indirect, fracture. The acetabulum may be broken by falls upon the feet.

Symptoms.—In pelvic fracture there is a history of violent force. There are great shock, swelling, and intense pain increased by attempts at motion, coughing, and straining. There is also inability to sit or to stand. Mobility becomes obvious on grasping an ilium in each hand and moving the hands. Crepitus may be noticed by this maneuver or by moving an ilium with one hand, a finger of the other hand being inserted in the rectum or vagina. In making movements for diagnostic purposes be very gentle, as rough manipulation may cause injury by sharp fragments. There may be doubt as to whether crepitus is to be referred to pelvic fracture or to fracture of the neck of the femur; in this case follow the rule of John Wood: "The surgeon grasps the femur with one hand and places the other firmly upon the anterior superior iliac spine or crest or upon the pubes; then, on moving the femur and abducting it freely, if a crepitus be detected, it will be felt the more distinctly by that hand which rests on or grasps the fractured bone." In from one to three days ecchymosis usually appears in the perineum and scrotum of the male and in the perineum and labia of the female. This sign is similar in origin to Battle's sign of fracture of the posterior fossa of the base of the skull (Coopernail, in "Medical Record," March 4, 1916). In a fracture of the pubes without much tearing of the soft parts there may be simply a linear discoloration.

Rupture of the bladder is made manifest by pain in the hypogastric region, intense desire to micturate, inability to pass urine in quantity, although a few drops of bloody urine may be voided, great shock, sometimes dulness on percussion in the loins, and evidences of extravasation in the prevesical space. The condition is proved to exist by practising the maneuvers suggested under Rupture of Bladder. The symptoms of ruptured urethra are set forth later. Bleeding from vagina or rectum points to laceration of the part by a fragment. The vagina may be badly lacerated and the bowels may emerge from the laceration (Maurice H. Richardson's case). Intestinal injury is apt to induce septic peritonitis. Fractures of the acetabulum occur. Fracture of the brim of the acetabulum permits dorsal dislocation of the femur which will not remain reduced, and causes shortening, which at once recurs when extension is abandoned; also inversion and adduction, although the power of eversion and abduction is preserved (Stokes). There is crepitus, and the head of the bone goes with the fragment upward and backward (Stokes). If the head of the femur be driven through the acetabulum into the pelvis, the injury is very grave; there are then found shortening, adduction, and semi-flexion of the thigh, absence of the prominence of the great trochanter, and more capacity for movement than is noted in dislocation. This injury is called

internal dislocation of the femur (Fig. 338). Fracture of the ischium rarely occurs alone.

Treatment.—Examine carefully to determine if the bowel, the bladder, the urethra, or the vagina is injured. If such an injury exists, radical operation is, of course, demanded. Always use a catheter to see if the urine is bloody. Bloody urine suggests, but does not prove, the existence of a torn bladder. It may be due to simple contusion of the bladder or to contusion of the kidney. In some cases the bladder is sutured. In others it is drained suprapubicly without suturing. In treating a pelvic fracture endeavor to restore the parts to a normal position, employing external manipulation and inserting a finger into the rectum or in the vagina. If reduction is difficult, administer ether. The pelvis should be encircled by a canvas binder and the patient should be placed upon a Bradford frame. If this is done he can be cleaned readily and the bed-pan can be easily used. If movements of the thighs distort the pelvic bones, each thigh should be bound to the frame. In fracture with separation

Fig. 338.—Rugh's case of fracture of the acetabulum with internal dislocation of femur.

of the pubic bones the bones should be wired in place. If urinary extravasation from urethral rupture occurs, perform perineal section. If there are signs of bowel injury or intraperitoneal rupture of the bladder, perform laparotomy; and if the bladder is found to be torn, apply sutures and drain suprapubically. All visceral injuries are treated by general rules. Remove the dressings in six weeks and allow the patient to get about in twelve weeks. In fracture of the acetabulum, if the limb is shortened, give ether and reduce by extension and counterextension. Treat these fractures in the same way as intracapsular fractures of the femur. Fractures of the ischium are best treated by the application of a pad and adhesive plaster, and rest in bed.

E. P. Quain ("Surgery, Gynecology, and Obstetrics," July, 1916) collected 126 cases of rupture of the bladder associated with fracture of the pelvis. To these he adds one of his own. In most of the cases a spicule of bone tore the bladder. Most of the lacerations were extraperitoneal and in several cases they were multiple. Only 34 of the cases recovered, a mortality of 74 per

cent. Forty four of the cases were reported since 1890, and of these 23 recovered, a mortality of 48 per cent. Out of 21 cases reported since 1905 only 8 died, a mortality of 38 per cent. Quain maintains that suturing or wiring of fragments is unsatisfactory when there is extravasation of urine. He practised indirect fixation of the pelvic bone fragments by "percutaneous screws and external clamps at points distant from the fracture and extravasated urine" (Ibid.).

Fractures of the Sacrum.—This bone may be broken by direct force, such as a kick, but the injury is rare. The sacral plexus is usually injured, and if it is, paralysis is observed in the territory of its branches.

The *symptoms* of fracture of the sacrum are pain, frequently incontinence of feces and retention of urine, irregularity of the sacral spines, ecchymosis, and crepitus. Crepitus may be sought for with one hand externally and a finger of the other hand in the rectum. The lower fragment passes forward and may obstruct or may tear the rectum. Paralysis may be found in the area of distribution of the sacral plexus.

Treatment.—In any case of fracture of the sacrum, if there are evidences of pressure upon nerves by displaced bone, expose and elevate the depressed bone. If the rectum is lacerated, sutures must be inserted. In many cases of fracture of the sacrum the older conservative treatment is sufficient. The conservative treatment is as follows: Press the fragments into place with a hand externally and a finger in the rectum. Do not plug the rectum. Put a pad over the upper fragment, hold it by a plaster or a binder, place the patient recumbent on a fracture-bed, and insert a large cushion underneath the pad. Some surgeons give opium to induce constipation, and allow a fecal support to accumulate in the rectum. Use a clean catheter regularly, and guard against bed-sores. Union occurs in about four weeks, when the dressing can be removed. The patient can get about again in six weeks. If urinary retention persists, or if intractable bed-sores form after eight or ten weeks, cut down on the seat of injury and elevate or remove the portion of bone causing pressure.

Fractures of the Coccyx.—The coccyx may be broken or be separated from the sacrum by a fall, a blow, a kick, or the straining of parturition. Its mobility is so great, however, that it does not often break.

Symptoms.—The chief symptom of fracture of the coccyx is pain, which is much aggravated by sitting, walking, or straining at stool. If the index-finger is inserted into the rectum, the displaced bone is felt; if the thumb of the same hand is also placed externally, a rocking motion will develop crepitus and preternatural mobility.

Treatment.—In treating fracture of the coccyx reduce by external pressure and by the manipulations of a finger in the rectum and put the patient to bed. In four weeks the fracture should be united. If union does not take place, defecation, micturition, rising from a chair, or even sitting, and all movements of the coccyx will cause excruciating pain by pressure on the last sacral nerve. A finger in the rectum will locate a very painful spot. This condition is known as *coccygodynia*. It was first described and named by Sir James Y. Simpson of Edinburgh in 1859.

It must not be understood that coccygodynia always results from fracture of the coccyx, or that fracture of the coccyx is the only cause. As a matter of fact, coccygodynia is a rare condition and is seldom a result of fracture of the coccyx. It may arise after confinement, or a fall or blow upon the region of the coccyx, may be due to caries, may result from exposure to cold and wet.

In most cases it is a referred pain due to some central trouble, and is common in various functional disorders of the nervous system. It is especially common in hysterical, neurasthenic, or anemic women. In the traumatic neuroses it is complained of not unusually, and it is frequently associated with irritable spine.

In very rare cases it is a neuralgia. The treatment is aimed at the causative condition. In very obstinate cases it demands a subcutaneous division of the nerve or of the muscles which move the coccyx. Resection of the bone, which was suggested by Tillaux in 1885 and has been advocated by a number of surgeons is only justifiable when the bone is diseased or distorted. The operation weakens the pelvic floor (Yeomans, in "Tr. Am. Proctolog. Soc.," 1914). Yeomans (Ibid.) warmly advocates injection of alcohol (80 per cent.) into and about the painful spot.

Fractures of the Vertebræ.—(See page 961.)

Fractures of the Skull.—(See page 885.)

Fractures of the Clavicle.—The clavicle is more often fractured than any other bone. The fracture may occur at any age, but is commonest before the sixth year (Hulke says one-half of the recorded cases). It may be simple, multiple, comminuted, oblique, transverse, complete, incomplete, or, very rarely, compound. Both clavicles may be broken. Fractures are most apt to occur just external to the middle, at the point where the inner or large curve meets the outer or small curve, at which junction the bone is at its smallest diameter. Fractures of the acromial end are more frequent than fractures of the sternal end, and less frequent than fractures of the shaft. The *causes* of fracture of the clavicle are direct violence, indirect violence, and, very rarely, the contractions of "the deltoid and clavicular fibers of the great pectoral" (Treves, in "Applied Anatomy," from Polaillon).

Fractures of the shaft are usually due to indirect violence, as falls upon the shoulder or upon the outstretched hand. In the latter accident, which is the usual mode of origin, the concussion of the fall travels up and the body weight travels down, and these two forces compress the bone, which snaps at its weakest point. Fractures from indirect force are oblique, and in children are of the green-stick form. Fractures from direct force are usually transverse, and are occasionally comminuted. Fractures from muscular action have been recorded (Rubini, the tenor, recorded by Melay).

Symptoms.—In fracture of the shaft of the clavicle the attitude of the patient is peculiar. He supports the elbow or wrist of the injured side with the hand of the sound side, and also pulls the extremity against the chest; the head is turned down toward the shoulder of the damaged side, as if trying to listen to something in the joint, thus relaxing the pull of the sternocleidomastoid muscle upon the inner fragment. The shoulder is nearer the sternum, on a lower level, and farther front than that of the sound side. Loss of function is shown by inability to abduct the arm, and in many cases by inability to place the hand on the top of the erect head. Considerable pain exists, which is increased by motion, by pressure, and by the extremity hanging down without support.

The deformity above noted is described by stating that the shoulder goes downward, inward, and forward (D. I. F.). The *downward* deformity is chiefly due to the weight of the extremity, which pulls down the unsupported outer fragment, and is contributed to by the action of the pectoralis minor muscle. The *inward* deformity is chiefly due to the contraction of the pectoralis minor and subclavius muscles assisted by the action of the pectoralis major. The *forward* deformity is due to rotation of the outer fragment, which is brought about by the serratus magnus muscle carrying the scapula forward. In this deformity the inner end of the outer fragment is below and behind the outer end of the inner fragment, which overrides it. The inner fragment, though pulled on by the sternocleidomastoid muscle and relatively higher than the outer fragment, is really but little, if at all, elevated, marked elevation being prevented by the attachment of the rhomboid ligament. After noting the deformity, detect with the finger the irregularity of bony contour. Examine for preternatural mobility and crepitus by raising and throwing back the shoulder. In looking for these signs in children it is to be remembered that the

fracture is probably incomplete. The prognosis is good, the bone uniting, but, if unoperated upon, with some shortening or inequality.

Complications.—Fractures of the shaft are rarely compound, because the sharp end of the outer fragment passes backward and because of the free play the skin makes over the bone (Pickering Pick). Both clavicles may be broken. One or more ribs may be fractured at the same time. In fractures from direct force deeper structures may be injured by fragments. Thus, injury of the brachial plexus will induce paralysis. There are 11 recorded cases of simple fracture of the clavicle complicated by laceration of a large vessel. Eight of these cases died. The vessel ruptured may be the subclavian vein, the subclavian artery, or the jugular vein. After a rupture a huge blood-clot forms (Gallois and Poillet, in "Rev. de Chir.," July and Aug., 1901).

Treatment.—In treating a fracture of the shaft of the clavicle correct the deformity as soon as possible by throwing the shoulder upward, outward, and backward. If the patient is a girl, it is desirable to minimize the deformity. Place her upon her back upon a hard bed, with a small pillow under her head, a firm and narrow cushion between the shoulders, a bag of shot resting over the seat of fracture, and the forearm lying on the front of the chest, the arm being held to the side by a sand-bag. In three weeks there will be union, practically without deformity. In a child with an incomplete fracture a handkerchief sling for the forearm, worn three weeks, is all that is needed. In a fracture of the collar-bone of an adult the Velpeau bandage is usually efficient. Before applying it, place lint around the chest and cotton over the elbow. Change the bandage every day for the first week, and after that period every third day. Each time it is changed rub the skin with alcohol, ethereal soap, or soap liniment, dry carefully, and examine for excoriations; if any are found, they are anointed with zinc ointment before the dressing is reapplied. The dressing is permanently removed at the end of four weeks, the arm being carried in a sling for another week. The classical apparatus of Desault is now rarely used. The posterior figure-of-8 bandage associated with the second roller of Desault, some turns being made from the elbow of the injured side to the shoulder of the sound side, can be used in cases in which the forward deformity is apt to return. The apparatus of Fox, which is very comfortable and useful, consists of a pad for the axilla, a sling for the forearm, and a ring for the opposite shoulder, to which ring are tied the tapes from both the pad and the sling (Fig. 339).

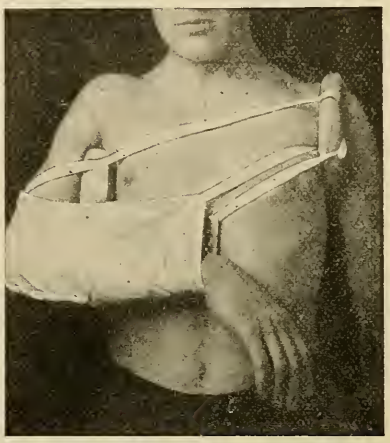

Fig. 339.—Fox's apparatus for fractured clavicle.

The dressing of Moore, of Rochester, is valuable in an emergency. It consists of a piece of cotton cloth, 2 yards long, and folded like a cravat until it is 8 inches in width at the middle. The center of the bandage rests upon the elbow, the posterior tail is carried across the front of the shoulder of the injured side. The forearm is at an acute angle with the arm, and the other end of the bandage is carried across the forearm, across the back over the opposite shoulder, and around the axilla, where the extremities are stitched together. The forearm is suspended in a bandage sling (S. D. Gross, in "A System of Surgery"). The four-tailed bandage is preferred by Pick. Sayre's dressing has many advocates (Fig. 340). For this there are required two pieces of rubber plaster, each piece being 3 inches wide and sufficiently long to go around the

chest one and a half times. The end of one piece encircles the arm of the injured side just below the arm-pit; the plaster strip is pulled across the back to the other side, to the front of the chest, and returns again to the middle of the back. This procedure pulls the elbow back and throws the shoulder out. The hand of the injured side is placed on the breast of the opposite side, cotton being interposed, and the second strip of plaster runs from the elbow of the injured side to the front of the opposite shoulder, around, and back, pressing the elbow forward, upward, and inward. If not changed frequently it may cause severe edema about the elbow. In children, if it is found difficult to immobilize the parts in them, the most satisfactory result is obtained by the application of the Velpeau bandage, which is overlaid by a thin plaster-of-Paris bandage. If the fragments cannot be coaptated, sterilize the parts, administer ether, incise, clear away the muscle from between the fragments, saw the ends, bore each end and hold them in contact by means of kangaroo-tendon or silver wire. The same procedure should be pursued when a fracture is compound or threatens to become so, or if signs indicate pressure upon vessels or nerves. If a large vessel has been injured, the operation is imperatively necessary. If a patient suffering under a fracture which threatens to become compound refuses the aid of operation, keep him in bed and hold the arm in abduction. In a number of cases I have wired the fragments with excellent results. Year by year I become more inclined to recommend wiring in cases of fractured collar-bone. It secures union without deformity, saves the vessels and nerves, and obviates the necessity of prolonged and very uncomfortable fixation of the arm and forearm.

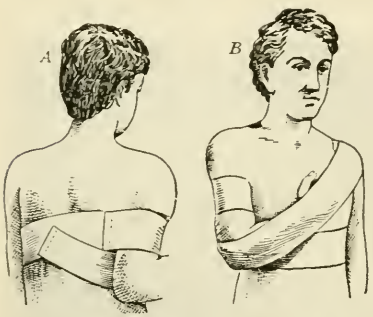

Fig. 340.—Sayre's adhesive-plaster dressing for fracture of the clavicle (Stimson): *A*, First piece; *B*, second piece.

After a broken collar-bone has united, if the shoulder is found to be stiff, make passive movements daily; if these fail, move the joint forcibly, first giving ether or nitrous oxid.

Fractures of the Acromial end of the clavicle are due to direct force. If the fracture is between the two coracoclavicular ligaments, deformity is very slight, crepitus is elicited by manipulating with the fingers, and pain exists, but loss of function is not markedly manifest unless it is due to pain. These fractures are treated by interposing cotton between the arm and the side, binding the arm to the side with the second roller of Desault, and hanging the hand in a sling. In fractures external to the ligaments crepitus is manifest on moving the shoulder, the outline of the bone is irregular, severe pain is developed by movement, and deformity is pronounced. The deformity is due to the serratus magnus muscle rotating the scapula forward, the inner end of the outer fragment of the clavicle often coming in contact with the anterior surface of the outer portion of the inner fragment. Fracture of the acromial end of the clavicle is reduced by pulling both of the shoulders strongly backward, and it is kept reduced by the use of a posterior figure-of-8 bandage. In fracture external to the ligaments the displacement frequently cannot be corrected by position and manipulation. Such cases demand incision and wiring. In either variety of fracture the dressings are worn for four weeks.

Fractures of the sternal end of the clavicle are very rare. They are caused by either direct or indirect force. In such a fracture there are found crepitus, projection at the seat of fracture, rigidity of the sternocleidomastoid muscle, and shortening of the clavicle. The inner end of the outer fragment always passes forward, and often also downward and inward. Reduce these fractures by pulling the shoulders back, and treat them by

means of the posterior figure-of-8 bandage worn for four weeks. Wiring may be necessary.

Fractures of the Scapula.—This bone is not often broken, as it rests upon thick muscles and elastic ribs; it is freely movable, and it has attached to it a bone which easily breaks.

Fractures of the Body of the Scapula.—These are due to direct violence. The *symptoms* are pain (which becomes agonizing on attempting to rotate the shoulder-blade), ecchymosis, and swelling. Crepitus is sought for by placing the hand over the bone and making movements of the arm; also by holding the point of the shoulder and lifting up the lower angle of the bone. The latter plan may develop mobility. The spine of the scapula is uneven only when it is itself fractured. Examine for unevenness of the vertebral border of the shoulder-blade. In fractures of the body of the scapula a shoulder-cap is applied, a gutta-percha splint is molded over the scapula, the arm is bound to the side, and the hand is carried in a sling. The apparatus is worn for four weeks.

Fractures of the spine of the scapula are treated as fractures of the body of the bone, and for the same time.

Fractures of the Neck of the Scapula.—Fracture of the *anatomical neck* has not been proved to exist. Fracture of the *surgical neck* is evinced by flattening of the shoulder, prominence of the acromion, and the presence of a lump in the axilla, crepitus being developed by pressing the axillary prominence upward and backward. The coracoid process descends with the humerus. The deformity is reduced with ease, but it at once recurs. The condition is treated by placing a pad in the axilla, a shoulder-cap on the shoulder, applying the second roller of Desault, and supporting the forearm and elbow in a sling. A Velpeau dressing can be used, associated with the application of a folded towel in the axilla. The dressing is to be worn for five weeks.

Fractures of the glenoid cavity are not very unusual, and may occur with or without dislocation. Fracture of this region arises from direct force applied to the shoulder. The existence of this fracture is determined by excluding fractures of other bones and by detecting crepitus when the arm is at a right angle to the body and the humerus is pushed against the glenoid cavity, the crepitus not being found when the arm hangs by the side.

Treatment is by the second roller of Desault and a forearm sling worn for four weeks; careful passive movements limit ankylosis. If ankylosis occurs, adhesions must be broken up while the patient is under ether or nitrous oxid.

Fractures of the acromion process are often met with as the result of direct violence. The existence of fracture of the acromion is indicated by pain, by inability to abduct the arm, by flattening of the shoulder, by sudden lowering of the point of the shoulder, by mobility, and by crepitus. To treat a case of this kind, put a large pad with the base down in the axilla, bind the arm over the pad with the second roller of Desault, lifting the elbow with turns of the roller carried over it and the opposite shoulder, thus splinting the bone in place by the head of the humerus pushing against the coraco-acromial ligaments. The dressing is to be worn for four weeks.

Fractures of the coracoid process rarely happen alone, and are usually due to direct force. Muscular action is very seldom the cause. Petty found in literature but three cases so caused. He adds one of his own (Annals of Surgery, March, 1907). But little displacement is found. Crepitus and mobility are usually detected. Inability to shrug the shoulder inward was pointed out as a symptom by Byers. Such a case is well treated by a Velpeau bandage, which is to be worn for four weeks.

Fractures of the humerus are divided into: (1) fractures of the upper extremity; (2) fractures of the shaft, and (3) fractures of the lower extremity. In examining any fracture of the humerus, feel at once for the pulse, so as to ascertain if the artery has been torn; in any fracture near the head of the humerus be certain that dislocation does not exist.

Examination of the Shoulder.—In some cases ether must be administered. Compare the injured shoulder with the sound shoulder, the patient, if not anesthetized, being seated on a chair or stool. The direction of the axis of the arm is noted. The surgeon grasps the flexed elbow with one hand and the shoulder with the other; he thus can move the extremity and palpate the joint and adjacent points. The shoulder is moved gently in every direction, and the surgeon notes if the head of the bone moves with the shaft. Examination shows if the head of the bone is in place or if the glenoid cavity is vacant—if the head of the bone is in an abnormal situation, if it is altered in contour, if there is crepitus or preternatural mobility, and if any movement is impaired. The acromion process, outer end of the clavicle, coracoid process of the scapula, and neck of the scapula are also investigated. The length of the arm is obtained by measuring from the apex of the acromion process of the scapula to the apex of the external condyle of the humerus, and it is compared with the length of the sound extremity.

Fractures of the upper extremity of the humerus include: (*a*) fractures of the anatomical neck; (*b*) fractures of the surgical neck; (*c*) fractures of the head, oblique and longitudinal, and (*d*) separation of the upper epiphysis.

Fractures of the Anatomical Neck of the Humerus.—The anatomical neck is the constricted circumference of the articular surface, and fractures of it, though rare, do occur, especially in the aged. The line of fracture in some cases follows the insertion of the capsule, in others it is entirely within the capsule, but in most it is without the capsule above and within the capsule below; hence the term "intracapsular" is rarely correct as a designation. Such a fracture may be impacted. The *cause* is direct violence or a fall or a blow upon the elbow when the arm is abducted. Polloson, of Lyons,[1] has reported a case due to muscular action. The patient died in eclampsia, and at the necropsy it was found that both humeral heads were fractured and impacted. The fractures must have been produced by the muscles throwing the heads of the bones violently against the glenoid cavities, probably by adduction.

The *symptoms* of fracture of the anatomical neck are pain, tenderness, swelling, ecchymosis, slight irregularity of the shoulder (which irregularity is soon hidden by tumefaction), and inability to abduct the arm actively. Deformity, as a rule, is slight or is absent, because the capsule is rarely entirely torn from the lower fragment. If deformity exists, it is due to the muscles inserted on the bicipital groove and to the coracobrachialis, which pull the lower fragment inward and forward. Treves says that a tear of the reflected fibers of the capsule leads to subsequent necrosis of bone because this joint has no ligamentum teres. In unimpacted cases there is crepitus, and mobility of the shaft can be detected near the head of the bone. In some cases impaction occurs, the upper fragment impacting into the lower. In this condition there are very slight shortening and trivial shoulder-flattening, no crepitus unless the tuberosity is broken off, no mobility, and, as Erichsen says, the head of the bone, while it can be felt through the axilla, is not in the axis of the limb.

The *prognosis* of fracture of the anatomical neck is usually good for bony union (Hamilton, Pick, and R. W. Smith), but a stiff joint is apt to result.

Treatment.—Feel the pulse to be sure the artery is untorn. In most cases an anesthetic should be given in order to examine with ease and dress with satisfaction. Sometimes the fragments are readily coaptated; occasionally they are not. In a case reported by Carl Beck the axes of the fragments were at right angles and they could only be kept in contact by holding the arm at a right angle to the body ("New York Med. Jour.," April 5, 1902). Albee, of New York, reported a series of these fractures treated by wiring and maintaining the arm at a right angle with the body. The result was com-

a right angle with the body, and carry up from the base of the fingers to above the elbow the turns of a spiral reversed bandage made of flannel. Interpose lint between the arm and the side, and place a V-shaped pad with the apex upward in the axilla, tying the tapes over the opposite shoulder. A shoulder-cap made of pasteboard (Pl. 7, Fig. 8) or plaster of Paris (Fig. 341), molded to fit and well lined with cotton, is applied. The plaster-of-Paris cap is the most satisfactory. It is applied "so as to cover the whole shoulder, the anterior and posterior aspects of the chest, and the outer side of the upper arm down to the external condyle of the humerus" (Scudder, on "The Treatment of Fractures") (Fig. 341). The arm with the shoulder-cap is fixed to the side by the second roller of Desault, and the wrist is hung in a sling (Fig. 342). The edges of the bandage should be stitched together. This apparatus is changed daily for the first few days, the body and arm being rubbed at each change with alcohol, soap liniment, or ethereal soap. After this period a change every third or fourth day is often enough. Massage is begun at the end of one week, but rotation and motion of the joint are not employed until after three weeks. The dressings are removed at the end of four weeks, the forearm being carried in a sling for two weeks more. In impacted fracture do not pull apart the impaction, do not use a pad, but apply a cap to the shoulder and fix the arm to the side for five weeks. The fracture unites with deformity.

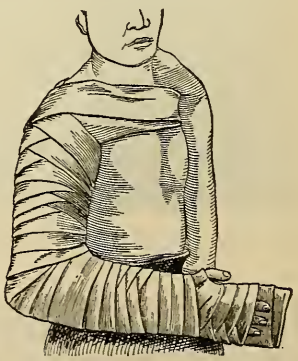

Fig. 343.—Internal angular splint and shoulder-cap in fracture of the surgical neck of the humerus.

Fractures of the Surgical Neck of the Humerus.—The surgical neck is the constricted portion of bone between the tuberosities and the upper line of the insertion of the muscles on the bicipital groove. Fractures in this region are usually transverse, but they may be oblique. The *causes* are: direct force almost always; indirect force occasionally; and muscular action in rare instances. The common cause is a fall or blow upon the shoulder when the elbow is fixed. When the shoulder is fixed forcible abduction of the elbow may cause the fracture. The middle aged and the elderly are most liable to this fracture but youths are not exempt. Over 13 per cent. of Ross's cases were under sixteen years of age ("Penn. Med. Jour.," 1914, xvii).

The *symptoms* in fracture of the surgical neck are: pain running into the fingers from pressure upon the brachial plexus; crepitus; mobility on extension; and flattening, which differs from the flattening of dislocation in that it occurs farther below the acromion and that this process is not so prominent. Shortening to the extent of an inch is noted. The head of the bone can be felt in the glenoid cavity, but it does not move on rotating the arm. The upper end of the lower fragment is felt and moves on rotating the arm. The displacement is pronounced. The lower fragment is pulled upward by the deltoid, biceps, coracobrachialis, and triceps; inward by the muscles of the bicipital groove, and forward by the great pectoral; thus, the upper end of the lower fragment projects into the axilla, and the elbow stands out from the side and backward. Péan holds that the violence drives the lower fragment forward. The upper fragment is abducted, rotated outward, and flexed, which position is due, it is generally taught, to the action of the supraspinatus, infraspinatus, and teres minor muscles. In some cases displacement is forward, and in other cases it is not obvious. The lower fragment may impact into the upper, in which case the symptoms are obscure and the diagnosis is made by exclusion. If the impaction is solid and complete, there are the history of direct force, the impaired movements, the slight deformity, and the absence of crepitus. In all fractures of the upper end of the humerus the distinction can be made from dislocation by feeling the head of the bone under the acromion and by noting that it does not move on rotating the arm. Among complications are fracture

of the tuberosities (nearly 18 per cent. of Ross's cases) and dislocation of the head of the bone (nearly 6 per cent. of Ross's cases).

The *prognosis* of fracture of the surgical neck of the bone is good.

Treatment.—Some surgeons treat a fracture of the surgical neck in exactly the same manner as a fracture of the anatomical neck. I prefer the following plan: In many cases give ether in order to examine and dress. Feel the pulse

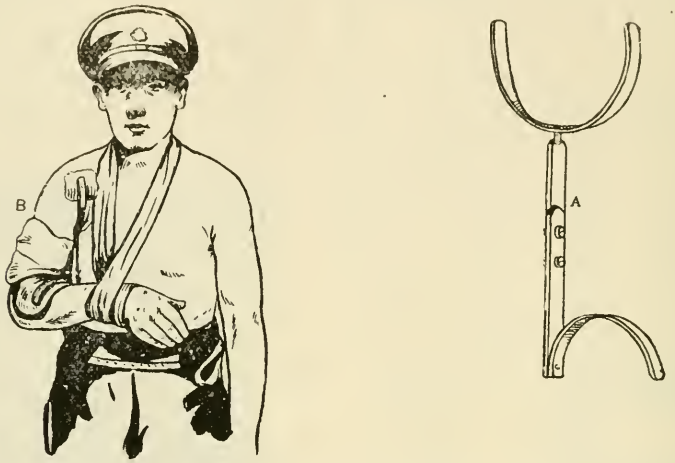

Fig. 349.—A, Depage modified humerus splint. B, Applied for fracture of right humerus.

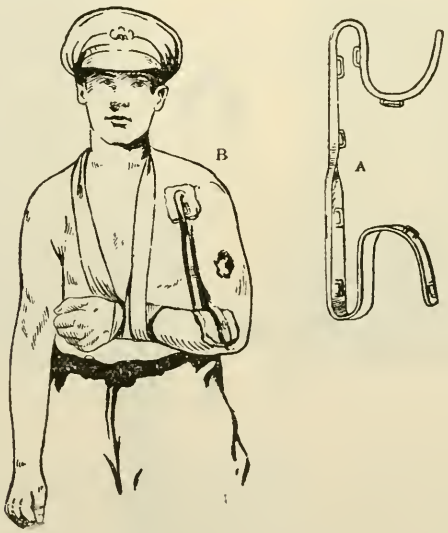

Fig. 350.—A, Extempore aluminum or strong wire splint for fracture of humerus. B, Applied for fracture of left humerus.

to see that the artery has not been damaged. Reduce by traction and manipulation, especially abduction. If there is an impaction do not pull it apart unless the fragments are in a vicious position. Take an internal angular splint (Pl. 7, Fig. 6) and pad it well, putting on extra padding at the points that are to rest against the palm, the inner condyle, and the axillary folds. Lay the arm and pronated forearm upon the splint. Apply a padded shoulder-cap. Fix the splint and cap in place with a spiral reversed bandage terminating as a

spica of the shoulder, and hang the hand or forearm in a sling (Fig. 343). The dressing is to be worn for four weeks, and the rules to be followed in changing it are the same as in fracture of the anatomical neck. Massage is used after one week, and passive motion to amend stiffness after four weeks. Forcible breaking up of adhesions is not admissible for at least three months. In rare cases—those with strong anterior projection of the lower end of the upper fragment—apply an anterior angular splint. If the deformity strongly tends to recur, support by a plaster-of-Paris trough on the back and sides of the arm and shoulder, or sling the extremity and obtain extension by weights and pulleys used with a frame, the patient being kept in bed (Jones' extension splint is a very valuable appliance). In a case with great deformity abduction with extension is a very useful method. I have reached the conclusion that quite a

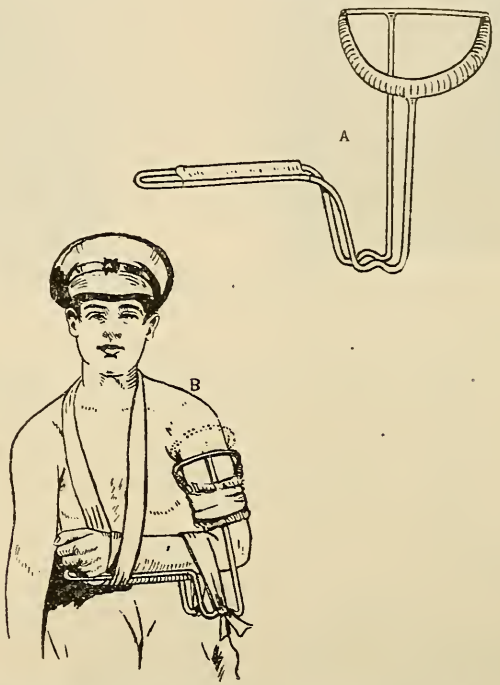

Fig. 351.—A, Jones' extension humerus splint. B, Applied for fracture of left humerus. The padded portion should be higher up in the axilla.

number of cases of fracture of the surgical neck are best treated by incision and fixation. Operation is often necessary if the upper end of the lower fragment is displaced to the outer side. If the fracture is complicated by a complete dislocation operation is needed to replace the head and fix the fragments. A partial dislocation may disappear under extension (Ross, Ibid.).

Longitudinal and Oblique Fractures of the Head of the Humerus.—By this term may be designated separation of the great tuberosity or separation of a portion of the articular surface, together with the great tuberosity, from the shaft and lesser tuberosity (Pickering Pick, Guthrie, and Ogston). The *cause* is usually direct violence to the front of the shoulder, but the greater tuberosity may be torn off by muscular action.

The *symptoms* in longitudinal and oblique fracture of the head are broadening and flattening of the shoulder with projection of the acromion. The upper fragment passes upward and outward, and the lower fragment passes upward and inward to rest on the margin of the glenoid cavity below the

coracoid process. The elbow is drawn from the side, there is some shortening, and the patient cannot abduct his arm. If the surgeon grasps the patient's elbow and holds it to the side and rotates the arm while with his other hand he grasps the upper fragment, crepitus is very positive. Examination develops wide separation of the fragments. The deformity cannot be entirely corrected, because the biceps tendon is apt to get between the fragments (Ogston), but a useful limb can usually be obtained.

Treatment.—The plan which gives the best result in treating longitudinal and oblique fracture of the head of the bone is to place the patient on his back upon a hard bed with a small, firm pillow under his head, abduct the arm above the head, rotate it outward so that the back of the hand rests on the bed, and hold it in place by sand-bags. This position should be maintained for three weeks, at the end of which period the fracture can be treated for three weeks more as a fracture of the anatomical neck. If the patient refuses to go to bed, treat the injury as a fracture of the anatomical neck, padding well over the tuberosities. The dressings should be worn for five weeks, passive motion being made after four weeks. In the above injury feel at once for the pulse, to see if the artery has been torn.

Fig. 352.—Linear fracture of humerus.

Separation of the Upper Epiphysis of the Humerus.—The epiphysis is united during the twentieth year. Separation is a rare accident and is produced by direct force.

Symptoms.—The chief symptom in separation of the upper epiphysis is projection of the upper end of the lower fragment inward, forward, and upward beneath the coracoid, and consequently a projection of the elbow backward and from the side. If the lower fragment passes forward and not inward, the elbow simply passes back. The upper end of the lower fragment is smooth and convex. Rotation of the shaft develops soft crepitus when the fragments are in contact.

The *prognosis* is good for bony union, though the future growth of the limb may be impaired.

The *treatment* for separation of the upper epiphysis is a pad in the axilla, a shoulder-cap, binding the arm to the side, and hanging the hand in a sling. Wear the dressing for four weeks, and begin passive motion as directed when dealing with fracture of the upper end of the humerus.

Fracture of the shaft of the humerus is a very common accident. The *cause* is usually direct violence, such as a blow. The fracture may arise from indirect violence, such as a fall upon the elbow. Muscular action is occasionally a cause, as in throwing a ball, in catching a tree-limb while falling, or in turning another's wrist outward as a test of strength (Treves). This test of strength is known by the French as "le tour de poignet."

The opponents sit opposite to each other and each rests his elbow on a table. They clasp hands and each one strives to rotate the other's hand outward. Ashhurst collected 57 cases due to throwing a ball and 23 cases due to "le tour de poignet." He believes that in some cases the humerus is broken as a stick may be broken by holding one end and swinging the other through the air and that in other cases fracture results from twisting (Astley P. C. Ashhurst, in "University of Pennsylvania Med. Bulletin," Feb., 1906). In fracture due to muscular action the break is nearly always below the deltoid insertion and the line of fracture approaches the transverse.

The *symptoms* of fracture of the shaft of the humerus are pain, tenderness, swelling, ecchymosis, inability to move the arm, mobility, and distinct crepitus. Shortening to the extent of ¾ inch occurs. The displacement varies with the

situation of the fracture and the direction of the force. If the fracture is above the insertion of the deltoid, the lower fragment is pulled up by the triceps, biceps, and deltoid, and pulled out by the deltoid, and the upper fragment is pulled inward by the arm-pit muscles. In fracture below the deltoid this muscle is apt to pull the lower end of the upper fragment outward, while the lower

Fig. 353.—Fracture of middle of humerus.

Fig. 354.—Apparatus for fracture of the humerus at any point above the condyles.

fragment passes inward and upward because of the action of the biceps and triceps. Injury of the *musculospiral nerve* sometimes occurs. The nerve may

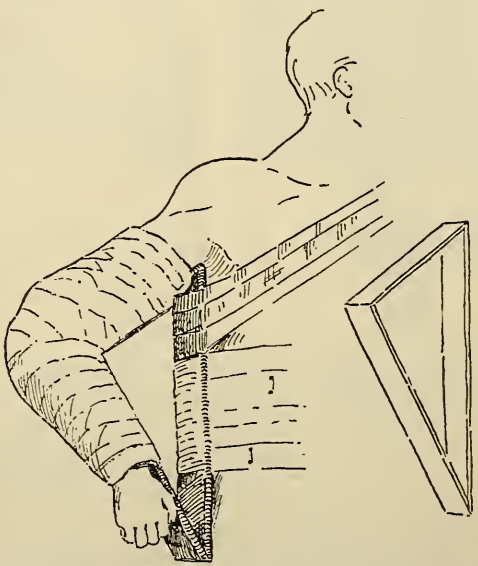

Fig. 355.—The humerus triangle. This splint is one of the most useful splints for the treatment of fractures of the arm and forearm (Hull).

be contused, producing pain at the seat of bruising, and tingling and numbness in the region supplied by the nerve. In most cases the symptoms soon pass away, but sometimes neuritis ensues. A severe contusion produces not

only pain, but paralysis of the muscles supplied by the nerve, and surface anesthesia. In most cases this condition is recovered from in a few weeks, but sometimes it lasts a long while or even permanently. In musculospiral paralysis the patient is unable to extend the wrist and fingers or to supinate the forearm. There is "complete loss or impaired sensation in the lower half of the outer and anterior aspect of the arm and in the middle of the back of the forearm as far as the wrist" (Scudder, in "The Treatment of Fractures"). The nerve may be divided by a sharp fragment, paralysis of motion and anesthesia resulting at once. In some cases the nerve is caught in and compressed by callus, scar-tissue, or fragments, motor and sensory disturbances resulting.

The *prognosis* is good, but the fact should always be remembered that ununited fractures are commoner in the humerus than in any other bone. Treves believes this to be due to entanglement of muscle between the fragments.

Fig. 356.—Modified Thomas splint used by Major Robert Jones in cases of fracture of the humerus (Hull).

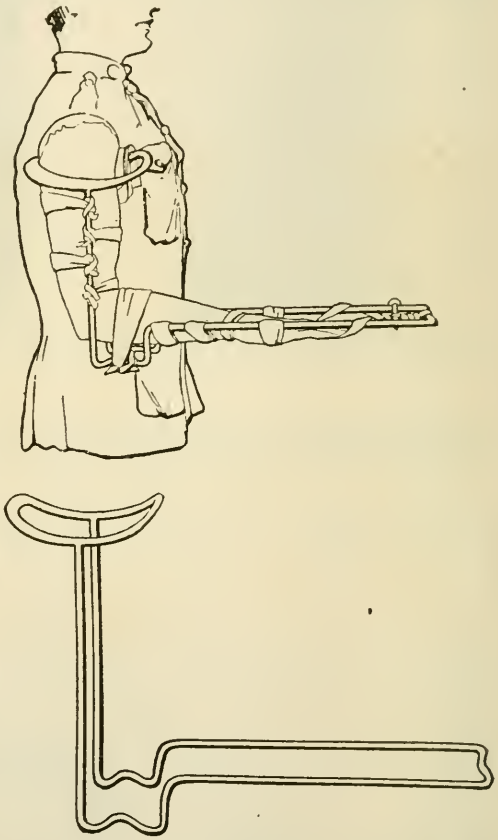

Fig. 357.—Jones humerus traction splint. The American pattern of the splint is here illustrated. By changing the pattern of the axillary crutch the splint is made adaptable to either side of the body. By slightly lengthening the forearm piece, traction on the forearm may be obtained (Osgood).

lack of fixation of the shoulder-joint, and imperfect elbow support. Hamilton believes that it is due to the facts that the elbow soon becomes fixed at a right angle, and that any movement of the forearm moves the seat of fracture and not the elbow.

Treatment.—It is rarely necessary to anesthetize unless the patient be a nervous woman or an excitable child. Feel the pulse, to be certain the artery has not been lacerated. Reduce the fracture by extension, counterextension, and manipulation. The injury may be treated by Bowlby's splint (Fig. 348), Jones's

extension splint (Figs. 351, 356 and 357) or Thomas's splint (Figs. 346 and 348) or the humerus triangle (Fig. 355). Depage's splint (Figs. 349 and 350) is a useful improvised appliance. I usually employ humeral splints (Fig. 345). The internal splint reaches from the axilla to just above the internal condyle of the humerus. A short straight splint is applied front and another back, each being the length of the arm. A shoulder-cap is applied, which cap "is prolonged below into an external angular splint reaching as far down as the lower third of the forearm" ("Manual of Surgical Treatment," by Cheyne and Burghard). The elbow is brought to a right angle with the arm and the forearm is placed midway between pronation and supination. As Cheyne and Burghard say: "It is necessary that the arm should hang vertically at the side with the long axis of the forearm parallel with the anteroposterior diameter of the trunk; if the forearm be brought at all forward across the chest, rotation of the lower fragment upon its vertical axis is apt to take place." Splints are to be worn for

FIG. 358.—Fracture of the shaft of the humerus. Note bandage to hand, forearm, and elbow; axillary pad and strap; coaptation splints and sling. Bandage does not cover fracture (Scudder).

FIG. 359.—Fracture of the shaft of the humerus. Note bandage to hand, forearm, and elbow; adhesive-plaster swathe holding arm upon axillary pad and covering coaptation splints. Sling (Scudder).

five or six weeks, and after the removal of the splints the wrist is hung in a sling. The sling is dispensed with eight weeks after the infliction of the injury. Passive movements are not to be made until the fracture is well united (after five or six weeks), for, if made too soon, they predispose to non-union, and, as no joint is involved, genuine ankylosis will not occur. Many surgeons treat these fractures by applying plaster of Paris to the forearm and the arm (the elbow being flexed to a right angle), binding the arm to the side, and hanging the wrist in a sling. Others apply a trough to the arm and forearm. With Scudder I usually prefer to bandage the hand, forearm, and elbow, and apply an axillary pad, coaptation splints, a swathe of adhesive plaster holding arm to the side, and a sling (Figs. 358, 359). In any case in which it is impossible to obtain and maintain correct apposition of the fragments, cut down upon them, and apply a plate. If the nerve is divided, an incision must be made at once, the nerve sutured, and the bone plated. If the nerve is caught in the callus, after repair has taken place it must be liberated by chiseling the callus away. Neuritis is

treated by blisters over the nerve, the use of the descending galvanic current, and the administration of salicylate of ammonium and the bromids.

Fractures of the Lower Extremity of the Humerus.—These fractures are spoken of as fractures in, or in the neighborhood of, the elbow-joint, and they include: (*a*) fractures of the external condyle; (*b*) fractures of the internal condyle; (*c*) fractures of the internal epicondyle; (*d*) fractures at the base of the condyles; (*e*) T- or Y-shaped fractures; (*f*) epiphyseal separation, and (*g*) fractures of the capitellum and trochlea. There may be more than one fracture, or there may be also a dislocation of the humerus, of the ulna, or of both bones. Rarely the fracture is compound. These fractures are frequent injuries in childhood, and are not uncommon in adults.

Method of Examination.—A fracture of the elbow is rapidly followed by great swelling, and the diagnosis is often very difficult. In most cases, when possible, the *x*-rays should be used in arriving at a diagnosis. In every case in which the *x*-rays are not used, and in most cases in which they are, the surgeon examines the parts carefully while the patient is under ether. If swelling is very great; it is necessary to abate it in order to reach any conclusion as to the condition. We can bandage the arm, rest it semiflexed on a pillow, and apply evaporating lotions or even an ice-bag for a few hours, or, what is better, temporarily diminish the swelling by Gerster's plan, which is as follows: Apply an Esmarch bandage from the hand to well above the seat of fracture; this will drive away extra-articular swelling and permit of thorough examination. It is a great advantage to have the patient anesthetized, for then not only can we make an accurate diagnosis, but we can reduce the fracture satisfactorily and apply a careful first dressing.

Compare the injured with the sound elbow. Note swelling and local ecchymosis. Feel for the radial pulse. Note the "carrying angle" (Fig. 361). Measure each arm from the tip of the acromion process of the scapula to the tip of the external condyle of the humerus. Feel each prominent bony point and note if it is mobile (condyles, olecranon, head of ulna). Feel the shaft just above the condyles. Mark with ink on each elbow the tip of the external condyle, the tip of the internal condyle, and the tip of the olecranon, and observe the relation between these points of each elbow in flexion and in extension. In an uninjured elbow a straight line transverse to the long axis of the limb with the joint in extension will pass through the condyles and leave the tip of the olecranon just a shade above it. "When the elbow is at a right angle, these three points will be found in the same plane with the back of the upper arm" (Scudder, in "The Treatment of Fractures"). Rotate the radius while a thumb is held against the head of the bone. Make flexion and extension of the elbow and determine if there is any lateral motion. Test for mobility just above the condyles. The above maneuvers will determine the presence or absence of crepitus, preternatural mobility, deformity, etc.

Fractures of the External Condyle of the Humerus.—A fracture of the external condyle runs into the joint and the capitellum is usually broken off. Such an injury occurs oftenest in children, being due to falling on the hand; but it may occur from direct force, and may happen to adults.

The *symptoms* of fracture of the external condyle are severe pain, great swelling, and crepitus (found on pressing or moving the condyle and on rotating the radius). Mobility may also be discovered. A projection is felt on the outer and posterior surface of the elbow. The forearm is semiflexed and supinated. The patient cannot use the joint.

Fractures of the Inner Epicondyle of the Humerus.—The inner epicondyle is an epiphysis which unites during the seventeenth year. It not infrequently breaks from muscular action or from direct violence, and the fracture does not involve the joint. Crepitus and mobility can be detected. Displacement is slight. The *outer epicondyle* is never fractured alone.

Fractures of the Internal Condyle of the Humerus.—The line of fracture after a break of the internal condyle runs into the joint through the trochlear surface of the humerus. The *cause* is nearly always direct violence. Packard, of Philadelphia, observed a case in which the condyle had been torn off while lifting a tub.

Symptoms.—In fracture of the internal condyle the fragment, accompanied by the ulna, goes upward and backward, and when the forearm is extended the ulna projects posteriorly, the lower end of the humerus being felt in front. The fragment forms a projection back of the elbow. Crepitus and preternatural mobility can be found if swelling is not too great. Crepitus is detected by flexing and extending the forearm. The space between the condyles is broader than normal, and the forearm takes a bend toward the ulnar side, the "carrying function" of the forearm being lost (Fig. 360). When a person carries a heavy object, such as a bucket of coal, he instinctively rests the inner condyle upon the pelvis, and the normal deviation of the forearm outward keeps the bucket from striking the leg. This deviation outward when the inner condyle rests against the ilium gives us the carrying function. In fracture of the inner condyle the broken condyle ascends and the "carrying function" is lost (Fig. 361). This deformity is known as *gunstock deformity*.

Fig. 360.—Loss of "carrying function" after fracture of inner condyle of the humerus.

Fractures at the Base of the Condyles of the Humerus (Figs. 362 and 363).—A fracture in this region is just above the level of the tip of the olecranon and is on a higher level behind than in front. The *cause* is direct force acting upon the olecranon.

The *symptoms* are loss of function, and pain from injury to the median or ulnar nerve. Crepitus and mobility are readily found. The lower fragment is drawn backward and upward by the action of the triceps, biceps, and brachialis anticus muscles. The lower end of the upper fragment projects in front of the joint. This lesion may be mistaken for dislocation of the bones of the forearm backward. In fracture the limb is mobile; in dislocation it is rigid. In fracture the deformity is easily reduced and strongly tends to recur; in dislocation the deformity is reduced with difficulty and does not tend to recur. In dislocation there is shortening of the forearm, but not of the arm; in fracture there is shortening of the arm, but not of the forearm. In dislocation there is a smooth, large projection below the crease in front of the elbow; in fracture there is a sharp projection above the crease. In fracture there is crepitus; in dislocation there is no crepitus.

The *diagnosis* can be settled by the *x*-rays.

T-fractures of the Humerus.—A T-fracture consists of a transverse fracture above the condyles plus a vertical fracture between them. The *cause* is violent direct force applied posteriorly.

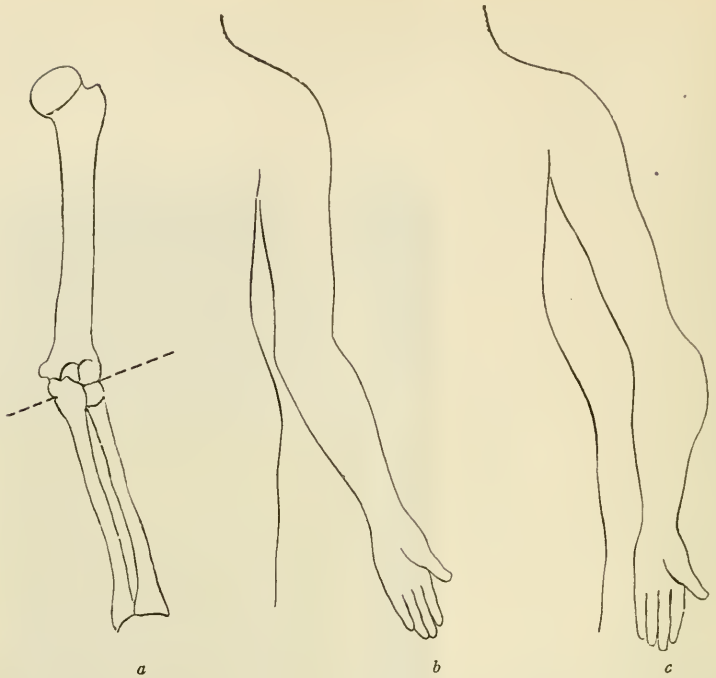

Fig. 361.—Diagram to exhibit the "carrying function" of the forearm, and the loss of this function in fracture of the inner condyle of the humerus: *a* and *b* show the normal relation of the parts when carrying; *c* shows the alteration of axis of the forearm when the inner condyle is fractured, what is known as gunstock deformity resulting (after Allis).

The *symptoms* are increase in breadth of the joint (Fig. 364), preternatural mobility, crepitus, pain and swelling. The internal condyle mounts up back of the elbow on the inner side of the joint. The external condyle mounts up back of the elbow on the outer side of the joint. The forearm is semiflexed and supinated, and the carrying function is lost.

Fig. 362.—Supracondylar fracture of the humerus.

Fig. 363.—Fracture of the humerus above the condyles.

Prognosis of Fractures In or Near the Elbow-joint.—In many fractures it is difficult or impossible to obtain reduction, and in some it is impossible to

maintain reduction. Stimson is undoubtedly right when he says that "in intercondyloid fracture with marked separation there is no practicable means merely to maintain reduction."[1] In fracture in or about the elbow-joint I have regarded the prognosis for complete restoration of function as poor, and believed that in most of these fractures some deformity and considerable stiffness are inevitable. Of late, however, influenced largely by Astley P. C. Ashhurst's study of "Fractures of the Lower End of the Humerus" ("Samuel D. Gross Prize Essay of Phila. Acad. of Surgery," 1910), I have been studying this question anew, and as a result take a less gloomy view of the situation, and am disposed to agree with Ashhurst that "in the vast majority of cases the ultimate results will be perfectly satisfactory." Nevertheless I am still cautious as to what I can safely predict to the patient and the patient's family. Ankylosis, partial or complete, is always a possible sequence. Ankylosis may result from prolonged immobilization, the muscles contracting and becoming fibrous, the fascia and ligaments about the joint shortening, the capsule shrinking and thickening, some of the cartilages becoming fibrous, and the joint being partly obliterated. It may result from extravasation of blood into the joint and tendon-sheaths with subsequent formation of fibrous tissue. It may arise from organization of inflammatory exudate within and about the joint and in the sheaths of muscles and tendons. It may arise from the formation of an excess of callus. Bruns claims that in fracture in the joint excess of callus rarely forms, and that masses of callus form chiefly in the line of fracture near but not in a joint.[2] Excessive callus formation is sure to take place if reduction is not thoroughly accomplished or if the fragments are not well immobilized, but move upon each other. A mass of callus in or about a joint limits or prevents motion. The two greatest causes of impaired function are blocking by callus and stiffness from traumatic arthritis (Jones, of Liverpool).

Fig. 364.—Deformity following fracture of the humerus between the condyles.

Treatment of Fractures in or Near the Elbow-joint.—Thoroughly set the fracture while the patient is under ether. It is advisable, when it can be done conveniently, to use the *x*-rays to confirm the diagnosis and to use them again after dressings have been applied, to be sure that the bones remain in good position. If swelling is very great, it may be necessary to delay setting for two or even three days, the arm being bandaged and laid upon a pillow or lightly supported on an anterior angular splint during the waiting period.

In all cases except transverse fracture above the condyles and fracture of the olecranon reduction is best effected by drawing upon the forearm, supinating it, extending it, and then bending it slowly into a position of acute flexion, the degree of flexion being in inverse ratio to the amount of swelling.

In transverse fracture above the condyles reduction is effected by drawing the forearm and the lower fragment downward and forward and at the same time pushing the upper fragment back.

Some surgeons advocate dressing the fracture on an anterior angular splint,

[1] "Transactions American Surgical Association," vol. ix.
[2] Max Oberst, in Volkmann's "Sammlung Vorträge."

the forearm being fully supinated (Fig. 365). The advantage claimed for this splint is that if ankylosis occurs the joint is in a position to be useful, which it is not if ankylosed in extension. Some deformity is usually apparent after treating a case with this splint; the deformity following fracture of the inner condyle is not corrected by it, but if the splint is carefully applied the result is usually a useful extremity in all cases except fracture of the inner condyle. In transverse fracture of the shaft of the humerus above the condyles the anterior angular splint is the best method of treatment, as it prevents displacement. The splint must not be applied when there is great swelling, and swelling must be removed by resting the extremity on a pillow, the elbow being semiflexed, applying evaporating lotions or even an ice-bag, employing massage, and gently compressing by bandaging. In some cases the joint should be aspirated. In order to apply this dressing, take a right-angled splint and pad its outer surface, being careful to place thick, soft pads over the convexity which will press in front of the elbow and over each end of the splint. Fasten the upper end to the arm, then make extension of the forearm, and if the fracture is found to be completely reduced, fasten the hand and forearm to the splint (Fig. 365). If the hand and forearm are first fixed to the splint, there will be no extension from the elbow and deformity will result. If posterior projection exists, a pasteboard cup is molded over the elbow. The extremity is hung in a triangular sling. At night the extremity is kept in the sling or laid on a pillow. Every third or fourth day, while the extremity is carefully steadied, the splint is removed, the arm and forearm well rubbed with alcohol, massaged, and the splint reapplied. The splint is worn between five and six weeks. At the end of the third week, after removing the dressings, slightly flex, slightly extend, and slightly pronate the forearm, and reapply the splint. At the end of the fourth week repeat this maneuver, making movements of greater range. In the middle of the fifth week and at the end of the fifth week do it again, and flex and extend as much as possible. Very early and very frequent passive motion is objectionable, as it leads to overproduction of callus and ankylosis, but passive motion as above described is imperatively necessary. Many surgeons at the end of the second week apply a Stromeyer splint, which permits the patient and the surgeon to make some motion by means of the screw without removing the dressings. In very stout persons an anterior angular splint will not stay in place. In such a case the forearm may be placed at a right angle to the arm and plaster of Paris be used. After the dressings are removed employ passive motion, massage, hot and cold douches, baking, inunctions of ichthyol or mercurial ointment, iodin locally, corrosive sublimate and iodid of potassium internally, and direct the patient to use the arm systematically. If in any case after four weeks non-union exists, put up the arm in a plaster splint for three or four weeks more. Some surgeons use a posterior right-angled trough instead of an anterior angular splint.

Fig. 365.—Anterior angular splint for fractures in or near the elbow-joint.

Allis warmly advocates treating fractures in and about the joint in extension. He holds that the extended position secures the best circulation, and if either condyle is unbroken secures the benefit derivable from a natural splint. Furthermore, in fractures of the inner condyle it restores the carrying function, which the flexed position does not do. For one week after the accident the patient stays in bed, with his arm extended upon a pillow. After swell-

ing subsides the limb is wrapped firmly in a spiral flannel bandage and plaster of Paris is rubbed in or the bandage is covered with plaster.

Some surgeons extend the limb and apply an ordinary plaster bandage, and in about three weeks substitute an anterior angular splint. The trouble with treatment in extension is that if ankylosis ensues the limb is nearly useless. Furthermore, treatment in extension requires confinement to bed.

Jones, of Liverpool, thinks that splints and bandages are largely responsible for the stiffness which so commonly ensues upon an elbow injury. He advocates treatment by supination and acute flexion in all elbow injures except fracture of the olecranon. It has been demonstrated that the position of acute flexion forces the fragments into place and holds them firmly between the coronoid process of the ulna, the trochlear surface of the ulna, the fascia, and the triceps tendon. The surgeon must be certain that the radial pulse is perceptible *after* the elbow has been flexed. Flexion is maintained by fastening a bandage around the wrist and neck. The bandage around the neck passes through a rubber tube, which serves to protect the neck. The ball of the thumb should rest against the neck. The bandage is fastened to a leather band around the wrist or to a glove, the fingers of which have been cut off. The most convenient dressing to maintain Jones's position is shown in Fig. 366.

Fig. 366.—Jones's dressing for injuries of the elbow-joint.

After the dressing has been applied certain precautions are to be observed. For the first week or ten days look at the arm daily. If the swelling grows worse, diminish the degree of flexion, and do the same if there is severe pain. If the radial pulse disappears, diminish the flexion until free circulation is obtained. This position is maintained from three to six weeks.[1] After the first two weeks lower the wrist an inch or two. At the end of three weeks make a little passive motion (just one movement in each direction). Passive motion and massage are applied as if an anterior splint were being used. The author has treated many cases by Jones's method, and now prefers it to any other plan in all fractures of the elbow except fracture of the olecranon, transverse fracture above the condyles, fracture of the inner condyle near the line of the ulnar nerve, and fracture between the condyles in which the coronoid process gets between the fragments in flexion. The first-mentioned injury must be dressed in extension, the transverse fracture above the condyles requires an anterior angular splint, and the other two injuries should be treated in extension. If a fracture near the line of the ulnar nerve is treated in acute flexion, the callus poured out will be apt to entangle and press upon the nerve.

If it is found impossible to reduce the fragments or to maintain reduction we should make an incision and nail or screw the fragments in place. A comminuted fracture requires operation.

In *young children* the anterior angular splint must not be used. It will become loosened, and motion will inevitably take place at the seat of fracture. Such cases can be treated satisfactorily in Jones's position, the arm being held to the chest by plaster-of-Paris bandages, or they can be treated in extension. Bertomier's plan is very useful in young children.[2] The extremity is dressed without pressure in extension and supination. This can be effected by flannel bandages. In from four to eight days a silicate of sodium bandage is applied

[1] "Provincial Medical Jour.," Dec., 1894, and Jan., 1895.
[2] "Révue de Chir.," vol. viii, 1888.

in order to prevent pronation. About the sixteenth day the bandage is cut so as to form two troughs. From this period every third day the splints are removed and gentle passive motion is made. The splints are removed permanently at the end of four weeks.

If *false ankylosis* follows fracture of the elbow, the adhesions should be broken up under ether, and for some time the hot-air apparatus should be used daily, and massage, passive motion, and the hot and cold douche should be employed. In *true ankylosis* an operation should be performed and the interlocking callus or the interposed tissue or fragment be removed, if a skiagraph shows that operation promises success. If gunstock deformity results and produces marked disablement, it should be operated upon. An osteotomy is performed on the inner condyle. The arm is set in the extended position, plaster of Paris applied, and is not removed for six weeks.[1]

Separation of the lower epiphysis of the humerus is not an unusual accident. The inferior extremity of the humerus may be separated, or the condyles may be separated from each other and from the shaft of the bone.

Fig. 367.—Fracture between the condyles treated by Jones's position. Degree of voluntary flexion obtained.

The *symptoms* are prominence in front of the joint, caused by the lower end of the shaft of the humerus; projection backward of the olecranon; the forearm rests midway between pronation and supination. Epiphyseal separation may retard growth and produce deformity.

Treatment.—Jones's position or an anterior splint as above directed.

Fractures of the ulna comprise the following varieties: (1) fracture of the coronoid process; (2) fracture of the olecranon process; (3) fracture of the shaft, and (4) fracture of the styloid process.

Fractures of the coronoid process of the ulna (Fig. 369) are rarely observed, and practically occur only as a complication of backward dislocation of the ulna or in association with other fractures.

Symptoms.—When fracture of the coronoid process is associated with a dislocation, crepitus is appreciated on reduction, and it is found that the deformity of the dislocation promptly returns on cessation of extension. The upper fragment may be pulled upward by the brachialis anticus muscle, and there exists an inability to flex the forearm completely. The position is one of extension with posterior projection of the olecranon. The broken piece is felt in front of the joint.

The *treatment* is by an anterior splint the angle of which is less than a right angle. Jones's position may be used in treating such a case. A stiff joint may follow.

Fractures of the olecranon process of the ulna occur not uncommonly in adults. Hulke states that such a fracture never occurs before the age of fifteen, but the writer has seen in the Jefferson Medical College Hospital a girl aged fourteen with a fractured olecranon. The *cause* is direct violence or muscular action. Only a small fragment may be torn away, or the entire olecranon may be broken off, and the break may be comminuted or may even be compound.

The *symptoms* of most fractures of the olecranon are: swelling; partial flexion of the forearm; separation of the fragments, the upper piece being pulled up

[1] G. G. Davis, "Phila. Med. Jour.," May 13, 1889.

from ½ inch to 2 inches by the triceps; the space between the fragments is increased by flexion at the elbow, and lessened by extension at the elbow; and there is inability to extend the arm. Bulging of the triceps and crepitus on approximating the fragments are observed. In some few cases there is no separation, the periosteum being untorn or the fascial expansions from the

FIG. 368.—Fracture between the condyles treated by Jones's position. Degree of voluntary extension obtained.

triceps holding the fragments in apposition. In such cases crepitus can be elicited by rocking the upper fragment from side to side.

When treated by non-operative methods the *prognosis* is usually fair, fibrous union being the rule. Some joint stiffness usually occurs, and much ankylosis may be unavoidable. The prospect of a freely movable joint is better when extra-articular wiring is practised.

FIG. 369.—Fracture of coronoid process.

Treatment.—Fracture of the olecranon is usually treated with a well-padded anterior splint almost, but not quite, straight. A perfectly straight splint is uncomfortable, and by opening a retiring angle between the fragments and into the joint favors non-union and ankylosis. The splint should reach from a level with the axillary margin to below the fingers. If the upper fragment does not come in contact with the lower, pull it down by adhesive plaster

and fasten the strips to the splint. The author in 1 case employed a glove to which strings from the adhesive plaster were attached. After applying the splint keep the patient in bed for three weeks. The danger of ankylosis in this fracture is very great, and, in case it occurs in the position of extension, an almost useless arm results. Follow the rule of T. Pickering Pick, and at the end of three weeks anesthetize the patient, press the thumb firmly down upon the top of the olecranon, carry the forearm slowly to a right angle, and apply an anterior angular splint and direct it to be worn for two weeks. When the anterior splint has been applied, passive motion should be made every other day, or every third day, and massage should be used at the same time. When the splint is removed, try to increase the range of motion as previously directed. Surgeons usually incise and apply wires only when it is found impossible to secure apposition of the fragments after fracture of the olecranon. Such a course is, I am persuaded, injudicious conservatism. I do not

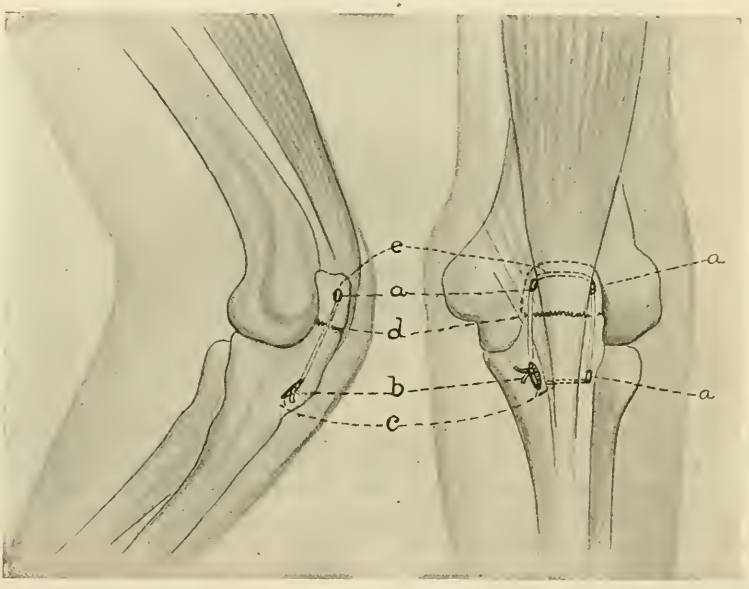

FIG. 370.—Murphy's method of treating fracture of the olecranon by subcutaneous extra-articular wiring. Lateral view and posterior view. Wiring the fragments of the olecranon together: *a*, Incision; *b*, twist or tie of wire; *c*, hole drilled in bone for passage of wire; *d*, fracture; *e*, passage of wire through tendon of triceps (Murphy).

advise that the rule should be to treat fractures of the olecranon as a routine by opening and wiring, but I do advise that we should treat them by extra-articular operation and wiring as advocated by John B. Murphy ("Jour. Am. Med. Assoc.," Jan. 27, 1906). The conservative non-operative treatment often fails. Sometimes the fragments cannot be approximated, frequently they cannot be maintained in approximation, and not unusually a stiff or actually ankylosed joint results. Murphy thus describes the operation which should be done ("Jour. Am. Med. Assoc.," Jan. 27, 1906) (Fig. 370): "A longitudinal incision ⅓ inch long was made on the external aspect of the ulna, ½ inch from its articular surface, and tissues were divided to the bone. A smaller incision was made on the corresponding inner side. I perforated the base of the olecranon with an eyelet drill, which ran transversely from outward inward. I threaded the drill with a fine aluminum-bronze wire, drawing it through this transverse canal. The wire was carried upward under the skin on the inner surface of the

elbow and then drawn out through another small incision, 1/16 inch, made at the level of the apex of the olecranon. The wire was then reinserted and directed transversely from inward outward, passing it through the tendon of the triceps above the olecranon, and then drawn out to corresponding outward point through a very small incision similar to that made on the inner side. The wire was again reinserted and pushed downward under the skin until it was finally brought out through the initial external incision. The circle once completed, traction was exerted on the wire until I was sure that the two fragments were in perfect coaptation, the latter being easily and satisfactorily accomplished. The ends of the wire were twisted several times and then divided by scissors close to the bone. By this procedure the skin was incised at four points, the largest incision being 1/3 inch in length." The extremity is placed in flexion upon an anterior splint, which is worn for four weeks. Passive motion is begun on the third day. A compound fracture and a comminuted fracture always require operation, in which the joint is freely opened. Non-union requires opening of the joint and wiring of the fragments.

Fig. 371.—Fracture of the shaft of the ulna (case in the Pennsylvania Hospital; skiagraphed by Dr. Gaston Torrance).

Fractures of the shaft of the ulna alone are most usual near the middle of the bone, are always due to direct violence, and are not infrequently compound. An injury which breaks the ulna is very apt to break the radius also.

Symptoms.—By running the finger along the inner surface of the bone there are detected inequality and depression; crepitus and mobility are easily developed; there are pain and the evidence of direct violence. The long axis of the hand is not on a line with the long axis of the forearm, but is internal to it. If deformity exists, it is due to the lower fragment passing into the interosseous space because of the action of the pronator quadratus; the upper fragment, acted on by the brachialis anticus, passes a little forward (Fig. 371). The forearm at and below the seat of fracture is narrower and thicker than normal.

Treatment.—In treating fracture of the shaft of the ulna place the forearm midway between pronation and supination, so as to bring the fragments together and to obtain the widest possible interosseous space, and thus limit the danger of union taking place between the radius and ulna. The position midway between pronation and supination is obtained by flexing the forearm to a right angle with the arm and pointing the thumb to the nose. Take two well-padded straight splints, one long enough to reach from the inner condyle to below the fingers, the other from the outer condyle to below the wrist; place a long pad of lint over the interosseous space on the flexor side of the limb, and another on the extensor side; apply the splints and hang the forearm in a triangular sling (Fig. 372). Passive motion is to be begun in the third week, and the splints are to be worn

for four weeks. Fractures of the ulna can be treated very efficiently by plaster of Paris. The best results are secured by wiring or plating.

Fractures of the styloid process of the ulna are due to direct force. The displacement is obvious.

Treatment.—In treating fracture of the styloid process push the fragment back into place and use a Bond splint with a compress for four weeks, or apply a plaster-of-Paris dressing.

Fractures of the radius include the following varieties: (*a*) Fractures of the head; (*b*) fractures of the neck; (*c*) fractures of the shaft, and (*d*) fractures of the lower extremity.

FIG. 372.—Two straight splints in fracture of both bones of the forearm.

Fracture of the head of the radius has been studied by Dr. T. Turner Thomas ("University of Penna. Med. Bulletin," Oct., 1905; and "Annals of Surgery," August, 1907). He has furnished me with the following résumé of his views, with which I entirely agree:

"Fracture of the head of the radius is not infrequent, and is usually the result of a fall on the hand with the elbow in extension and the forearm in pronation. In extension of the elbow the capitellum of the humerus is in contact with only the anterior part of the radial head. Since the carpus articulates almost entirely with the radius, the force of the usual fall on the hand is transmitted almost entirely through this bone, and at the elbow is received by only the anterior part of the radial head. According to the degree of violence applied, more or less damage may be done to the head, or head and neck. The anterior portion of the rim may be split off, the intact ulna preventing the humerus from pursuing the detached fragment and pushing it away from its fellow, and the intact orbicular ligament holding the two in close apposition. This uncomplicated fracture is the most common, but the least troublesome. Union with ultimately good function is the rule, even though the fracture go unrecognized and untreated, because of the close splinting of the untorn orbicular ligament. Since it is the same accident, a fall on the outstretched hand, which usually produces Colles's fracture, fracture of the external condyle of the humerus, fracture of the neck of the radius, fracture of the coronoid process, and posterior dislocation of both bones of the forearm, any one or several of these injuries may complicate the fracture of the radial head. When the anterior part of the head breaks off the bony resistance to the descent of the capitellum by the radius is lost, so that if the force of the accident is severe enough, lateral bending of the elbow to the radial side with further descent of the capitellum may result with greater separation of the fragments, tearing of the orbicular ligament, and more damage to the head. The descent of the condyle in a posterior dislocation may carry before it the detached fragment of the head, and this fragment be left buried in the tissues of the forearm several inches below its normal position after the dislocation has been reduced.

"*Prognosis.*—In the vertical or oblique fissured fracture of the head with close approximation of the fragments, after union takes place, limitation of all movements of the elbow results from adhesions and slight irregularities in the bone. The function rapidly returns in the succeeding weeks, although some limitation of extension will continue for months. More marked irregularity in the circumference of the head may last much longer and may produce permanent limitation of rotation. Bony union between the head and corresponding surface of the ulna will prevent all rotation of the forearm. In

either case flexion and extension usually return almost if not completely. Non-union of the fragments may induce pain and limitation of movement, especially rotation; but with close approximation of the fragments and an untorn orbicular ligament, an apparently perfect return of function may follow, the fragments moving smoothly as one piece within the ligament. The prognosis will depend chiefly upon the degree of damage done to the head and the separation of the fragments.

"*Symptoms.*—The most characteristic feature of this fracture is its obscurity. The thick muscular covering of the radial head, except posteriorly, the splinting effect of the orbicular ligament, and the close contact of the head with the humerus and ulna, make the diagnosis of the small intra-articular fracture particularly difficult. In the uncomplicated vertical fracture there will usually be no movements of the fragments on each other, and, therefore, no crepitus, and there will be no deformity. A history of a fall on the hand; some swelling of the elbow, particularly on the radial side; severe pain and limitation in all movements of the elbow, particularly in rotation; pain and tenderness distinctly localized to the head of the radius; and the exclusion of fracture of the humerus, ulna, and the shaft of the radius, will point strongly to a fracture of the head of the radius. If the injury is treated as a fracture, and two or three weeks later, when fixation is removed, there is marked limitation of all movements of the elbow, the diagnosis will be more than reasonably assured. The *x*-ray may be misleading unless directed in the line of the fracture, and this is not easy to accomplish, since the position of the fragments in their relation to the humerus vary with every change in rotation of the forearm. In most cases an exposure to the *x*-ray in the transverse plane of the humeral condyles, with the forearm in pronation, will give a successful skiagraph. If the *x*-ray is directed at right angles to the line of fracture the skiagraph will usually be negative. If the fragments are freely separated and if crepitus is elicited, the diagnosis will be more easily determined.

"*Treatment.*—In the uncomplicated fracture without crepitus or deformity, Jones's position or a right-angled splint for three weeks will be sufficient. The resulting fibrous ankylosis will largely disappear from forced use in the following weeks, but several months will be necessary before extension is complete. If crepitus is present, four or five weeks' fixation will be better, and in this case the return of function will probably take longer. As a rule, if union is obtained function will return. If pain on movement persists for many months, a detached fragment or the whole head should be excised. Marked limitation of movement from enlargement of the head or bony union between it and the ulna calls for excision of the head."

Fracture of the neck of the radius (Fig. 373) is by no means so rare an accident as was thought before the discovery of the *x*-rays. It seldom occurs alone and is usually associated with fracture of the radial head. These fractures are transverse and frequently impacted. The cause is a fall upon the pronated hand when the forearm is extended.

Symptoms.—In this structure the forearm is pronated and the patient is found to have the lost power of voluntary pronation and supination. Under forced pronation and supination it will be noted that the head of the radius does not move unless there is impaction. Crepitus is sometimes absent because of impaction. Thomas points out that there is angulation of the neck due to driving of the radial head downward and forward ("Annals of Surgery," August, 1907). Reduction is always difficult and may be impossible.

The *treatment* for fracture of the neck of the radius is the same as for other fractures of the elbow-joint—namely, an anterior angular splint or Jones's position.

Fracture of the shaft of the radius (Fig. 374) is far commoner than fracture of the shaft of the ulna. It may occur above or below the insertion of the

pronator radii teres muscle. It may arise from either direct or indirect force. Fracture of the shaft of the ulna may coexist as a result of the same accident.

Fracture of the Shaft of the Radius Above the Insertion of the Pronator Radii Teres Muscle. *Symptoms.*—The upper fragment is drawn forward by the biceps and is fully supinated by the biceps and the supinator brevis. The lower fragment is fully pronated by the pronator quadratus and pronator radii teres, and its upper end is pulled into the interosseous space. There are crepitus, mobility, pain, narrowing and thickening of the forearm below the seat of fracture, and loss of the power of pronation and supination. The head of the bone is motionless during passive pronation and supination. The hand is prone.

Treatment.—In treating this fracture do not put the forearm midway between pronation and supination, as this position will not bring the fragments into contact, the upper fragment remaining flexed and supinated. To bring the lower fragment in contact with the upper, flex and fully supinate the fore-

FIG. 373.—Fracture of the neck of the radius.

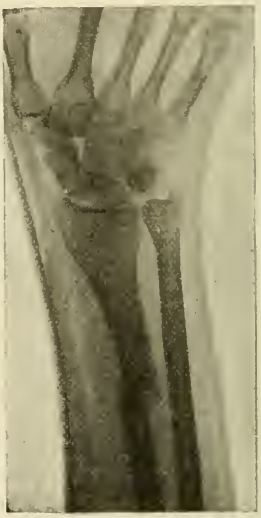

FIG. 374.—Fracture of radius alone.

arm. Apply an anterior angular splint to the extremity for four weeks, and begin passive motion in the third week.

Fracture of the Shaft of the Radius Below the Insertion of the Pronator Radii Teres Muscle (Fig. 374).—In this variety of fracture the upper fragment is acted on by the biceps, the supinator brevis, and the pronator radii teres, and it remains about midway between pronation and supination, passing forward and also into the interosseous space. The lower fragment is acted on by the supinator longus and the pronator quadratus, the latter being the more powerful of the two, hence the lower fragment is moderately pronated, its upper extremity being drawn into the interosseous space. Other symptoms are identical with those of fracture above the insertion of the pronator radii teres.

Treatment.—In treating fracture below the pronator radii teres the forearm is flexed and is placed midway between pronation and supination; two interosseous pads and two straight splints are applied as for fracture of the ulna (see Fig. 372). The splints are worn for four weeks, and passive motion is begun in the third week. Plaster of Paris is a most satisfactory dressing. Loss of function is best obviated in this fracture by incision and fixation.

Fracture of the shafts of both bones of the forearm (Figs. 375–379) is not frequently seen. It is caused either by direct or indirect force. If due to indirect force the radius breaks first.

Symptoms.—After fracture of both bones of the forearm the hand is pronated, and the two lower fragments come together and are drawn upward and backward or upward and forward by the combined force of flexor and extensor muscles, shortening being manifest and the projection of the lower fragments being detected on either the dorsal or the flexor surface of the forearm. The upper fragment of the ulna is somewhat flexed by the brachialis anticus; the upper fragment of the radius is flexed by the biceps and is pronated and drawn toward the ulna by the pronator radii teres. The forearm is narrower than it should be (the ends of the fragments having passed into the interosseous space) and is thicker than normal from front to back (the contents of

Fig. 375.

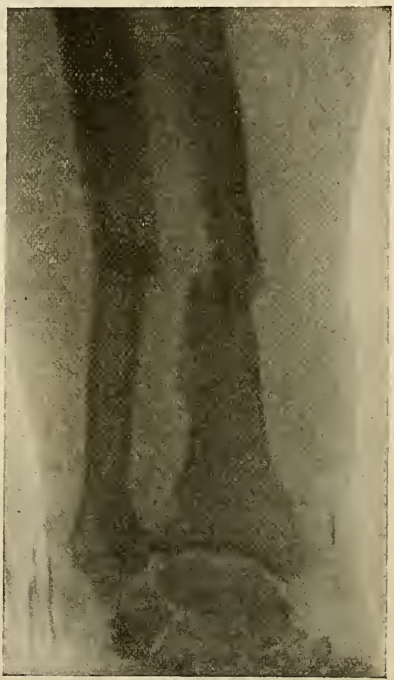

Fig. 376.

Figs. 375, 376.—Fracture of both bones of the forearm.

the interosseous space having been forced out). Crepitus, mobility, pain, and inequality exist, the power of rotation is lost, and on passive rotation the head of the radius does not move. The forearm is prone and semiflexed.

Treatment of this fracture usually consists in the application of two straight splints and two interosseous pads, the forearm being flexed to a right angle and placed midway between pronation and supination (see Fig. 372). As a matter of fact if the ulna is held straight the radius will take care of itself (Sir Robert Jones, in "Amer. Jour. of Orthop. Surg.," 1913, xi). The splints are worn for four weeks, and passive motion is begun in the third week. Before the callus has become hard the surgeon must ascertain that supination is possible. Instead of these splints a plaster-of-Paris dressing can be used. I am persuaded that pronation and supination are best preserved by incision and fixation (Figs. 378 and 379).

Fractures of the Lower Extremity of the Radius.—Until comparatively recent years what we call Colles's fracture was called backward dislocation of the wrist. It was long taught that all wrist injuries were dislocations. Poutean, of Lyons, was the first to describe fracture of the lower end of the radius. He did so in 1783 ("Dislocations and Joint Fractures," by Cotton). In 1814 Colles, of Dublin, fully described the fracture which bears his name. In 1820 Dupuytren made a study of it and it is known to the French of today as Dupuytren's fracture. It took long years for the views of Colles and Dupuytren to gain general acceptance. *Colles's fracture* is a transverse or nearly transverse fracture of the lower end of the radius, between the limits of ¼ inch and 1½ inches above the wrist-joint, the lower fragment

Fig. 377.—Fracture of both bones in the lower third of the forearm.

Fig. 378.

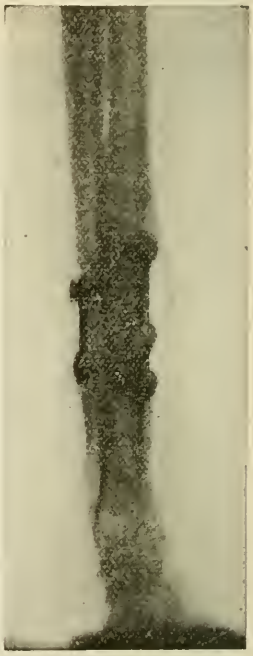

Fig. 379.

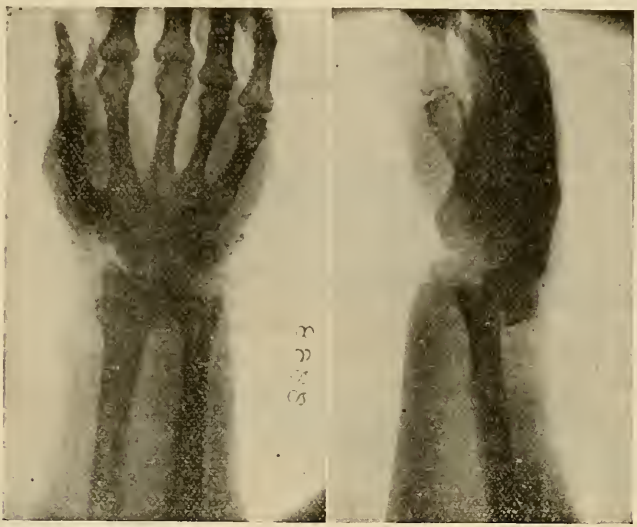
Figs. 378, 379.—Ununited compound comminuted fracture of both bones of forearm (*x*-ray by Dr. Senders).

sometimes mounting upon the dorsum of the upper fragment (Fig. 380), the two fragments sometimes impacting (Fig. 381). An oblique fracture beginning within ½ inch of the joint and passing into the joint is known as *Barton's fracture* (Fig. 382). It was described in 1838 by John Rhea Barton. *Reversed Colles's fracture* was described by R. W. Smith in 1850 and by Callender in 1865. In it the lower fragment undergoes displacement to the flexor side, producing the "*gardener's spade deformity.*" *Chauffeur's fracture* is caused by cranking an automobile. It "may be of various types, the most frequent of which is one splitting off the outer surface of the articular surface of the radius through the base of the styloid process" (Ashhurst's "Surgery, Principles and Practice"). Colles's fracture is a very common injury, is met with most frequently in those beyond the age of forty, and oftener in women than in men. It is due to transmitted force (a fall upon the palm of the pronated hand). Some think that the force is received by the ball of the thumb and passes to the carpal bones and the edges of the radius; a fracture beginning posteriorly rather than anteriorly and the force driving the lower fragment upon the dorsal surface of the radius, the carpus and lower fragment moving upward and outward. It is much more likely that this fracture is due to cross-strain on the bone.

There is sudden traction upon the anterior ligaments, which drag upon the bone and break it at a point where the cancellous end of the radius joins the compact



A B

Fig. 380.—Colles's fracture before reduction: A, Anteroposterior; B, lateral views.

shaft (Fig. 383). The fragments are not unusually impacted (Fig. 381). In the author's experience dislocation of the lower end of the ulna is not a very unusual complication. It arises from a fracture of the ulnar styloid or tearing off of the internal lateral ligament of the wrist.

Fig. 381.—Impacted Colles's fracture.

Fig. 382.—Barton's fracture.

Symptoms.—In Colles's fracture there are pain, swelling, tenderness of the region and very acute tenderness along the line of fracture. This line of tenderness can be tracked by the pressure of a lead-pencil all the way around the radius (Dwight, in "Surg. Report of Roosevelt Hosp. of N. Y.," 1915).

The hand is abducted (drawn to the radial side of the forearm) and pronated, the head of the ulna is prominent, the styloid process of the radius is raised, and the lower fragment may mount on the back of the lower end of the upper fragment, causing a dorsal projection, termed by Liston the "silver-fork deformity" (Figs. 384, 385). Silver-fork deformity is present in from 60 to 70 per cent. of cases. The lower end of the upper fragment can be felt beneath the flexor tendons above the wrist. The position in deformity is produced by the force. Some consider it is maintained by the action of the supinator longus and the flexor and extensor muscles, but particularly by the extensors of the thumb. Pilcher has demonstrated the fact that in this fracture a portion of the dorsal periosteum is untorn, and this untorn portion acts as a binding band to hold the fragments in deformity. Pronation and supination are lost. In this fracture the hand can be greatly hyperextended (*Maisonneuve's symptom*). Crepitus, which is best obtained by alternate hyperextension and flexion, can be secured unless swelling is great or impaction exists. Crepitus on side movements is rarely obtainable. Impaction may greatly modify the deformity, though displacement generally exists to some extent, and the fragments do not

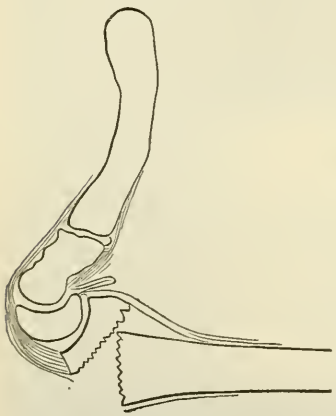


Fig. 383.—Effect upon the lower end of the radius of the cross-breaking strain produced by extreme backward flexion of the hand (Pilcher).

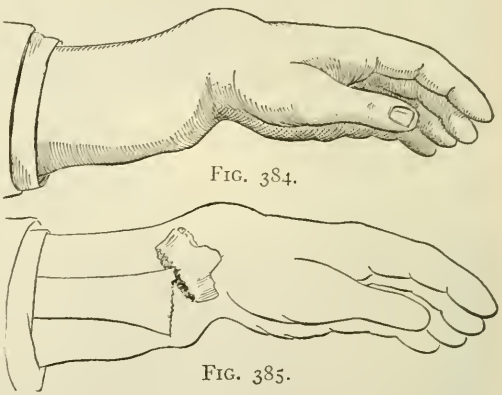

Fig. 384.

Fig. 385.

Figs. 384 and 385.—Deformity at the wrist consequent upon displacement backward of the lower fragment of the radius after fracture at its lower extremity (Levis).

ride easily on each other. The styloid process of the ulna may be broken, or the inferior radio-ulnar articulation may be separated (dislocation of the lower end of the ulna). This latter complication allows the lower fragment to roll freely upon the upper, and the characteristic silver-fork deformity does not appear. If the styloid process of the ulna is broken, pressure over it causes great pain. If a person in falling strikes the back of the hand and a fracture of the radius occurs, the lower fragment is driven upon the front surface of the upper fragment and is felt under the flexor tendons at the wrist (*reversed deformity*). An elaborate study of fracture of the radius with forward displacement of the lower fragment has been published by John B. Roberts.[1]

Treatment.—In treating an ordinary Colles's fracture reduce the deformity by hyperextension to unlock the fragments and relax the dorsal periosteum, follow by longitudinal traction to separate the fragments, and forced flexion to force them into position. This formula was introduced many years ago by the late R. J. Levis. It is of the first importance to reduce this fracture thoroughly, and very often it is not thoroughly reduced. Imperfect reduction means permanent deformity, stiffness of the tendons and wrist, and possibly an almost useless

[1] "Am. Jour. Med. Sci.," Jan., 1897.

hand. Reduction under ether is easier and in difficult cases more complete than reduction without the aid of an anesthetic. The extremity can be placed upon a Levis splint (Fig. 386), the position maintaining reduction and the tense extensor tendons giving dorsal support. Some surgeons use Gordon's pistol-shaped splint. The favorite splint in Philadelphia practice in the past has been Bond's (Pl. 7, Fig. 7). It places the hand in a natural position of rest (semiflexion of the fingers, semi-extension of the wrist, and deviation of the hand toward the ulna). Two pads are used: a dorsal pad which overlies the

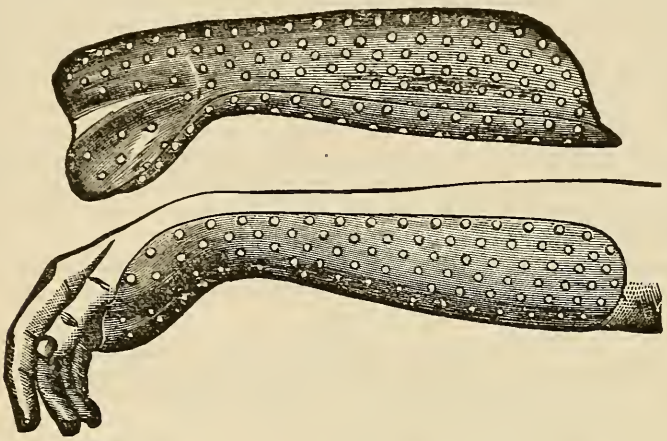

Fig. 386.—Levis's radius-splints, right and left, for fracture of the lower end of the radius.

lower fragment, and a pad for the flexor surface which overlies the lower end of the upper fragment. A bandage is applied, the thumb and fingers being left free (Fig. 387). Passive motion is begun upon the fingers in three or four days, and upon the wrist during the second week. The splint is removed in three weeks, and a bandage is worn for a week or two more because of the swelling. In applying the Bond splint, do not pull the hand too much up on the block, or the fracture will unite with a projection upon the flexor surface of the extremity and the tendons of the wrist will be apt to be caught in the callus. The most satisfactory dressing is the straight dorsal splint advised by Roberts (Fig. 388). It runs from just below the external condyle to the beginning of the fingers. I use it almost invariably. It prevents the recurrence of deformity and is mechanically the proper mode of treatment. It should be worn for three weeks. Undoubtedly more or less stiffness often follows Colles's fracture, and some very able surgeons have been so impressed with the frequency of crippling stiffness that they have dispensed with the use of a splint. Sir Astley Cooper long ago spoke of simply placing the arm in a sling as proper treatment for fracture of the radius. Moore, of Rochester, applied a cylindrical compress over the ulna, held in place for six hours by adhesive plaster, then cut the plaster, placed the forearm in a sling, and let the hand hang over the edge of the sling. Pilcher applies a band of adhesive plaster around the wrist and supports the wrist in a sling, but, as Storp says, dispensary patients are apt to disarrange this dressing. Storp wraps a piece of rubber plaster 4 inches wide around the wrist, and places a second piece around the first so arranged

Fig. 387.—Bond's splint in Colles's fracture.

as to form a fold over the radius; an opening is made through the fold for the passage of a sling. In ten days the plaster is removed and the forearm is carried in a sling. Massage is begun in the third week. Impaired function follows in about 40 per cent. of these fractures. If a stiff joint and limited tendon motion eventuate from the fracture, use massage, frictions, sorbefacient ointments, tincture of iodin, electricity, hot and cold douches, and the hot-air apparatus, or give ether and forcibly break up adhesions. If reduction was not thoroughly effected and too great a length of time has not elapsed, and the hand is helpless and painful, the bone should be refractured. In a young or middle-aged person, in whom a useless hand has followed an ill-reduced fracture, osteotomy is justifiable.

Fracture of Both the Radius and Ulna Near the Wrist.—Colles's fracture may be complicated by a fracture of the ulna other than of its styloid process.

Symptoms.—In fracture of the radius and ulna near the wrist the lower ends of the upper fragments come together, the upper fragment of the radius is pronated, and the lower fragment of the radius is drawn up. Pain, crepitus, mobility, shortening, and loss of function exist.

Treatment.—Fracture of the radius and ulna near the wrist should be treated by the straight dorsal splint, as is Colles's fracture.

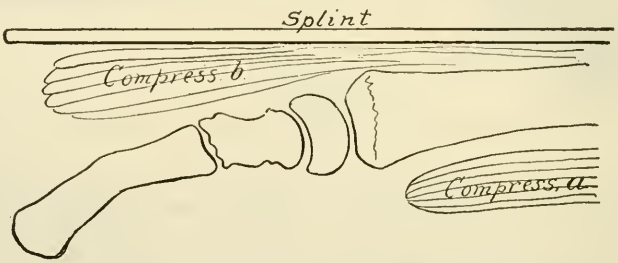

Fig. 388.—Diagram showing the arrangement of compresses and splint best adapted to retain fragments in proper position after reduction (Pilcher).

Separation of the Lower Radial Epiphysis.—This accident occurs in children from falling upon the palm of the hand. It never happens after the twentieth year.

Symptoms.—In separation of the lower radial epiphysis the lower fragment mounts upon the upper and produces a dorsal projection like that found in Colles's fracture, but the hand does not deviate to the radial side. The deformity resembles that of a backward carpal dislocation, but is differentiated from dislocation by the unaltered relation in the fracture between the styloid processes and the carpal bones.

The *treatment* in separation of the lower radial epiphysis is the same as for Colles's fracture.

Fractures of the carpus were until recently thought to be infrequent, but the *x*-rays have taught us differently, and we now know that many supposed sprains of the wrist are, in reality, simple fractures of the carpus. Ernest Amory Codman and Henry Melville Chase show that a majority of carpal injuries "are either simple fractures of the scaphoid or anterior dislocations of the semilunar bone," the two injuries being frequently combined ("The Diagnosis and Treatment of Fracture of the Carpal Scaphoid and Dislocation of the Semilunar Bone," in "Annals of Surgery," March and June, 1905). The *cause* of carpal fracture may be violent direct force or a fall upon the extended palm.

Symptoms.—Fractures of the carpus in general are indicated by pain,

tenderness, swelling, evidences of the infliction of direct force, sometimes crepitus, loss of power in the hand, and a very little displacement.

Treatment.—Many compound comminuted fractures of the carpus require amputation. In an ordinary compound fracture asepticize, drain, dress with antiseptic gauze and a plaster-of-Paris bandage, cutting trap-doors in the plaster over the ends of the drainage-tube. In a simple fracture dress the hand upon a well-padded straight palmar splint (Pl. 7, Fig. 10) reaching from beyond the fingers to the middle of the forearm, and place the hand and forearm in a sling. The splint is worn for four weeks, and passive motion of the wrist is begun in the second week.

Fracture of the carpal scaphoid (see previously quoted article by Codman and Chase) usually results from falls upon the palm of the extended hand and is most common in males between the ages of twenty-five and thirty-five. It is rarely recognized at the time of the accident; the patient complains of severe pain, tenderness, and disability and is thought to have a sprain. According to Codman and Chase, the symptoms improve up to a certain

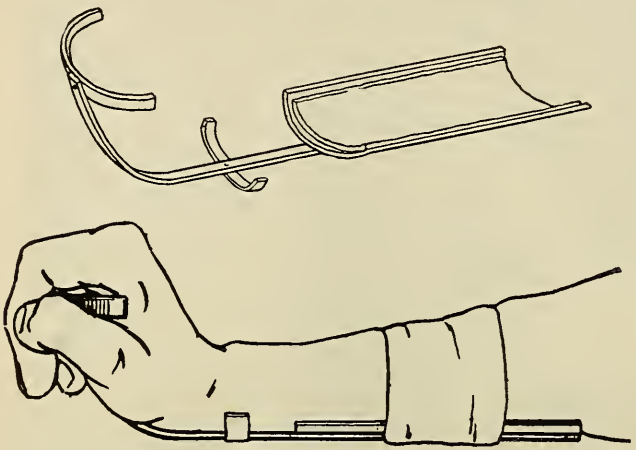

Fig. 389.—Jones's "cock-up" or "crab" wrist splint (Osgood).

point, but not beyond it, and the joint remains in a condition of irritation and weakness. After months or, perhaps, years the diagnosis is made. In one case of my own, a locomotive engineer, the injury resulted from a blow on the palm with the reverse lever. He came to me three years after the injury, when I recognized the condition as the one described by Codman and Chase. These writers say that the fingers are normally flexible, active and passive movements of the wrist are restricted to one-half or more of the normal excursion, and movements of flexion or extension beyond this are limited by muscular spasm, resembling the spasm occurring in a tuberculous joint. Any attempt forcibly to overcome the spasm produces violent pain. Crepitus is absent. The radial side of the wrist-joint exhibits some swelling, which obscures somewhat the flexor tendons of the thumb. There is tenderness on pressure over the scaphoid and it is most acute in the anatomical snuff-box. The *x*-ray shows a transverse fracture of the scaphoid bone ("Annals of Surgery," March and June, 1905). Professor Dwight considers the above-described injury to be due to the two portions of the bone (there are two centers of ossification) having never formed a bony union and having been wrenched apart by violence. Codman believes the injury is the result of violence acting on a normal bone, the resulting non-union being due to lack of fixation and the presence of synovial fluid between the fragments.

The fracture may be accompanied by forward dislocation of the semilunar bone. If for several weeks after an accident causing fracture of the scaphoid the wrist is immobilized, union may occur, otherwise non-union will surely result.

Treatment.—This injury should be thought of when violence has been applied to the carpus. It may be treated by a straight palmar splint if the case is seen early. Cases do best when treated with the wrist in dorsiflexion (Fig. 389). If seen when there is non-union, the proximal half of the scaphoid should be excised (the incision being posterior and external to the extensor communis digitorum tendons) and passive motion should be begun within one week (Codman and Chase, Ibid.).

Fractures of the Metacarpal Bones.—Fracture of the metacarpus is very common. One or more bones may be broken. The first metacarpal bone is oftenest broken; the third is seldom broken (Hulke). The *cause* is direct or indirect force. Fracture at the base of the first metacarpal bone was described by E. H. Bennett in 1881. It is called *Bennett's fracture*, or, as its discoverer named it, *stave of the thumb*. The fracture may be transverse at the neck or longitudinal, "the anterior basal projection being broken off" (Raymond Russ, in "Jour. Amer. Med. Assoc.," June 16, 1906). This injury results from violent force applied to the distal end of the metacarpal (as in striking with the fist) or to the end of the extended thumb, and Russ regards it as the most common metacarpal fracture. It is usually mistaken for a sprain of the thumb and is sometimes regarded as subluxation backward of the first metacarpal.

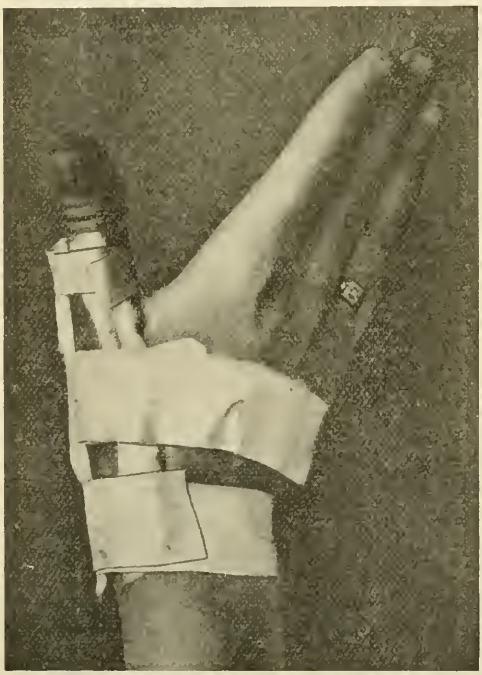

Fig. 390.—Coaptation traction splint of Russ.

Symptoms.—The signs of a metacarpal fracture are: dorsal projection of the upper end of the lower fragment or the lower end of the upper fragment; pain, crepitus; and often evidences of direct violence. In fracture of the first metacarpal (Bennett's fracture) there is swelling, particularly evident in the flexor tendon sheaths on the thenar eminence (Russ), disability, pain, tenderness near the base of the metacarpal, and deformity, apparent shortening of the thumb, and crepitus on reduction. The *x*-rays solve a doubtful case.

Treatment.—To treat a fracture of a metacarpal bone reduce by extension; place a large ball of oakum, cotton, or lint in the palm to maintain the natural rotundity, and apply a straight palmar splint like that used for fracture of the carpus. It may be necessary to apply a compress over the dorsal projection. The duration of treatment is three weeks, and passive motion is begun after two weeks. A plaster-of-Paris dressing is often used. Raymond Russ ("Jour. Amer. Med. Assoc.," June 16, 1906) describes the following splint as successfully used in a case of Bennett's fracture (Fig. 390). I have used it in a case with much satisfaction. "The thumb was put in strong abduction and three wooden butcher's skewers neatly padded were placed about the metacarpal,

one posteriorly in the interosseous space, one along the outer border, and the third over the thenar eminence. These extended from well above the metacarpal bone to the first phalangeal joint. They were fastened tightly in place by two strips of adhesive plaster. Traction was then exerted on the thumb and maintained by strips of adhesive plaster passing about the first phalanx and the projecting ends of the three skewers. This dressing was reinforced by a rectangular cardboard splint. Accurate coaptation and sufficient traction to overcome the deformity and muscular action are most necessary in the treatment of this fracture. Slate pencils or small lead pencils can be used in place of the wooden skewers. The soapstone slate pencils are less brittle than the ordinary kind."

Fracture of the Sesamoid Bones of the Thumb.—There are two sesamoid bones on the palmar surface of the metacarpophalangeal articulation in the

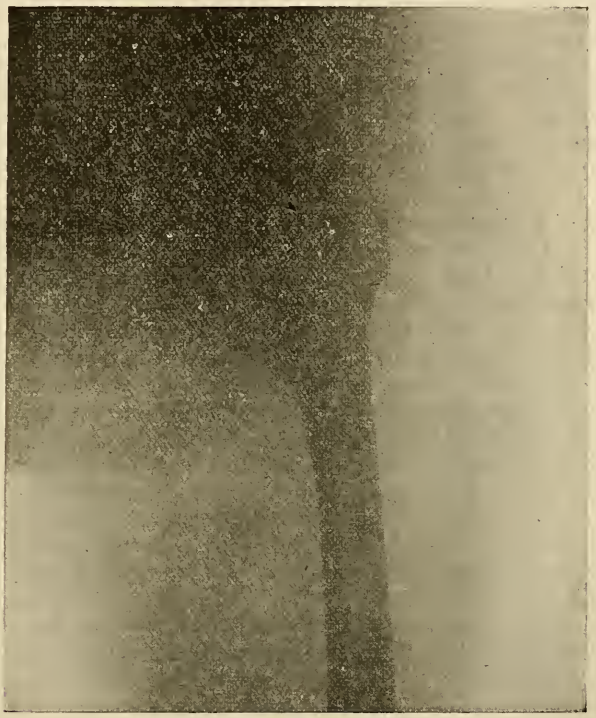

FIG. 391.—Intracapsular fracture of the hip (author's case).

thumb, lying in the tendons of the flexor brevis pollicis, and one in the palmar surface of the interphalangeal joint of the thumb. Skillern ("Annals of Surgery," 1915, lxii) reports a case of fracture of the ulnar sesamoid of the thumb and says three cases have been reported previously. The condition causes swelling of the thumb, ecchymosis of the thenar eminence, and acute tenderness at the base of the first metacarpal bone. The treatment is immobilization for four weeks and then passive motion and massage.

Fractures of the Phalanges.—The phalanges are often broken. The fracture may be compound. The *cause* usually is direct force.

Symptoms.—Fracture of a phalangeal bone is indicated by pain, tenderness, bruising, crepitus, and mobility, with very little or no displacement.

Treatment.—If the middle or distal phalanx is broken, mold on a trough-like splint of gutta-percha or of pasteboard, which splint need not reach into

the palm. If the proximal phalanx is broken, carry the splint into the palm of the hand. Make the splint of gutta-percha, pasteboard, wood, or leather. The splint is worn three weeks. A sling must be worn, otherwise the finger will be knocked and hurt. Some cases require a dorsal as well as a palmar splint. These cases may be treated very satisfactorily with a silicate of sodium or plaster-of-Paris bandage.

Fracture of the femur is a very common injury. The divisions of the femur are: (1) the upper extremity; (2) the shaft; (3) the lower extremity.

Fractures of the upper extremity of the femur are divided into: (*a*) intracapsular; (*b*) extracapsular; (*c*) of the great trochanter, and (*d*) epiphyseal separation (either of the great trochanter or the head).

Examination of the Hip.—It is sometimes though seldom necessary to give ether. Remove all the patient's clothing and place him recumbent upon a table. Note the position of the extremity. Feel with care the great trochanter and femoral neck. Very gradually and gently make movements to determine if there be impairment, undue mobility, or crepitus. Never make sudden or violent movements in looking for crepitus. The diagnosis can be made even if crepitus is not obtained, and rapid or violent movements may tear apart an impaction. Measure the sound extremity and the injured extremity. The measurement is made from the anterior superior spine of the ilium to the inner malleolus. Other symptoms to be looked for are set forth on pages 667 and 668.

Intracapsular Fracture of the Femur.—Intracapsular fracture of the neck of the femur is transverse or only slightly oblique (Fig. 391), and is not unusually impacted (see Figs. 304, 305, 306). Stokes follows Gordon, of Belfast, in classifying fractures of the femoral neck. He divides them into intracapsular and extracapsular, and subdivides intracapsular fractures into fracture with penetration of the cervix into the head; fracture with reciprocal penetration; intraperiosteal fracture at the junction of the cervix and head; intraperiosteal fracture of the center of the cervix; extraperiosteal fracture, with laceration of the cervical ligaments. The last-named fracture is the most common. The first four forms may unite by bone, the fifth form will not because of non-apposition, lack of nutrition, effusion of blood, synovitis, or interstitial absorption.[1] Stokes points out that we may have penetration without impaction. The *cause* is often slight indirect force, of the nature of a twist, acting upon a person of advanced years (more often a woman than a man), but not unusually a fall upon the great trochanter is the cause. A fall upon the knees, a trip, or an attempt to prevent a fall may produce this fracture. It often happens that the fall is due to the fracture rather than that the fracture arises from the fall. Intracapsular fracture is never caused by direct force unless it is due to gunshot violence. The aged are more liable to intracapsular fracture than the young or the middle-aged, because, first, the angle which the neck forms with the axis of the femur becomes less obtuse with advancing years, and may even become a right angle; this change is more pronounced in women than in men; second, the compact tissue becomes thinned by absorption, the cancelli diminish, the spaces between them enlarge, the bony portions of the cancellous structure are thinned and destroyed, and the cancellous structure becomes fatty and degenerated. The injury is not, however, limited to the aged. It has been positively shown that this fracture may occur in the young, even before the union of the epiphyses. In fact, fracture of the femoral neck is not very uncommon in children and in young and vigorous adults (Royal Whitman, "Med. Record," March 19, 1904). I have seen one case in a man of twenty-five, one in a man of twenty-eight, and several cases in those under forty-five. In the aged the fracture is, of course, complete, but in children and even in young adults it is usually

[1] Stokes, in "Brit. Med. Jour.," Oct. 12, 1895.

incomplete, and for this reason the fracture is often not recognized in children and young adults.

Symptoms.—In intracapsular fracture there is usually *shortening* to the extent of from ½ to 1 inch, but in some cases no shortening can be detected. Shortening of ¼ inch does not count in making a diagnosis, for one limb is often naturally a little shorter than the other. If the reflected portion of the capsule is not torn, the shortening is trivial in amount or is entirely absent. In some cases shortening gradually or suddenly increases some little time after the accident. This is due to separation of a penetration or of an impaction, tearing of the previously unlacerated fibrous synovial reflection, or restoration of muscular strength after traumatic paresis has passed away. A gradually increasing shortening arises from absorption of the head of the bone. Shortening is due chiefly to pulling upon the lower fragment by the hamstring, the glutei, and the rectus muscles.

Pain is usually present anteriorly, posteriorly, and to the side. The area of pain is localized, and motion or pressure greatly increases the suffering. Pain is not commonly severe except upon motion or from pressure, when it may be localized in the joint. In some cases the pain is violent.

Eversion exists and is spoken of as *helpless eversion*, though in a very few instances the patient can still invert the leg. The eversion is due to the force of gravity, the limb rolling outward because the line of gravity has moved externally. That eversion is not due to the action of the external rotator muscles, as was taught by Sir Astley Cooper, is proved by the fact that when a fracture happens in the shaft below the insertion of these muscles the lower fragment still rotates outward. This is further demonstrated by the considerations that the internal rotators are more powerful than the external, that some patients can still invert the limb after a fracture, and that eversion persists during anesthesia.[1] In some unusual cases *inversion* attends the fracture. Inversion, if it exists, is due to the fact that the limb was adducted and inverted at the time of the accident, and after the accident it remains in this position (Stokes). Besides shortening and eversion, the leg is somewhat flexed on the thigh and the thigh on the pelvis, the extremity when rolled out resting upon its outer surface. *Abduction* is commonly present. Limited abduction suggests impaction.

Loss of power is a prominent symptom: the limb can seldom be raised or inverted; although in rare cases, when the fibrous synovial envelope is untorn, the patient may stand or even take steps. *Crepitus* often cannot be found, either because the fragments cannot be approximated, because there is impaction or penetration, or because the bone is greatly softened by fatty change. To obtain crepitus the front of the joint must be examined while the limb is extended and rotated inward. But why try to obtain crepitus? The diagnosis is readily made without it; in many cases it cannot be detected, and the endeavor to obtain it inflicts pain and may produce damage. These fractures in the aged have a not very flattering chance for repair, and efforts to find crepitus may produce serious damage.

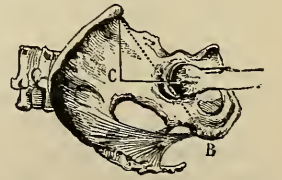

FIG. 392.—A–B, Nélaton's line; A–C–D, Bryant's ilio-femoral triangle (Owen).

Altered Arc of Rotation of the Great Trochanter (*Desault's Sign*).—The pivot on which the great trochanter revolves is no longer the acetabulum, and the great trochanter no longer describes the segment of a circle, but rotates only as the apex of the femur, which rotates around its own axis. It is needless to try to obtain this sign; to do so inflicts violence on the parts.

Relaxation of the fascia lata (*Allis's sign*) simply means *shortening*. The

[1] Edmund Owen, "A Manual of Anatomy."

fascia lata is attached to the ilium and the tibia (iliotibial band), and when shortening brings the tibia nearer to the ilium, this band relaxes and permits the surgeon to push his fingers more deeply inward on the injured side, between the great trochanter and the iliac crest, and nearer the knee above the outer condyle, than on the sound side. In this examination each limb should be adducted. Allis has pointed out another sign: when the patient is recumbent the sound thigh cannot be lifted to the perpendicular without flexing the leg; the injured thigh can be.

Lagoria's sign is relaxation of the extensor muscles.

Ascent of the Great Trochanter Above Nélaton's Line.—This line is taken from the anterior superior iliac spine to the most prominent part of the ischial

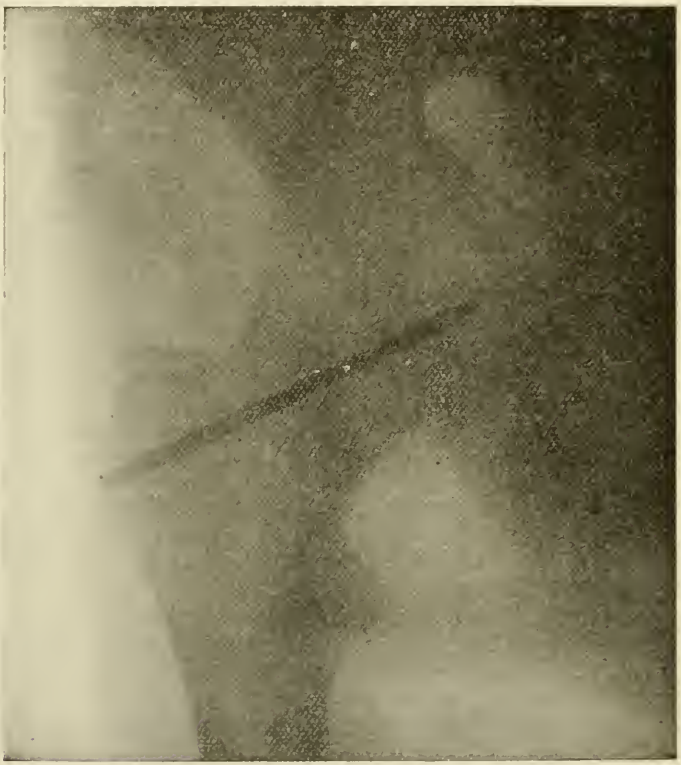

Fig. 393.—Author's case of recent intracapsular fracture in a woman aged forty successfully nailed. Nail is still in place after five years.

tuberosity (Fig. 392). In health the great trochanter is below, and in intracapsular fracture it is above, this line.

Relation of the Trochanter to Bryant's Triangle (Fig. 392).—Place the patient recumbent, carry a line around the body on a level with the anterior superior iliac spines, draw a line from the anterior iliac spine on each side to the summit of the corresponding great trochanter, and measure the base of the triangle from the great trochanter to the perpendicular line to determine the amount of ascent. The difference in measurement between the two sides shows the amount of ascent of the trochanter; that is, shows the extent of shortening.

Morris's measurement shows the extent of inward displacement. Measure from the median line of the body to a perpendicular line drawn through the trochanter on each side of the body.

Diagnosis.—The *x*-rays are a valuable aid to diagnosis (Fig. 393). Intra-

capsular fracture without separation of fragments may be mistaken for a mere contusion, and the diagnosis may continue obscure unless the fragments separate. Loss of function in contusion is rarely complete or prolonged, although occasionally the head of the bone undergoes absorption. Early after a contusion, and usually throughout the case, there is no alteration between the relation of the spine of the ilium and the trochanter, and no shortening. Some time *after* a severe contusion the head of the bone may be absorbed. Contusion of a rheumatic joint leads to much difficulty in diagnosis. Intracapsular fracture may be confused with *extracapsular* fracture or with dislocation of the hip-joint. Extracapsular fracture, which is common in advanced life, but is met with not unusually in middle life and even occasionally in the young, results usually from great violence over the great trochanter; if non-impacted, there are noted shortening of from 1½ to 3 inches, crepitus over the great trochanter, and usually, but not invariably, eversion; if impacted, there is less eversion, crepitus is absent, and the shortening is limited to about an inch. The extensor muscles are relaxed. Great tenderness exists over the great trochanter in both impacted and non-impacted fractures. In dislocation on the dorsum of the ilium the patient is usually a strong young adult. There is a history of forcible internal rotation. There are inversion (the ball of the great toe resting on the instep of the sound foot), rigidity, ascent of the great trochanter above Nélaton's line, and shortening of from 1 to 3 inches. The head of the bone is felt on the dorsum of the ilium, and the trochanter mounts up toward the spine of the ilium, and pressure upon it causes no pain. In dislocation into the thyroid notch there is possibly eversion, but it is linked with lengthening. Gay points out that a diagnosis of dislocation has no standing in the aged, that occasionally a person with fracture "can rotate the limb slightly, or even raise it from the bed" and that the cardinal symptoms of a hip fracture are "loss of function, eversion of the foot and severe pain on motion" (George W. Gay, in "Boston Med. and Surg. Jour.," Sept. 5, 1918).

In *fracture of the brim of the acetabulum* there is shortening, which occurs on the removal of extension, inversion, abduction, flexion of the knee, the head of bone is drawn upward and backward with the acetabular fragment, and there is retention of the power of eversion and of adduction (Stokes). Crepitus is most distinctly appreciated by a hand resting on the ilium.

In *fracture of the fundus of the acetabulum* (see Fig. 338) there is shortening, and the head of the bone enters the pelvis (Stokes).

The *prognosis* is not favorable for perfect restoration of function. Some aged patients die in a day or two from shock. Not a few perish later from hypostatic congestion of the lungs, kidney, failure or exhaustion. The majority of cases recover with a little shortening, some stiffness, and a permanent limp. There is a much better chance for firm union if the fracture is impacted than if it is not. Even if non-union results after an intracapsular fracture, and it is not unusual, a patient may get about fairly well with a proper support. In some cases after intracapsular fracture rheumatoid arthritis develops. Many surgeons have maintained that bony union never occurs, but it certainly does sometimes take place. Stokes holds that bony union is possible in fractures with penetration, and even in fractures without penetration when the fracture is within the periosteum.[1]

Treatment.—In treating a very feeble old person for intracapsular fracture make no attempt to obtain union. Keep the patient in bed for two weeks; give lateral support by sand-bags; tie around the ankle a fillet, attach a weight of a few pounds to the fillet, and hang the weight over the foot-board of the bed. When pain and tenderness abate, order the patient to get into a reclining-chair, and permit him very soon to get about on crutches. If hypostatic congestion of the lungs sets in, if bed-sores appear, if the appetite and digestion

[1] See the masterly paper by Stokes, before quoted.

utterly fail, or if diarrhea persists, abandon attempts at cure in any case, and get the patient up and take him into the sunshine and fresh air, simply immobilizing the fracture as thoroughly as possible by means of pasteboard splints or plaster of Paris. In the vast majority of cases, no matter how old the patient may be, undertake treatment. We may be forced to abandon it, but should at least attempt to obtain a cure. If it is determined to treat the case, place the patient on a hair mattress, several boards being laid transversely under the mattress in order to prevent unevenness and the formation of hollows. A fracture-bed is a valuable adjunct to treatment.

Treatment by the Extension Apparatus of Gurdon Buck.—Extend the knee and place the leg in a natural posture, and put a pillow beneath the knee.

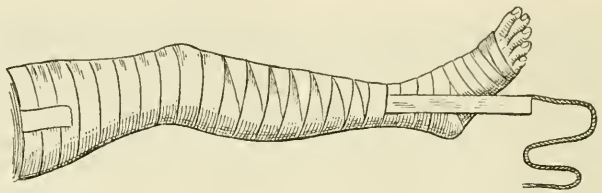

Fig. 394.—Adhesive plaster applied to make extension.

Combine extension with lateral support by means of sand-bags. The extension should be gentle, never forcible. It is not wise to pull apart an impaction in an old person, but it should always be done in a young or middle-aged person. Place the subject on a firm mattress or a fracture-bed. Shave the leg. Cut a foot-piece out of a cigar-box, perforate it to admit the passage of a cord, wrap it with adhesive plaster as shown in Plate 7, Figs. 15 and 16, run the weight-cord through the opening in the wood, and fasten a piece of adhesive plaster on each side of the leg, from just below the seat of fracture to above the malleolus (Pl. 7, Fig. 14). The plaster is guarded from sticking to the malleoli by having

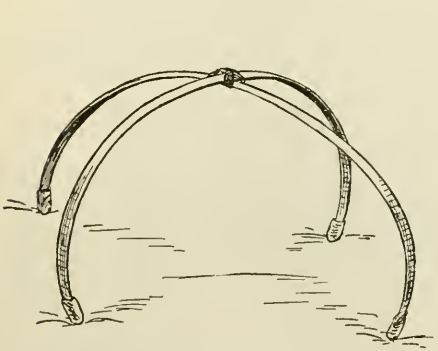

Fig. 395.

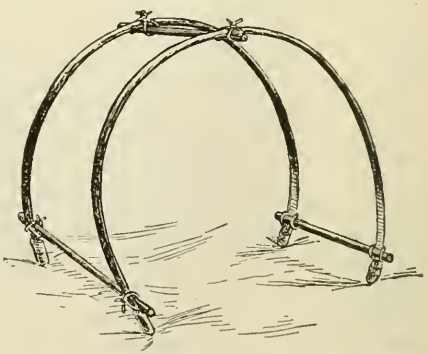

Fig. 396.

Figs. 395 and 396.—Cradle to keep clothing from leg, made from two barrel-hoops (Scudder).

another piece stuck to its under surface opposite each of these points. Apply an ascending spiral reversed bandage over the plaster to the groin (Fig. 394) and finish the bandage by a spica of the groin. Slightly abduct the extremity. Put a brick under each leg of the bed at its foot, thus obtaining counterextension by the weight of the body. Run a cord over a pulley at the foot of the bed, and obtain extension by the use of weights. In an adult from 15 to 20 pounds will probably be necessary at first, but after a few days from 8 to 10 pounds will be found sufficient (remember that a brick weighs about 5 pounds). Dawbarn's rule as to the proper weight to be attached is 1 pound for every year up to twenty. When the foot of the bed is raised and the weight to make extension is applied, very gently rotate the extremity, put the foot at a right angle with the

leg, and make a bird's-nest pad of cotton or oakum to save the heel from pressure. Take two canvas bags, one long enough to reach from the crest of the ilium to the outer malleolus, the other long enough to reach from the perineum to the inner malleolus. Fill the bags three-quarters full of dry sand, sew up their ends, cover the bags with slips, and put the bags in place in order to correct eversion. The slips may be changed every third or fourth day Keep the bed-clothing from coming in contact with the extremity by means of a cradle (Figs. 395, 396). The bowels are to be emptied and the urine is to be voided in a bed-pan, unless using a fracture-bed. For two weeks the patient remains recumbent, after which time he can be propped up on pillows. Maintain extension for three

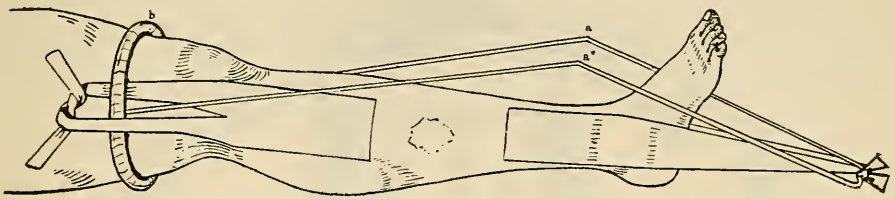

Fig. 397.—Method of using Thomas' arm splint for fracture of leg bones (in C. C. S. or base hospital only). The lower and upper strips of plaster make extension and counter-extension respectively, and are prevented from slipping by encircling bandage or plaster strapping. Perforated zinc or calico bandage slings support the fragments and popliteal space. Rotation of the foot is prevented by padding on each side or by a wire "foot piece." The splint is slung from a, a* and b (Captain R. D. Laurie).

weeks, then simply maintain support by sand-bags or molded pasteboard splints upon the part, and keep up this support three to five weeks more. After removing the extension he can be transferred daily to a couch. In from six to eight weeks after the infliction of the injury he can be moved about in a wheeling-chair, the leg being extended or the knee flexed in accordance with the

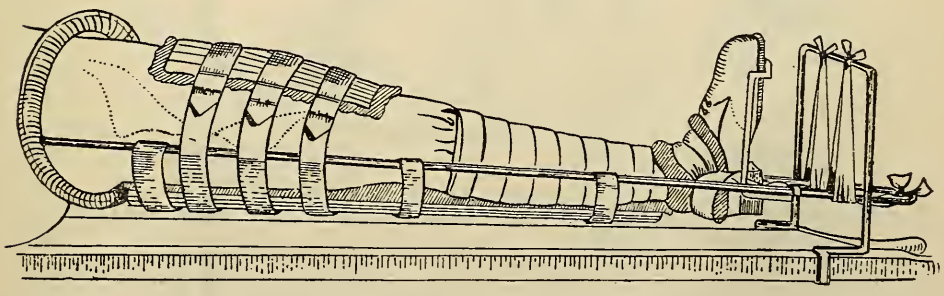

Fig. 398.—Fracture of thigh put up in Thomas's splint.

dictates of comfort. After a week or so of such movement a thick-soled shoe is placed on the sound foot and the patient is allowed to use crutches; but weight is not put upon the injured extremity until from ten to twelve weeks have elapsed from the time of the accident. For many months, at least, and possibly permanently, he walks with the aid of a cane. Union, if it takes place, is usually cartilaginous, but is sometimes bony, and there will surely be some shortening and also some stiffness of the joint. Passive motion is not made until at least eight weeks have elapsed since the accident. Treatment by the extension apparatus is far from satisfactory, as it does not afford sufficient immobilization.

Treatment by Thomas's Splint.—Scudder, in his valuable treatise on "The Treatment of Fractures," advocates in intracapsular fracture the use of Thomas's hip splint. If the bones are unimpacted, the fragments are brought into apposition by extension, inversion, and pressure upon the great trochanter, and the Thomas splint is bent to fit, is padded, and is applied (Figs.

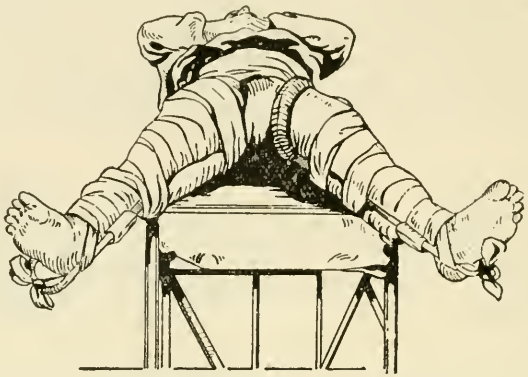

FIG. 399.—Jones' abduction frame applied for fracture of right femur. The extension strapping should reach high up on each limb.

401, 402). When the bed-pan is to be used or the bed is to be smoothed, the patient can be lifted without disturbing the fracture. He can be turned on the sound side. If hypostatic congestion is developing, raise the head of the bed and tie the splint to the iron of the head of the bed. In addition to the use of the splint Scudder advocates the making of lateral pressure over

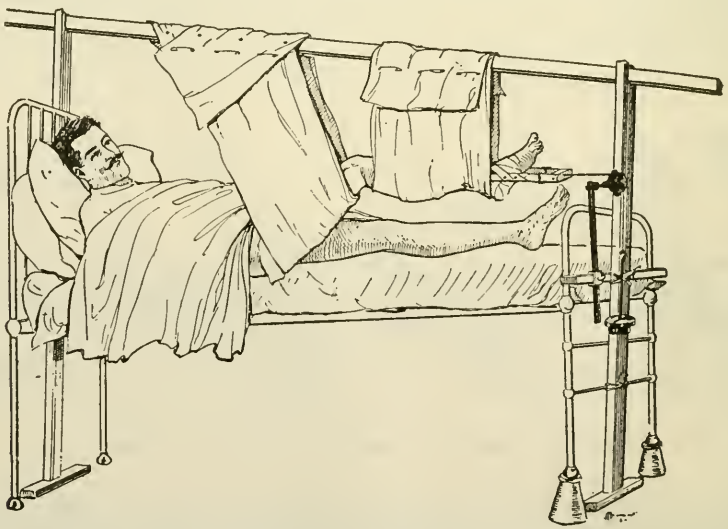

FIG. 400.—Balkan splint as used at the American Ambulance, Neuilly-sur-Seine, Paris, France. (Crile, in "Annals of Surgery," July, 1915. Attributed to Lt.-Col. Miles by Sir Geo. H. Makins, "Brit. Med. Jour.," June 16, 1917.)

the great trochanter by a graduated compress and a bandage. The splint is worn for six or eight weeks. It is then removed, the patient remaining in bed four weeks longer without any apparatus (Scudder, from Ridlon).

Jones, of Liverpool, treats fractures of the femoral neck by means of an extension frame (see Fig. 414). Some surgeons use the Hodgen splint.

Whitman's Treatment in Abduction.—The plan advocated by Royal Whitman ("Med. Record," March 19, 1904) is a most excellent one. It aims to abolish traumatic depression of the neck of the femur.

We can apply this plan in a young person to any fracture even if impacted. In an aged person we apply it in a complete non-impacted fracture only. In a young person we usually give ether and pull apart an impaction by abduction. In an aged person we should not do so.

In regard to impaction Jones says, if the shortening is trivial and there is no rotation an impaction is not to be pulled apart; if there is marked shortening and eversion, it is to be.

Whitman says ("Lancet," June 14, 1913) in complete fracture the limb is shortened, somewhat flexed, rotated outward and usually slightly abducted. The outer fragment (that is the lower fragment) is turned forward and upward and is usually on a lower plane than the head. One cannot control the inner fragment so the outer fragment must be carried to the inner. The patient is to be anesthet-

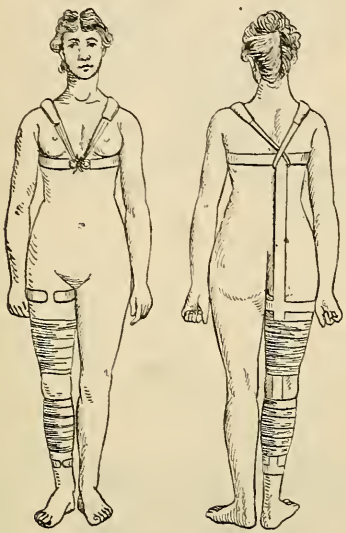

Fig. 401.—Thomas's single hip-splint in position (Ridlon).

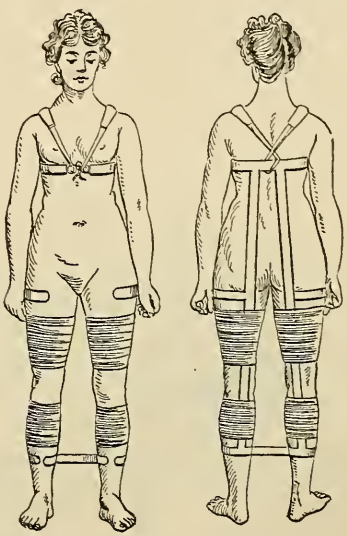

Fig. 402.—Thomas's double hip-splint in position (Ridlon).

ized, placed upon a sacral support, the shoulders are to be rested on a box of equal height and the lower limbs are to be extended and supported. The assistant abducts the sound limb to the anatomical limit. The degree depends upon age and individual limitation. It is usually 40°–50°. This gives us a gauge on the proper position in which to place the other hip. The surgeon flexes the thigh of the injured side and thus separates the fragments. The shortening is abolished by the manual extension of an assistant. He then performs inward rotation and abduction to the proper degree. The abduction relaxes the muscles which interfere with reduction and carries the outer fragment against the inner.

The extremity is set in extension and extreme abduction. The tension of the capsule pushes the outer fragment against the inner and holds it; fixation is obtained by the neck of the femur being in contact with the acetabulum and the great trochanter with the pelvis, deformity cannot be caused by muscular action, and the psoas helps pull the fragments together (Whitman).

The limb is kept fixed in abduction by plaster-of-Paris for six weeks and then

a Thomas splint with extension is used. Jones uses an abduction frame instead of plaster of Paris.

Extracapsular Fracture (*Fracture of the Base of the Neck of the Femur*).—The line of extracapsular fracture is at the junction of the neck with the great trochanter, and is partly within and partly without the capsule, the fracture being generally comminuted and often impacted. The *cause* is violent force over the great trochanter (as by falling upon the side of the hip). This fracture is most usual in elderly people, but is met with in the middle aged and is not very uncommon in young adults. Stokes has described six forms of extracapsular fracture: extracapsular fracture with partial impaction posterior;

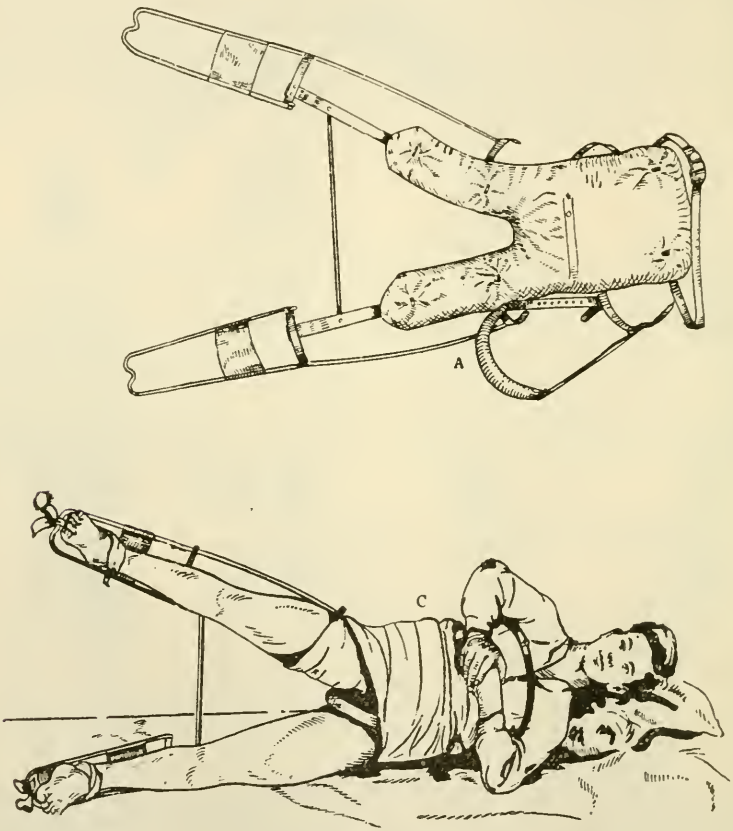

Fig. 403.—A, Jones' abduction frame for fracture of femur, when the accompanying wounds prevent the use of Thomas's splint outfit. These frames ought to be made with joints opposite the hip, so that they can be used for either side and can be "closed" for transport on a stretcher. C, To show the method of application. Temporary clove-hitch used around each ankle.

fracture with complete impaction; fracture with partial impaction above; fracture with partial impaction below, the shaft being split; splitting of the neck longitudinally without impaction; comminuted non-impacted fracture.[1]

Symptoms.—When impaction is absent there is marked crepitus on motion, which is manifested most distinctly when the fingers are placed upon the great trochanter; there is severe pain, pressure upon the great trochanter is very painful, swelling and ecchymosis are marked; there is absolute inability on the part of the patient to move the limb, and passive movements cause

[1] "Brit. Med. Jour.," Oct. 12, 1895.

violent pain; there is shortening to the extent of at least 1½ inches, and sometimes to the extent of 3 inches, and this shortening is made manifest by noting the ascent of the trochanter above Nélaton's line, by a comparison of measurements of the injured limb and the sound limb, and by measuring the base-line of Bryant's triangle on each side. Absolute eversion usually exists with slight flexion both of the leg and the thigh. In some rare cases there is inversion. This happens if at the time of the accident the limb was inverted and adducted (Stokes). Langoria's sign, Desault's sign, and Allis's sign are present. All these symptoms follow violent direct lateral force to the great trochanter. In the *impacted* form of extracapsular fracture, in addition to the aid given the surgeon by the history, there is severe pain, which is intensified by movement or pressure; shortening probably to the extent of 1 inch, which is not corrected by extension; limited abduction; great loss of function; and whereas the limb may be straight or even inverted, it is usually everted. The trochanter is above

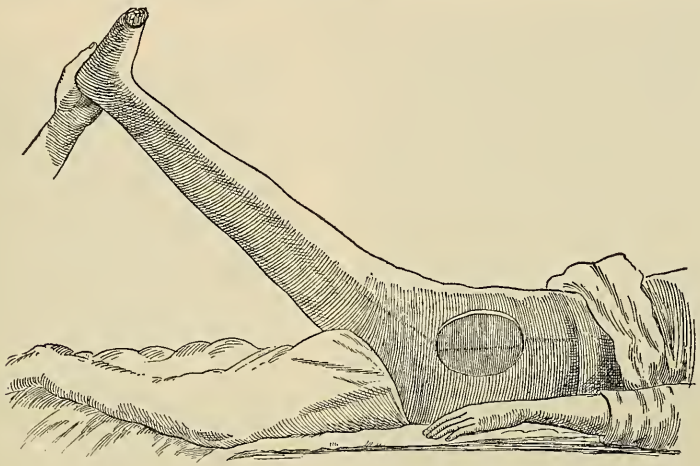

Fig. 404.—The long spica as applied for fracture of the neck of the femur in the adult; illustrating the advantage of an appliance which permits movement without danger of displacing the fragments; an opening has been made to lessen the constriction of the abdomen (Whitman).

Nélaton's line, the base-line of Bryant's triangle is shortened, but not so much as in the unimpacted form; there is no crepitus unless the impaction is loose or is pulled apart, and the arc of rotation of the great trochanter is larger than in a non-impacted fracture.

Treatment.—In impacted extracapsular fracture it is best to pull apart the impaction if the patient is in good physical condition. Southam, of Manchester, in an impressive article has insisted on the absolute necessity of pulling apart an impaction. He gives ether, and when the patient is anesthetized unlocks the fragments.[1] This unlocking is best accomplished by abduction, the rim of the acetabulum acting as the fulcrum of the lever (Whitman). In treating extracapsular fracture we can use the extension apparatus with sandbags (see page 670) for three weeks and then apply a plaster dressing. Get the patient on crutches after the plaster has been in place for two weeks. Remove the plaster at the end of four weeks. Thomas's splint may be used instead of Buck's extension. Some prefer one of the apparatus shown in Figs. 399, 400, 403.

Fractures of the Femoral Neck in Children.—Fracture of the femoral neck in children and in young adults can scarcely be regarded as very unusual, and is certainly more often encountered than separation of the upper epiph-

[1] "Lancet," Dec. 21, 1895.

ysis. The accident results from a fall rather than, as so often in an adult, from a twist, and it is the product of considerable violence rather than of slight force. In children such fractures may be impacted, and most of those which are unimpacted are of the green-stick variety. The disability is not nearly so great as in an adult; in fact, it is not unusual for the victim of such an injury to be able to hobble about a few days afterward. The symptoms are shortening, some eversion, impairment of joint movements, and a limp when the patient gets about. Fractures of the hip in children are often unrecognized and lead frequently to permanent impairment because of the development of coxa vara. The *x*-rays should be used in making the diagnosis.

A green-stick fracture may be treated with Thomas's splint, and after four weeks in bed "the child may be allowed up, wearing a traction hip-splint for several months until union is so firm that the danger from coxa vara is practically eliminated. A light plaster-of-Paris spica bandage from the calf to the axilla will maintain immobility after the splint is omitted" (Scudder, on "The Treatment of Fractures"). An impacted fracture, after the impaction has been pulled apart, is treated exactly as a green-stick fracture. Royal Whitman's plan for treating a green-stick fracture is very satisfactory. This surgeon ("Med. Record," March 19, 1904) dresses these cases by placing the limb in extreme abduction and holding it so by means of a plaster-of-Paris spica (Figs. 404, 405). In a case of acute disability of the hip-joint in a child, following some time after fracture of the femoral neck, make a careful differentiation from tuberculous disease of the joint and apply a traction splint to support the body and give rest to the joint. If coxa vara becomes marked and causes great disability, osteotomy is justifiable.

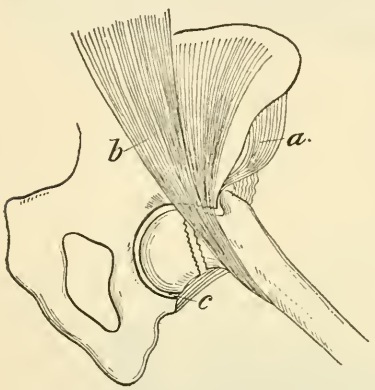

Fig. 405.—Reduction and fixation in abduction, showing security assured by direct bony contact of the neck and trochanter with the pelvis, also the effect of the attitude on muscular action: *a*, Abductor group; *b*, iliopsoas; *c*, capsule (Whitman).

Operative Treatment of Fracture of the Femoral Neck.—I have practised this but once. The patient was a woman forty years of age and the result was excellent (see Fig. 393). The operation is not indicated in elderly subjects. It is not indicated at all if the fragments can be coaptated and retained by extension and counterextension or by abduction. In a youth or a middle-aged person in whom retention in correct posture is impossible it is indicated. McGlannan sets forth the following contra-indications to operation ("Surgery, Gynecology, and Obstetrics," March, 1916): Dilated heart, intermittent pulse, irregular pulse, very high blood-pressure, pulmonary congestion, marked renal insufficiency, evidences of a nervous breakdown, signs of uremia, alcoholism or a drug habit.

Some advocate incision, suture of the torn capsule, and nailing. In my case I nailed through a very small skin incision and did not suture the capsule. It is held that suture of the capsule improves the circulation in the broken off head, but possible attainment of the object is not justification for the risk. The small cutaneous incision and nailing answers the purpose. It is not necessary to drill the trochanter as König did.

Before operating an *x*-ray picture is taken, while the fragments are brought into apposition by abduction or by extension and counterextension. From this picture the angle of the neck is noted and the length of nail required is determined. A silver nail may be used. When ready to operate, the fragments

are again brought into apposition by extension and counterextension or abduction. A small incision is made through the skin over the external aspect of the great trochanter, and the nail is driven through the trochanter and neck into the head. The wound is closed and dressed. The pelvis and extremity are then put up in plaster, a trap-door being cut over the seat of incision. The plaster dressing is retained for five or six weeks. Cure is obtained without shortening and with retention of joint mobility. This operation is also used for ununited fracture. Dr. G. G. Davis was the first to do a nailing operation for a recent intracapsular fracture of the femur. Albee prefers a peg of bone cut from the tibia, because he believes that nails of metal act as foreign bodies, retard callus formation, produce necrosis of adjacent bone and loosen. One incision is made in front over the fracture. Another is made over the great trochanter. The bone-graft is shaped into a peg. The neck of the femur is drilled and the peg is inserted. The extremity is put in abduction and is so

Fig. 406.—Comminuted fracture of upper third of femur.

Fig. 407.—Epiphyseal separation of head of the femur.

held in plaster for six weeks ("Annals of Surgery," 1915, lxii). If a fracture of the femoral neck is found to have united in a deformity which is crippling subtrochanteric osteotomy is the treatment.

Separation of the upper epiphysis of the femoral head (Fig. 407) is a very rare result of accident; it occurs most often from disease. It is met with in early youth, results in considerable permanent shortening, and perhaps in coxa vara.

Symptoms and Treatment.—The *symptoms* are like those of fracture of the neck, except that the crepitus is soft. The *treatment* is as for fracture of the neck.

Fractures of the Great Trochanter.—This is a very rare injury. There seem to be only 8 cases on record, but probably the diagnosis has been missed in some cases in which the fragment was held to the bone by periosteum. This process may be (1) broken off without any other injury. In some cases it is completely broken off; in some it remains attached by periosteum and fibrous tissue. (2) The line of fracture may run through the trochanter and leave one portion of the trochanter attached to the head and neck and the other part attached to the shaft of the femur. The *cause* is violent direct force over

and behind the great trochanter or a fall (Armstrong, in "Annals of Surgery," August, 1907). Neck reported a case due to muscular action ("Zentralb. für Chir.," 1903).

Symptoms and Treatment.—The *symptoms* of the first form resemble those of epiphyseal separation and, of course, there is no shortening. The symptoms of the second form are similar to those of the extracapsular fracture. On rotating the femur the lower part of the trochanter moves with it, but not the upper. The lower fragment goes upward and backward and projects by the side of the sciatic notch. There are shortening, eversion, crepitus, and altered position of the trochanter. The *treatment* of the second form is like that in extracapsular fracture, and the first form is treated like separation of the epiphysis of the trochanter.

Fig. 408.—Intertrochanteric fracture.

Separation of the epiphysis of the great trochanter is a rare accident. The *cause* is direct violence and the injury occurs in those under eighteen years of age. Poland in 1898 collected 12 cases.

Symptoms.—The trochanter, if completely separated, is found to have ascended and passed posteriorly; there is no shortening of the thigh; all the motions of the hip-joint can be obtained; if the thigh is flexed, abducted, and rotated externally, and the fragment is pushed downward and forward, crepitus may be obtained—soft in epiphyseal separation, hard in fracture. There is no shortening. If the process is not completely separated, diagnosis is impossible without the *x*-rays.

Treatment.—If the epiphysis is not completely separated, immobilize the limb in the position of abduction. If it is completely separated, incise the soft parts and either suture or nail the fragment in place.

Separation of the Epiphysis of the Small Trochanter.—This is a rare lesion. Metcalf ("Jour. Am. Med. Assoc.," 1915, lxiv) reported two cases and discussed the lesion. It may be due to direct or indirect force but is usually caused by sudden and forcible contraction of the iliopsoas muscle. It causes severe local pain and tenderness. The patient cannot flex the hip. *Ludloff's sign* may be present. That sign consists of swelling and ecchymosis at the base of Scarpa's triangle. The case is treated by flexing and immobilizing the thigh.

Fractures of the shaft of the femur may affect any portion of the shaft, but especially the middle third, and may occur at any age. Fracture of the upper third is a rare accident. Allis estimates that each year in Philadelphia there is 1 case of fracture of the upper third of the femur to every 100,000 inhabitants. Separation of the lower epiphysis occasionally occurs. The *cause* of fractures in the upper third is usually indirect force; fractures in the lower third are due to direct force; and in fractures of the middle third these two causes are about equally potential. Fracture from muscular action occasionally occurs. Oblique fracture is the usual variety. In many cases the soft parts are badly lacerated and sometimes a great vessel is torn.

Symptoms.—The chief symptom in fracture of the shaft of the femur is great displacement, except when impaction occurs, when the break is due to direct force, or when the injury is in a child. In a child the line of fracture is often transverse and the periosteum may be untorn. Green-stick fractures occur in children. As a rule, in fracture of the shaft of the femur the lower fragment is drawn upward and the upper end of the lower fragment is found posterior and somewhat to the inside of the lower end of the upper fragment, and the lower fragment also undergoes external rotation (the drawing up is due to rectus and hamstrings; the passing inward is due to the adductor muscles; the rotation outward arises from the weight of the limb). If a fracture of the lower two-thirds of the shaft is produced by direct force, there is usually but

FIG. 409.—Deformity following fracture of upper third of femur.

little deformity, because the line of fracture is nearly transverse. If produced by indirect force, there is often great deformity, the line of fracture being oblique. In fracture of the lower third of the shaft the gastrocnemius pulls upon the condyles and tilts the lower fragment, so that its upper end projects into the popliteal space and may damage the vessels. In fracture of the upper third the upper fragment is apt to be thrown strongly forward and outward (Fig. 409). Some attribute this to the action of the psoas, iliacus, and external rotator muscles, but Allis thinks it is due chiefly to the lower fragment pushing the upper fragment into this position, a part of the tendon of the gluteus maximus acting as a hinge for the fragments.[1] In rare cases the angular deformity is backward. In fracture of the shaft of the femur there is complete loss of function, the thigh

[1] "Fracture in the Upper Third of the Femur Exclusive of the Neck," by Oscar H. Allis, "Medical News," Nov. 21, 1891.

and leg are slightly flexed and usually everted. In some cases the leg and lower fragment are inverted. There are shortening to the extent of 2 or 3 inches, pain on movement, preternatural mobility, crepitus, and obvious deformity, and the ends of the fragments can be felt by the surgeon. In impaction there is alteration of the axis of the limb and some shortening. Always feel for the pulse below the fracture to learn if the artery is damaged.

Treatment.—In setting and dressing a fracture of the thigh ether should be given and the parts must be handled with great care to prevent a sharp end of bone from tearing the soft parts and puncturing the skin. In fracture of the shaft of the femur, if impaction exists, the fragments must be pulled apart, when the case should be treated exactly as is a non-impacted fracture.

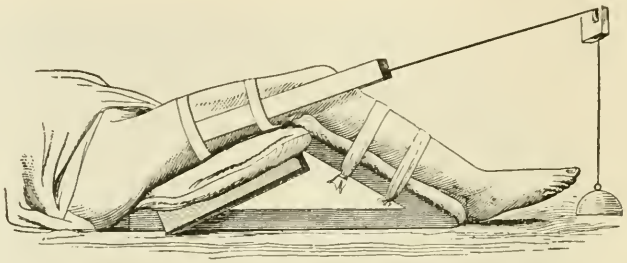

Fig. 410.—Dressing of fracture of the femur in the upper third with extension upon a double inclined plane (Agnew).

After a fracture of the shaft of the femur some amount of permanent shortening is almost inevitable. In *fracture of the upper third* in an adult conservative treatment is usually unsatisfactory, and there is permanent shortening from angular union or from overlapping. In youths under fifteen a good result is obtained in over 90 per cent. of cases. Horizontal extension fails to correct the displacement of the upper fragment in fracture of the upper third. The double inclined plane will not correct the tilting of the upper fragment while shortening exists. Agnew used a double inclined plane and corrected shortening by the use of extension in the axis of the partly flexed thigh (Fig. 410). This plan is one of the most serviceable of those usually employed, but it too fails completely to correct the displacement. If, notwithstanding position and extension, the upper fragment projects, it should be pushed into place and be retained if possible by short splints bound upon the thigh. In many cases a Thomas knee-splint is the best apparatus. In fracture of the upper third with marked projection of the upper fragment the abduction frame may prove satisfactory. Extension should be continued for four weeks, a plaster-of-Paris bandage being used for four weeks more, the patient being then allowed to go about on crutches. Some surgeons, in fracture of the upper third, apply a plaster-of-Paris bandage to the leg, thigh, and pelvis, extension being made from the foot while the dressing is being applied. This method does not give good results because such extension will not correct the tilting of the upper fragment. The anterior splint of Nathan R. Smith is used by some in treating fractures of the upper third of the femur (Fig. 411). It is bent to the desired shape, fast-

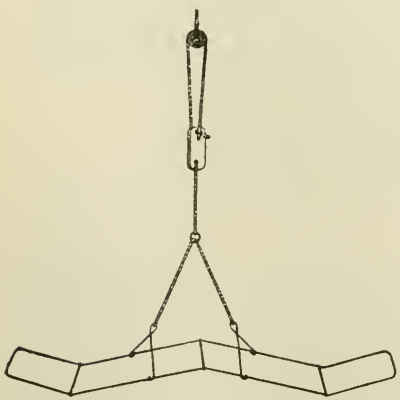

Fig. 411.—Smith's anterior splint.

ened to the anterior surfaces of the leg and thigh, and hung to a gallows, the limb being suspended at the desired height. This splint is open to the same objection as the double inclined plane. Suspension, adjustment by weights and traction by Blake's splint or a like apparatus is used by many (Figs. 323, 398, 399, 400). In fact, in many fractures of the upper third of the shaft of the femur no apparatus will maintain reduction. In such cases it is advisable to incise, separate the muscles from between the fragments, and fasten the ends of the bone-fragments together with bone plates. This radical treatment has certain dangers of its own, but it is the plan which promises best to secure a thoroughly

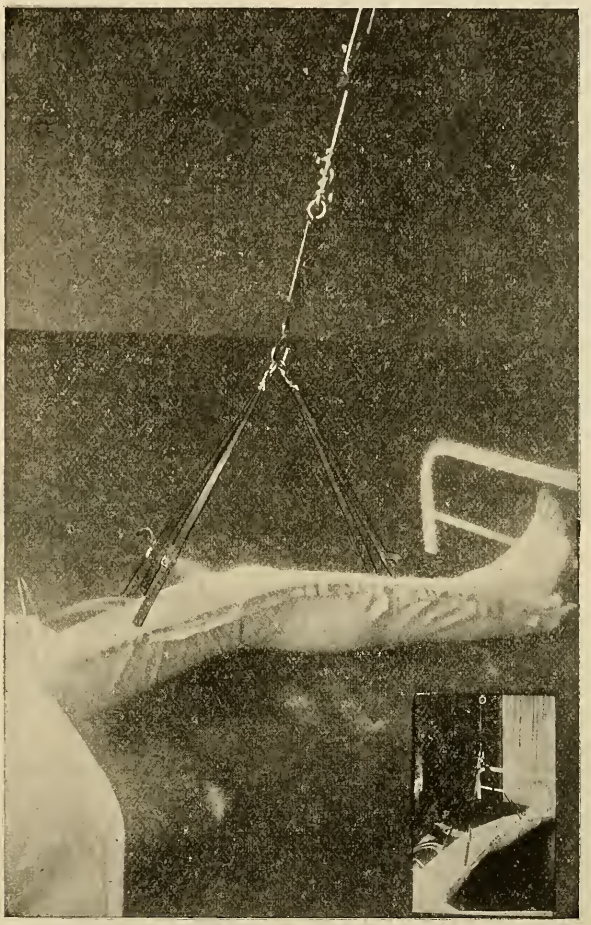

FIG. 412.—Hodgen's apparatus as applied by Dr. George S. Brown.

good limb. In *fracture of the middle third* or *upper part of the lower third* of the shaft of the femur the Thomas knee-splint is an excellent instrument. The extension apparatus and sand-bags will usually secure a satisfactory result (Pl. 7, Fig. 14). The strips of adhesive plaster are carried to just below the seat of fracture, and the turns of the roller bandage should be taken to a little above this point. Extension should be continued for four weeks, when the plaster-of-Paris bandage ought to be applied. The plaster is kept in place for four weeks. Many surgeons use Hodgen's splint in treating fractures of the thigh. The limb is suspended in a cradle and extension is obtained by strapping the foot of the cross-bar of the frame and pulling upon the frame by cords (Fig. 412). Hodgen's

apparatus as applied by Brown, of Birmingham, Ala., is one of the most satisfactory methods of treatment in fracture below the upper third. The extremity can be raised or lowered at will without disturbing the approximation of the fragments, extension to the required degree can be obtained, and the patient can be moved in bed. I consider this apparatus one of the most comfortable appliances which can be worn and excellent results are obtained by its use. Blake's splint is even more comfortable and useful (Fig. 323). In fracture of the middle third or upper part of the lower third of the shaft if the line of fracture is transverse and there is little deformity, as is seen often after a fracture by direct force, and often in children, immobilization in an immovable dressing may be all that is required; but if shortening exists, extension must be used. If extension is used, continue it for four weeks and then substitute a plaster-of-Paris dressing for four weeks. The amount of weight required is pointed out by Dawbarn—1 pound for each year up to twenty.[1] In *fracture near the knee-joint* (*lower part of the lower third* of the femur) it may be impossible to effect reduction by horizontal traction. In such a case make traction, and while it is being made gradually bring the leg to a right angle.

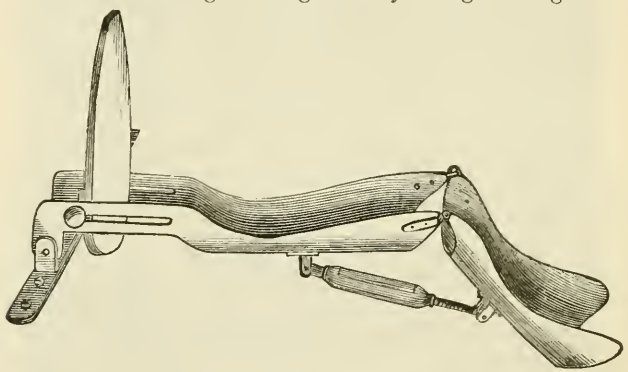

Fig. 413.—McIntyre's splint.

Place the limb in a double inclined plane (Pl. 7, Fig. 2). A McIntyre splint (Fig. 413) is a useful form of double inclined plane. After four weeks of the use of a double inclined plane apply a plaster-of-Paris dressing, which is to be worn for four weeks. Useful appliances for fracture of the femur are shown in Figs. 398, 399, 400 and 403.

Fractures of the Shaft of the Femur in Children.—In children under three years of age the extension apparatus will not satisfactorily immobilize the fragments. Fractures of the thigh in children are reduced by extension and counterextension; a well-padded splint reaching from the axilla to below the sole of the foot may be applied to the outer side of the limb and body. This splint is held in place by bandages which are overlaid by plaster of Paris. It is worn for four weeks, when it is removed and a plaster bandage, applied so as to include the entire limb, is worn for four weeks.

The abduction frame (Fig. 414) is a very useful plan of treatment.

Bryant's extension (Fig. 415) is very satisfactory in treating a young child. Both the injured limb and the sound limb should be flexed to a right angle with the pelvis, fixed by light splints, and fastened to a bar above the bed. The weight of the body produces counterextension and the child can be easily cleaned.[2]

Another plan is that of Theodore Dunham.[3] The child is placed upon a table, and the knee and hip are partly flexed. After first applying flannel

[1] "Annals of Surgery," Oct., 1897.
[2] Thomas Bryant's "Practice of Surgery."
[3] "Phila. Med. Jour.," April 23, 1898.

rollers, plaster-of-Paris bandages are applied from the roots of the toes to the spine of the tibia, and as a spica about the upper part of the thigh and pelvis. Two pieces of iron, suitably bent, are used to anchor the two plaster bandages together. One end of one iron is attached to the plaster over the groin and one end of the other iron is attached to the plaster over the front of the leg. The free ends of the irons overlap. At the points over the joints and the front of the leg where the irons are to rest masses of plaster are placed. The iron is sunk into the plaster and supported at each spot by several turns of a plaster bandage. While the irons are being adjusted the thigh is so held as to prevent bending or rotation, and the hip and knees are semiflexed. When the plaster has set an assistant makes extension on the leg and another assistant makes counterextension by pressing on the pelvis. Any shortening is thus reduced and the two irons are lashed together by strong cord (Fig. 416).

Fig. 414.—Jones's abduction frame, showing continued traction and counter-extension (courtesy of Sir Robert Jones, Liverpool, England).

Van Arsdale's triangular splint is a very useful appliance. It is made of binders' board. A. Ernest Gallant[1] describes its preparation and application as follows: Measure the length of the sound thigh from the middle of the groin to the end of the femur. Draw upon cardboard an outline of a double spade (playing-card spade) (Fig. 417). Each of the four sections (*A*, *B*, *C*, *D*) must be equal to the length of the child's thigh, the flanged portions being equal to the widest part of the thigh. The figure is then cut out. The cardboard is moistened on one side and folded on the dotted line, section *A* being lapped over *D*, so as to form a triangle. It is fastened together by adhesive plaster. The thigh is flexed and the triangle is applied so that one flanged portion embraces the thigh and the other flanged portion rests upon the abdomen (Fig. 418). The triangle is fixed in position by bandages, figure-of-8 turns being made around the knee and around the thigh and body. Plaster or starch bandages are then applied to fix the splint firmly. The leg should be bandaged from the toe to the knee to prevent swelling (Fig. 418). This splint is worn for three weeks. A child wearing this splint can sit on a chair, nurse, play on the floor and crawl about, may sleep on either side, and the dressing is not soiled by the evacuations.

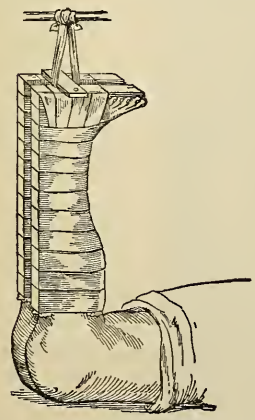

Fig. 415.—Bryant's extension for fracture of the thigh in a child.

If a thigh is fractured during parturition, or during the first few weeks of life, *Wyeth's dressing* may be very serviceable. It is applied as follows: The leg is flexed on the thigh and the thigh on the abdomen. A flannel bandage is applied so as to include the leg, the thigh, and the body from the axilla to the

[1] "Jour. Amer. Med. Assoc.," Dec. 18, 1897.

pelvis. Plaster of Paris is applied over this; the dressing is worn for four weeks. A better dressing than the above is *Ware's*, a modification of *Van Arsdale's splint* ("Annals of Surg.," August, 1905) (Fig. 419). It is lighter, the patient can be moved about with ease, the child's toilet can be carried out efficiently, and breathing is not embarrassed. A right-angled triangle is made of bookbinders' board. The length of one side is the distance from the trunk at the level of the lower angle of the scapula to the inguinal fold. The length of the other side is the length of the thigh. The hypotenuse is, of course, longer than the sides. The cardboard is marked, bent into the triangle, and the overlapping edges are secured by means of adhesive plaster. The thigh is flexed and abducted, the inner surface of the splint is padded, the apparatus is applied and retained by a muslin spica about the trunk and thigh. Several

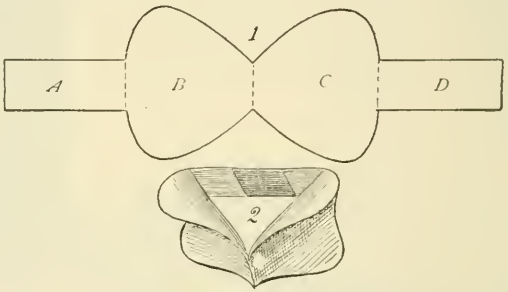

Fig. 417.—1, Diagram showing outline of Van Arsdale's splint; the end band to be folded on the dotted lines; each section to equal the length of the child's thigh. 2, Diagram, splint folded, fastened by rubber plaster, flanges bent to embrace the thigh and abdomen, ready for adjustment (Gallant).

turns of a dextrin bandage are applied over this to give strength. The leg hangs free. The dressing is worn for three or four weeks. Figure 419 shows this dressing applied for fracture of the right femur, and Fig. 420 shows it applied when both bones are broken.

Fractures Just Above the Condyles of the Femur.—The *line* of fracture above the condyles is well above the epiphyseal line. The popliteal artery is in danger

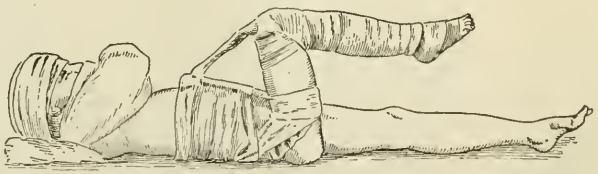

Fig. 418.—Showing Van Arsdale's triangular splint in position. Note the wide space between the dressings and the excretory passages (Gallant).

from the fragments. The *cause* of the break, as a rule, is direct violence. Indirect force is sometimes responsible (falls upon the feet). The knee-joint may be opened. The fracture is sometimes compound.

Symptoms.—The upper end of the lower fragment is drawn upward and backward, because of the action of the rectus, hamstrings, gastrocnemius, and popliteus. The upper fragment passes inward, and the deformity is very manifest. There are pain, tenderness, shortening, crepitus, and mobility. The

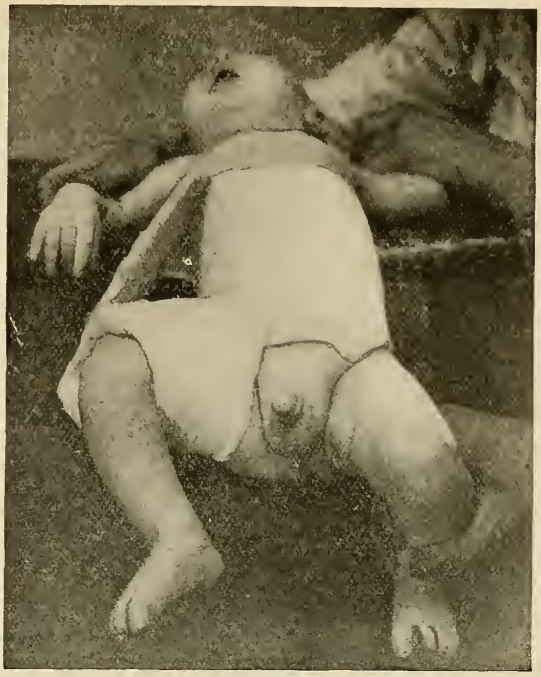

FIG. 419.—Ware's combined pasteboard triangle and plaster-of-Paris spica apparatus for fracture of the femur in infancy (Ware, in "Annals of Surgery," August, 1905).

FIG. 420.—Ware's apparatus for treatment of fracture of both femora (Ware, in "Annals of Surgery," August, 1905).

ends of the fragments can be felt by the surgeon. If the force has been very great, a T-fracture results. In T-fracture the knee is broadened and crepitus is obtained by moving the condyles, one up and the other down. The popliteal vessels may be torn. Always feel for the pulse below the fracture.

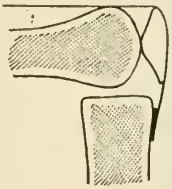

Fig. 421.—Mechanism of fracture of the patella by muscular action (after Treves).

Treatment.—In treating fracture above the condyles, reduce the deformity by horizontal extension. If this fails, make traction at the same time, gradually bringing the leg to a right angle with the thigh. Place the limb on a double inclined plane for five weeks, then begin passive motion once every other day, reapplying the splint after the movements are completed. At the end of eight weeks after the accident remove the dressings, and, if the knee-joint be stiff, use for some time massage, passive motion, hot air, hot and cold douches, ichthyol inunctions, etc. Bryant treats this fracture in extension, cutting the tendo Achillis, if necessary, to amend deformity. It is occasionally necessary to plate the fragments. Some cases demand amputation because of injury to the structures in the popliteal space.

Fracture Separating Either Condyle.—The *cause* is direct force.

Symptoms and Treatment.—The broken piece is drawn upward, the leg bends toward the injury, crepitus exists, the knee is much broadened, there is no shortening, and considerable swelling is sure to arise. In treating a fracture separating either condyle, use a double inclined plane as directed above. If there is great displacement, the condyle should be nailed in place.

Longitudinal fractures run upward from the knee-joint. The *cause* is a fall upon the feet or the knees.

Fig. 422.—Fracture of the patella.

Fig. 423.—Senseman's case of fracture of lower epiphysis of the femur in a boy seven years of age.

Symptoms and Treatment.—The *symptoms* of longitudinal fracture are often obscure. The femur is broadened when the knee is flexed. The split may be detected between the condyles. The *treatment* is the straight position in plaster for eight weeks.

Separation of the lower epiphysis occurs only before the twenty-first year. It is not a very rare accident in children.

The *symptoms* in separation of the lower epiphysis are like those of transverse fracture, but crepitus is moist. The lower fragment is tilted, so that the articular surface looks forward. The lower end of the upper fragment projects into the popliteal space. There is danger to the structures in the popliteal space. The growth of bone may be stunted. Feel for the pulse in the leg or foot.

Treatment.—Reduction may be effected in some cases by horizontal extension. Occasionally this is impossible.[1] In such a case adopt the plan of Hutchinson and Barnard, make extension, and while it is being made gradually place the leg at a right angle to the thigh. This is effected by an assistant

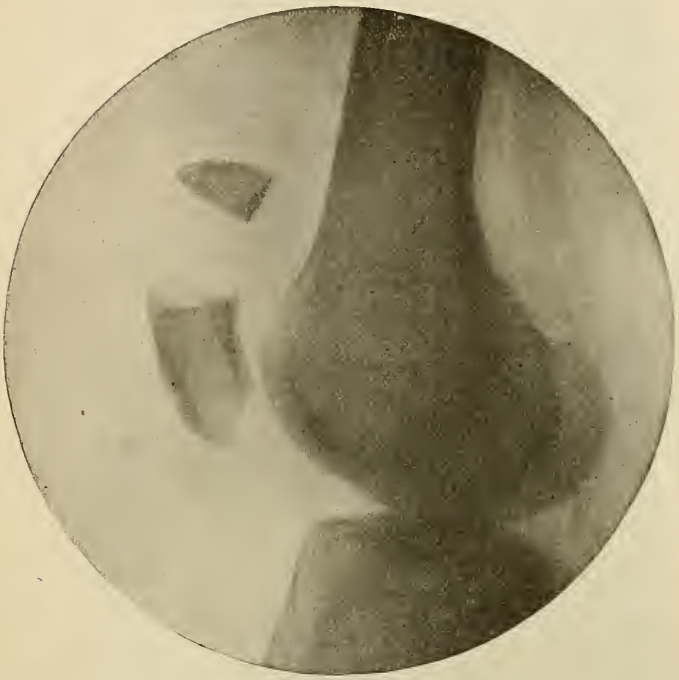

Fig. 424.—Fracture of the patella, showing wide separation of the fragments (author's case).

making traction on the leg, while the surgeon clasps his hands beneath the lower part of the thigh and draws upward. The treatment for separation of the lower epiphysis is the use of a double inclined plane as above directed. In some cases replacement is impossible without incision. In a case of my own, amputation was performed because of laceration of the popliteal vessels.

Fracture of the patella is a very common accident. The *cause* is direct force (often producing vertical, star-shaped, or oblique lines of fracture, but not uncommonly transverse) or muscular action (producing a transverse line of fracture).

Transverse Fracture of the Patella.—The knee-cap is more often broken by muscular action than is any other bone. When the knee is partly flexed the middle third of the patella rests upon the condyles of the femur and the upper third of the knee-cap projects above them: when in this position a

[1] See the case reported by Jonathan Hutchinson, Jr., and Howard L. Barnard, "Lancet," May 13, 1899.

contraction of the quadriceps may cause easily a fracture near the center of the bone (Fig. 421). The accident may be due to sudden flexion of the knee when the quadriceps is contracting. The most usual cause is a fall or an attempt of the patient to save himself from a fall backward. Both patellæ may be broken at once. In fracture of the patella the joint, and often the prepatellar bursa, are opened. Fractures by muscular action and many fractures from direct force are transverse. The injury is more common in males than in females, and is extremely rare in the very young and the old. It is usually an injury of active manhood and middle life, but I have seen a woman of eighty-six with fracture of the patella.

Symptoms.—When the accident happens there is often an audible crack. As a rule, the patient will not try to use the limb, although it is possible for

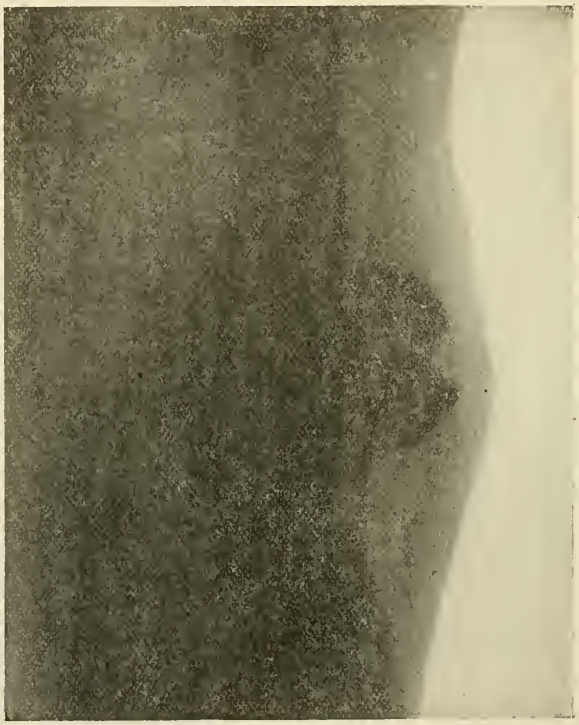

FIG. 425.—Fracture of the patella (Pennsylvania Hospital case; skiagraphed by Dr. Gaston Torrance).

him to stand, to walk backward, and to move slowly forward when the extremity is kept straight. After the accident there is rapid and enormous swelling, due to the effusion first of blood and then of synovia and inflammatory products into and around the joint. The patient is absolutely unable to raise the limb from the bed. The fragments are movable and usually widely separated (Fig. 424), this separation being distinctly manifest to the touch unless swelling is great. The separation is accentuated by flexion of the leg. The separation may be to the extent of 1 inch or even more. In cases in which the lateral fibrous expansions and periosteum are but slightly torn, there may be trivial separation or no separation. Separation is due in part "to the retraction of the quadriceps and the tension of the fascia lata, and in part to distention of the joint by blood and exudate.[1] If fragments are not approxi-

[1] Stimson's "Treatise on Fractures and Dislocations."

mated and union does not occur, the separation becomes gradually greater because of the progressive shortening of the muscle and the retraction of the ligamentum patellæ (Stimson). In some cases an anterior angular displacement occurs because of the intra-articular distention (Fig. 425). It may be produced by the pressure of bandages or strips of plaster when the fragments have been brought together. Crepitus is detected if the upper fragment can be pushed down until it touches the lower piece; but if swelling is great, or if fibrous tissue is interposed between the bones, crepitus cannot be elicited. It is not necessary to obtain crepitus in order to make the diagnosis: the condition is usually obvious without this sign. The anterior fibroperiosteal layer is torn, and the tear does not correspond exactly with the line of fracture. A portion of this torn fibroperiosteal layer may, as Macewan pointed out, drop between the fragments and prevent union (Fig. 426). The lateral expansions of the capsule are usually extensively torn. If union occurs after a transverse fracture, it will probably be ligamentous, and if the patient gets about too soon, even apparently well-united fragments will by degrees stretch far asunder.

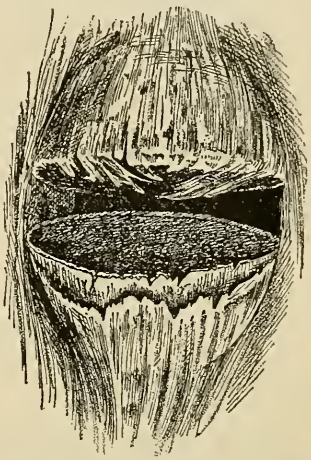

Fig. 426.—Transverse fracture of the patella; fractured surface partially covered by irregular flaps of torn aponeurosis (Hoffa).

Treatment of Transverse Fractures of the Patella.—*The Conservative Plan.*—If the swelling is so great as to prevent approximation of the fragments, reduce it by bandaging for a day or two, by using ice-bags, or by aspirating the joint. As a rule, the blood does not coagulate for several days. After it coagulates it cannot be withdrawn by aspiration, but only by incision. When the swelling diminishes, bring the two fragments into apposition, pull them together by adhesive plaster, and put on a well-padded posterior splint. Carry a piece of adhesive plaster over the upper end of the upper fragment, draw the bone down, and fasten the plaster to the splint behind and below the level of the joint. Carry another piece of plaster over the lower end of the lower fragment, draw the bone up, and fasten the plaster to the splint behind and above the joint. Carry a third piece over the junction of the fragments to prevent tilting. Agnew's splint enables us to accomplish satisfactorily this approximation (Pl. 7, Figs. 11, 12). A bandage holds the splint in place, and may be carried around the knee by figure-of-8 turns. The heel is sometimes raised upon a pillow so as to extend the leg and to semiflex the thigh, but this is not essential. Remove and reapply the dressing every few days, as it inevitably becomes loose. At each removal employ massage. At the end of three weeks remove the splint permanently and apply a plaster-of-Paris dressing from just above the ankle to the middle of the thigh, and get the patient about on crutches. Have the plaster cut so that it may be easily removed and every day employ massage and gentle passive movements, the surgeon fixing the upper end of the upper fragment by his thumb during the movements. The dressing is to be worn for five weeks. After eight weeks of treatment allow the patient to walk about on crutches, the joint being left free at night, but kept fixed during the day by pasteboard splints or by a light plaster-of-Paris bandage. After four weeks more he gets about with canes or a cane. For months after removing the splints and plaster a lacing knee-cap of leather should be worn in the daytime to support the joint. The plan of prolonged immobilization renders more or less muscular atrophy and joint-stiffness certainties, but these are less serious impediments than the wide separation of the fragments that inevit-

ably attends an early use of the joint. Bryant, of New York, has devised an ambulatory dressing.

Operative Treatment.—Malgaigne's hooks are obsolete.

It is said that John Rhea Barton wired an ununited fracture of the patella in 1843. In 1877 Hector Cameron wired an ununited friction of the patella, and a few months later Lord Lister operated on a fracture of the knee-cap two weeks after the accident. The question of the advisability of suturing a recent fracture has been very much disputed. The ordinary non-operative plans of treatment do not endanger life and generally give a fairly good functional result, although the joint remains insecure on extension, the patient is apt to fall, and a fall may refracture the bone. The operative method will usually succeed, and is capable of obtaining a better functional result and of obtaining it more rapidly. There is some danger of infection, and if infection should occur, the results may be most disastrous. Some cases obviously cannot be treated by the conservative method with any chance of success; cases, for instance, in which a flap of fibroperiosteum intervenes between the fragments, or cases in which from some other cause the bones cannot be approximated. Such cases should, of course, be operated upon. But in the great majority of cases a good result will follow conservative treatment, and conservative treatment should be trusted unless the case is in the hands of a surgeon and in a place where every antiseptic precaution can be taken. We agree with Stimson when he says that operative methods can be used with confidence when surrounded by every protection; he habitually uses them, but he never teaches

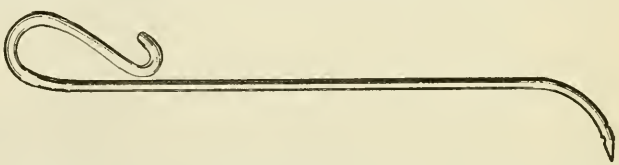

Fig. 427.—Needle specially designed to carry a thick wire. The eye is drilled obliquely, and should receive only a little loop on the end of the wire; this loop should be made previously.

them as proper routine practice, and strongly advises against their use except by those who have had experience in operating, who have formed the habit of taking precautions, and who have the aid of skilled assistants.[1] Operation should only be performed on healthy persons of suitable age, when the separation is over ½ inch or when there is much laceration or interposition of the capsule.[2] If a patient is still able to extend the limb and the lateral expansions of the quadriceps have not been widely torn, a useful limb will be obtained by conservative treatment even if the bone-fragments separate, and operation is not demanded. A working man needs the operation more than a gentleman of leisure because he is in more vital need of a sound knee-joint. A young or middle-aged person is more active than an elderly person, hence, in him operation is more strongly indicated than in an elderly man. Barker believes strongly in wiring recent transverse fractures. He does it with antiseptic care soon after the accident, and permits passive motion or even slight active motion immediately after the operation. Massage is begun the day after the operation, and is practised daily for two weeks.

Barker[3] uses a special needle (Fig. 427) and silver wire of the thickness of a No. 1 English catheter. This wire is straightened and softened in a spirit-flame. He rubs the bone-fragments together in order to dislodge blood or fibrous material, and when marked grating occurs, introduces the wire. A punc-

[3] See the objections of Sir William Stokes to Barker's method, in "Brit. Med. Jour.," Dec. 3, 1898.

ture with a small knife is made through the middle of the upper attachment of the patellar ligament. The needle, not carrying any wire, is made to enter

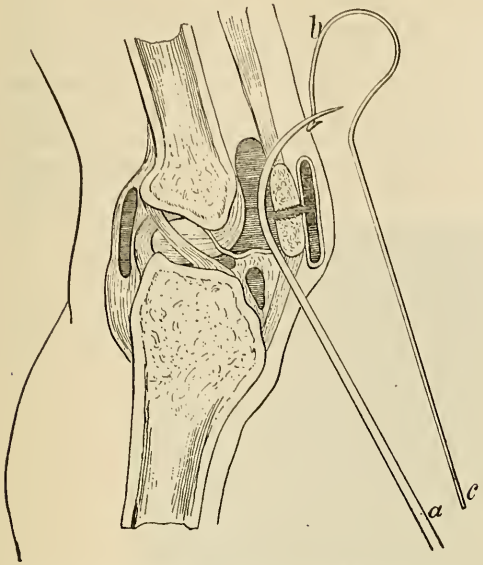

Fig. 428.—Needle (*a*) introduced behind the fragments, and receiving one end (*b*) of the silver wire (*b*, *c*) (Barker).

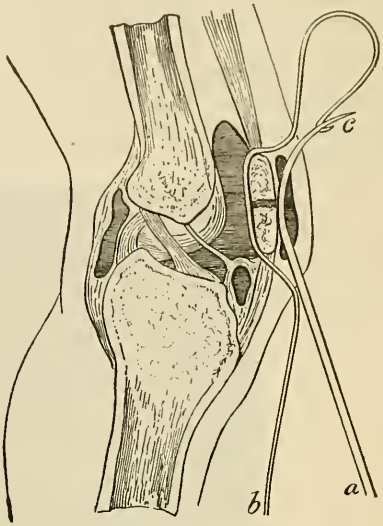

Fig. 429.—Needle (*a*) passed in front of the fragments and receiving the other end (*c*) of the silver wire (*b*, *c*) (Barker).

through this opening into the joint, is passed back of the fragments, pierces the tendon of the quadriceps, at the upper edge of the upper fragment, and its point is cut upon with a knife. The wire is inserted into the eye of the needle and the needle is withdrawn and unthreaded. The empty needle is pushed through the lower opening, is carried in front of the patella, is made to emerge at the upper opening, is threaded with the protruding wire and withdrawn (Figs. 428, 429). The wires are threaded into bars and twisted (Fig. 430), the ends are cut off, and antiseptic dressings are applied. There are objections to Barker's operation: It does not allow us to remove blood-clots from the joint; if a bit of tissue intervenes between the fragments, it cannot be removed; and a foreign body is left permanently in the joint.[1] If an operation is thought advisable, we deem it best to do an open operation. An open operation may be performed within a very few hours of the injury. If it is not done then it should be postponed for five days or longer. In the period between the first day and the fifth, tissue resistance is lowest and the parts are most prone to infection. By the

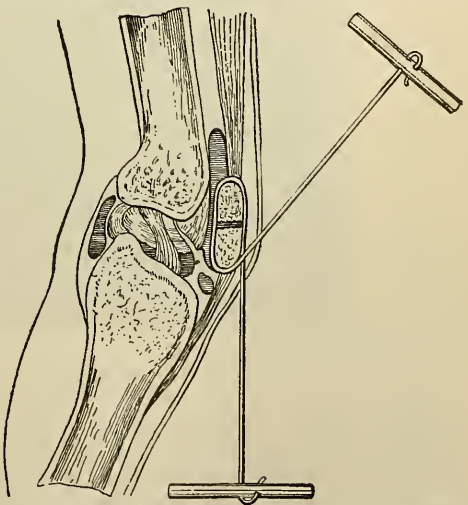

Fig. 430.—Wire in position around fragments and threaded through metal bars. The lower and posterior wire runs upward to the left of the upper, ready for twisting (Barker).

[1] "Brit. Med. Jour.," April 11, 1896.

tenth or eleventh day it will be found more difficult to separate the tissue and hemorrhage may be profuse.

To perform the open operation make a semilunar or a central longitudinal incision, free the joint from blood-clots by irrigation with hot salt solution, remove all tissue from between the fragments, drill the fragments, pass silver wire, twist the wire and draw the fragments together, and close the wound (Fig. 431). Wire seems to have a tendency to set up arthritic changes. Instead of wire, silk may be used. In cases in which there is no very strong tendency to separation the fragments can be held together by several catgut sutures through the capsule, the periosteum at the fractured edges and the peripatellar

Fig. 431.—Wired fracture of the patella (St. Joseph's Hospital case; operated upon and skiagraphed by Dr. Nassau).

ligaments, or by a strong catgut or silk suture passed through the ligamentum patellæ and the quadriceps tendon and carried in front of the fracture (Stimson). The limb should be placed on a posterior splint. In seven or eight days the superficial sutures are removed and a plaster-of-Paris splint is applied. In a few days the patient gets about on crutches. In a month the dressing is cut down the front and worn only in the daytime, and passive motion is begun. The splint is discarded at the end of the third month.[1] Among other operative procedures we may mention the following: encircling the fragments by a silk suture (the circumferential suture), which, however, may impair bone nutrition and retard union; drilling the bones subcutaneously and passing wire through

[1] Stimson, "Annals of Surgery," August, 1898.

the drill-holes in the form of a figure of 8 (Ceci); passing subcutaneously a ligature around and over the fragments (Butcher); and incising and approximating of the fragments by fixation hooks or metal pins.

Fractures of the patella by direct force are vertical, stellate, oblique, V-shaped, or transverse; are often incomplete and occasionally compound or comminuted (Fig. 432). Ransohoff maintains that fractures from direct force are more common than from muscular action and are usually transverse and associated with some comminution ("Jour. Amer. Med. Assoc.," Oct. 13, 1906).

Compound fracture of the patella is very rarely seen in Philadelphia hospitals. The records of the Boston City Hospital (an institution in which multitudes of fractures are treated) show only 8 compound fractures of this bone in forty-two years (Scannell, in "Boston Med. and Surg. Jour.," Nov. 15, 1906).

Symptoms of Simple Fracture.—Fractures of the patella by direct force are followed by discoloration, swelling, great difficulty in movement, and much pain. There may or may not be crepitus. The degree of separation of the fragments depends upon the direction of the line of fracture and the extent of bone in-

Fig. 432.—Comminuted fracture of patella.

volved. Bony union is apt to occur after such a fracture when there has not been wide separation.

Treatment.—A fracture resulting from direct force may often be treated by a posterior splint and the application of a bandage. If there is any separation, the fragments should be approximated by adhesive strips, bandages, and compresses. At the end of three weeks remove the posterior splint, apply a plaster-of-Paris splint, and get the patient about on crutches. The danger in these cases is ankylosis rather than non-union; hence, in the fourth week cut the plaster splint down the front and begin passive motion of the knee-joint. At the end of six weeks cease wearing the dressing in the daytime, and at the end of three months discard it entirely. In those cases in which an oblique fracture or a transverse fracture with wide separation arises from direct force, treat as advised for transverse fracture from muscular action. The question of operation is practically the same as for transverse fracture from muscular action. In every compound fracture of the patella, if amputation can be avoided, incise the soft parts freely and irrigate the joint with hot saline fluid. Remove hopelessly loosened fragments. Those not completely separated may in some cases be sutured into place. Drain for twenty-four or forty-eight hours.

Ununited and Badly United Fracture of the Patella.—There is usually a band of union, but it may be very thin and the fragments may be far asunder. It is commonly taught that the degree of functional impairment depends directly on the amount of separation. This is not strictly true. There may be great separation and but little impairment of function, the fragments being firmly united by a dense fibrous band. There may be little separation and yet lameness, stiffness of the joint, and imperfect power of extension. The reason for this has been pointed out by Bruns, of Tübingen.[1] He says there may be complete failure of union, even when the separation is trivial, and failure of union produces impaired function. If separation is considerable, the fragments are apt to tilt and tissue is often interposed between them. Functional difficulty is more often met with when the fragments are far apart than when they are near together, because non-union is more common. As a matter of fact in most cases of non-union John B. Murphy said a man could get along very well "without his patella" ("Surgical Clinics," vol. i, No. 3, page 326 and vol. iv, No. 4, page 771). In non-union the quadriceps is still able to act upon the tibia by means of the fascia lata, ligaments at the sides of the joint, or bands from the vasti to the lower fragment. Besides non-union, functional impairment may be due to anchoring of the upper fragment to the femur. The upper fragment may be anchored to the femur by the interposition of the fibrous investment of the knee-cap, which covers the fractured surface of the upper fragment and may grow fast to the capsule of the joint (Bruns).

The *treatment* of ununited and badly united fracture is discussed on page 610.

Fractures of the Leg.—In leg-fractures both bones or only one bone may be broken.

Fractures of the tibia are divided into: (1) fractures of the upper end; (2) separation of the upper epiphysis; (3) fractures of the shaft; (4) fractures of the lower end, and (5) separation of the lower epiphysis.

Fractures of the upper end of the tibia are uncommon. They may be transverse, oblique, or vertical, running into the joint. The *cause* is direct violence.

Symptoms.—In fracture of the upper end of the tibia there is contusion of the soft parts. In a *transverse* fracture there are mobility and crepitus, but there is little displacement. In *oblique* fracture crepitus and mobility are marked, the axis of the limb is altered, and the fragments may be displaced. In fractures entering the joint there is great swelling of the knee-joint. *Comminuted* fractures exhibit marked signs, union is readily obtained, but if the joint has been damaged, stiffness is sure to ensue.

Treatment.—Reduce displacement by extension and manipulation. The special apparatus used for treatment depends on the case. In some cases extension is required, in some a posterior splint is applied and the limb is suspended from a gallows, in some a double inclined plane is employed, and in some a plaster-of-Paris splint is used.

The double inclined plane in the form of McIntyre's splint is frequently employed, or a double inclined plane in the form of a fracture-box may be preferred. The Balkan splint secures traction and is very useful (Fig. 400). The extremity should be immobilized for four weeks, when passive motion should be begun. Passive motion is to be made daily, the dressing being reapplied after each séance. In five or six weeks the dressings are removed and the patient allowed to go about on crutches. The crutches are soon abandoned for a cane, and later all support is dispensed with. If a fracture extends into the knee-joint and the ill-adjusted fragments block the articulation, the joint should be opened and the fragments placed and fixed in proper position.

Separation of the tubercle of the tibia is due to violent contraction of the

[1] "Beiträge zur klinischen Chirurgie," "Mittheilungen aus der chirurg. Klinik zu Tübingen," Bd. iii, Heft 2, 1888.

quadriceps, and occurs only in those under twenty years of age. The fragment is drawn up and can be felt, and the patient is unable to use the limb. In a case in which the tibial spine has been torn off, it may be nailed in place, or the limb should be placed on a posterior straight splint and the fragment should be pulled down into place by adhesive strips and bandages. The splint should be worn for five weeks.

Avulsion of the Spine of the Tibia.—This is a very rare accident. There are but very few cases on record, and in only 1 of them (Pringle's) was the diagnosis made during life, and it was made in that case by exploratory incision. The tibial spine is torn off by the anterior crucial ligament. The causative force is probably flexion, abduction, and internal rotation of the leg (J. Hogarth Pringle, "Annals of Surg.," August, 1907). After the accident the leg at the knee is in extreme abduction. Exploratory incision may be necessary for diagnosis. The treatment is to suture or nail the bone-fragment in place.

Separation of the Upper Epiphysis of the Tibia.—This is an injury of extreme rarity. It does not seem to occur after the sixteenth year. It is caused by a twist or crush, or by violent abduction or adduction of the leg. It may lead to lessened growth of the limb. I have seen two cases. One in a boy of twelve who was knocked down by a trolley car. One in a boy of fifteen who was riding on the back of a truck while another truck ran into it. In both cases amputation was performed; in one case because of hemorrhage from the popliteal vessels, in the other because of gangrene. The *treatment* is as for a fracture of the upper end of the bone.

Fractures of the Shaft of the Tibia.—The *causes* of these fractures are direct force, indirect force, or torsion. A fracture in the upper part of the bone is usually transverse; in the lower part it is usually oblique (T. Pickering Pick).

Symptoms.—In transverse fracture of the shaft of the tibia there is no deformity, and the support of the fibula may even permit of walking; there is fixed pain; there may or may not be inequality of the fragments felt by the finger; and there are pain, tenderness, crepitus, mobility, and often linear ecchymosis. In oblique fractures there usually exist crepitus, a little mobility, and distinct deformity. The deformity depends on the direction of the line of fracture, and, as this line is usually from above downward, inward, and a little forward, the lower fragment usually passes behind the upper fragment and rotates inward.

Treatment.—In treating fractures of the shaft of the tibia effect reduction by making extension from the foot and counterextension from the knee, the knee-joint being in partial flexion. If there is much swelling, put the limb in a fracture-box (Figs. 433, 434, and Pl. 7, Fig. 1), swing the box from a gallows, and apply an ice-bag for twenty-four hours. A silicate of sodium or a plaster-of-Paris dressing is applied when the swelling subsides, or the dressing may be used at once instead of a fracture-box if swelling is slight. As soon as the limb is immobilized in a silicate or plaster dressing the patient gets about on crutches. The dressing is removed after five weeks, and the patient goes about for one week on crutches, lightly using the foot, and then for a time walks with the aid of a cane. At the end of eight or nine weeks the cane may often be dispensed with, the amount of use of the leg being daily augmented. The Thomas arm splint is an efficient emergency apparatus for fracture of the tibia (Fig. 397).

Fractures of the Lower End of the Tibia: Fracture of the Inner Malleolus.—The *cause* of fracture of the inner malleolus is direct force or traction upon the internal lateral ligament.

Symptoms and Treatment.—The *symptoms* of fracture of the inner malleolus are pain, tenderness, some downward displacement, depression above the ends of the fragments, mobility, and crepitus. The *treatment* is to push the fragments into place and use side-splints or a fracture-box for two weeks, when a plaster-of-Paris or a silicate dressing may be substituted and the patient ordered to use

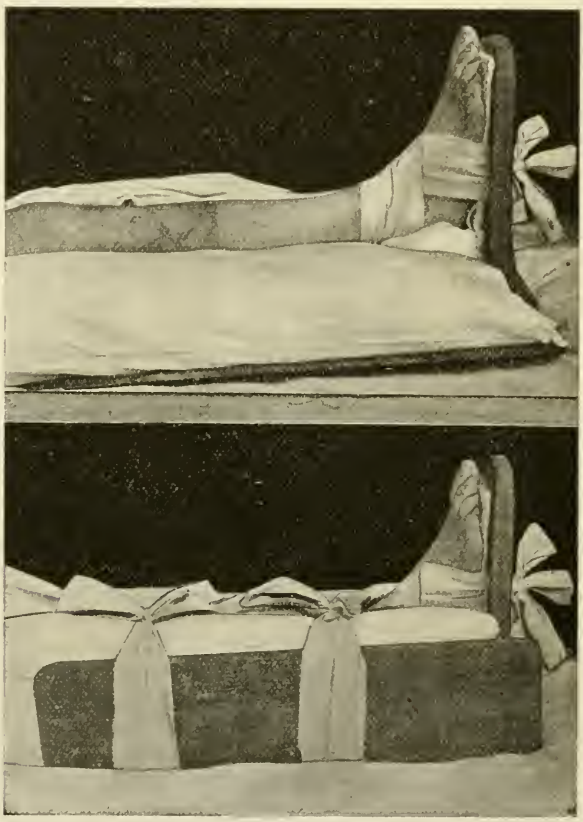
crutches. Remove the plaster four or five weeks after it is applied, and direct the patient gradually to bear his weight upon the leg, as outlined above.

Separation of the lower epiphysis of the tibia is a rare accident, but is commoner than separation of the upper epiphysis. The *treatment* is a fixed dressing for six weeks.

Fracture of the fibula alone is commoner by far than is fracture of the tibia alone. Fractures in the upper two-thirds, which are rare, are usually due to direct force. Fractures in the lower third are frequent, and arise from indirect force.

Fractures of the Upper Two-thirds of the Fibula.—In these fractures the *cause* is direct force.

Symptoms.—In fracture of the upper two-thirds of the fibula the patient is frequently able to walk. The bone is deeply situated, and displacement



FIGS. 433, 434.—Fracture-box in fractures of the bones of the leg.

cannot often be detected. There is a fixed pain, which is intensified by movement and by pressure. Pressure upon the lower fragment does not move the upper fragment. Crepitus is sometimes obtained, and linear ecchymosis is apt to appear. The bone is normally elastic, hence slight mobility is of no value diagnostically.

Treatment.—In treating a fracture of the upper two-thirds of the fibula apply a plaster-of-Paris or a silicate bandage and direct that it be worn for five weeks. Weight is not to be put upon the foot for six weeks after the accident.

Fractures of the Lower Third of the Fibula.—In these fractures the *cause* is usually indirect force, especially twists of the foot. Forcible inversion of the foot pulls upon the external lateral ligament and the external malleolus, forces the

fibula outward, and tends to break it, the lower fragment being displaced outward. Forcible eversion pulls the internal lateral ligament from the inner malleolus (often breaks the malleolus) and fractures the fibula above the ankle, the bone being displaced inward.

Pott's Fracture.—By the term "Pott's fracture" is meant a fracture of the lower fifth of the fibula produced by eversion and abduction of the foot. Stimson points out that the production of Pott's fracture is often aided by the weight of the body. The lesions which arise depend upon whether the chief force is eversion or abduction. "If eversion is the sole, or main, movement, the force is exerted through the internal lateral ligament and breaks the internal malleolus squarely off at its base; then it presses the external malleolus outward, rupturing the tibiofibular ligament, and breaks the fibula close above the malleolus. Sometimes instead of pure rupture of the tibiofibular ligament there is avulsion of the portion of the tibia to which it is attached."[1] Stimson further points out that if abduction is the preponderating force there is an oblique fracture of the anterior portion of the internal malleolus or more frequently rupture of the anterior portion of the internal lateral ligament. There are, as in the former case,

Fig. 435.—Pott's fracture. Dupuytren's splint. Note length of splint; position of straps; arrangement of padding; space between foot and splint (Scudder).

Fig. 436.—Pott's fracture.

rupture of the tibiofibular ligament and an oblique fracture of the fibula several inches above the external malleolus. It is evident that the degree of injury produced by eversion and abduction depends on the point at which the force is arrested. It may be arrested after the inner malleolus has been separated or the anterior fibers of the deltoid ligament torn, and in this case the tibiofibular articulation remains intact and the fibula is not broken. It may cease after separating the tibiofibular articulation, and in this case too the fibula escapes. It may be continued until the fibula breaks. In this fracture the astragalus passes outward, somewhat backward and also upward, the later deviation being due to separation of the tibiofibular articulation. The

[1] "A Practical Treatise on Fractures and Dislocations," by Lewis A. Stimson.

chief trouble in reduction and treatment is this outward and backward dislocation of the foot.

Symptoms.—The foot is displaced outward, and a little backward and upward, and the inner malleolus or the tibia from which it was torn is extremely prominent. There is great lateral mobility and often anteroposterior mobility at the ankle-joint. Stimson points out that there are three points where pressure is certain to provoke pain; in front of the tibiofibular ligament, at the base or anterior border of the inner malleolus, and over the seat of fracture through the fibula.

Treatment.—Thorough reduction is of the greatest importance. If thorough reduction is effected, a good result will probably be obtained; but if thorough reduction is not effected, the patient will be permanently crippled to a greater or less extent. In order to effect reduction it may be necessary to anesthetize the patient. The patient's knee is flexed, the heel is pulled strongly forward and inward, and the lower end of the tibia is pushed backward. This corrects the ankle dislocation, and then the valgus must be overcorrected (Jones). Inversion of the ankle is imperative.

Some surgeons at once after reduction apply a plaster-of-Paris bandage. This treatment is objectionable because the deformity may be partially reproduced after the application of the dressing, the surgeon being unable to see it and unable to correct it.

If there seems to be no strong tendency to a recurrence of deformity, a fracture-box can be used. After reducing displacement in such a case, place the limb in a fracture-box containing a soft pillow. A bird's-nest pad of cotton or oakum is made for the heel (see Figs. 433, 434). A fillet around the ankle fastens the foot to the foot-piece of the box; a pad of oakum rests between the foot-piece and the sole. A compress is placed below the outer malleolus and another one above the inner malleolus. Close the sides of the box and tie them together with a bandage, and swing the box on a gallows. Every day let down the sides of the box and rub the leg, the ankle, and the foot with alcohol. In ten days apply a plaster-of-Paris bandage and let the patient get about on crutches. Remove plaster at the end of the fifth week after the accident, and let patient go about with crutches for one week and with a cane for a week longer.

I am accustomed to dress most cases of Pott's fracture with a *Dupuytren splint.* This is a straight splint (Fig. 435 and Pl. 7, Fig. 9) which reaches from above the head of the tibia to below the sole of the foot. This splint is padded, and a pyramidal pad with the base down is laid upon the inner surface of the leg, above the inner malleolus, the splint being put upon the inner surface of the leg, over the pad. The splint is fastened as shown in Plate 7, Fig. 9, and Fig. 435. If the short splint shown in Plate 7 is used (it only goes to the head of the tibia), the leg is semiflexed upon the thigh and is laid upon its outer surface upon a pillow. After ten days of Dupuytren's splint, apply the plaster-of-Paris bandage, which is to be worn as above directed. Bryant treats Pott's fracture with a posterior splint, two lateral splints, and a swing. Stimson uses a posterior and lateral splint of plaster of Paris. This splint does not slip, as may Dupuytren's dressing, and does not hide the seat of fracture from view, as does complete encasement with plaster of Paris. It is a most useful dressing. When the patient begins to walk the callus may bend. If it does, eversion will be produced. In order to prevent this make the patient walk for a number of weeks upon a shoe heel raised on the inside in order to induce the position of varus. A very heavy man should also wear for several weeks an iron brace on the outside. I have given above the conservative treatment of Pott's fracture. I have come to the conclusion that operation should be the rule in this injury and not the exception. The fracture is so often followed by pain, swelling, and disability. Pain and disability are so largely due to malunion or fibrous union of the broken malleolus, and it is so easy to fix the fragment in

place by nails or sutures, that the conclusion seems obvious that in proper subjects operation should be performed. As Heath and Selby show, in an important article ("Annals of Surg.," Jan, 1908), operation also allows us to return the tibialis posticus to its normal position and thus flat-foot is prevented. The plan suggested by Heath and Selby ("Annals of Surgery," Jan., 1908) is excellent. The fragment may be sutured in place by silver wire or chromic gut. If the tendon of the posterior tibial is displaced, the torn annular ligament is sutured so as to hold the tendon in place, a drain of rubber tissue is carried down to the bone, and the soft parts are sutured. The parts are dressed and a fixation apparatus is applied. The drain is removed in twenty-four hours. In eight weeks the patient should be walking freely (see cases reported by Heath and Selby, Ibid.). Pott's fracture may be *compound*, a portion of the inner malleolus or of the tibia above it projecting through the wound. If it is necessary to introduce through-and-through drainage, the foot must be placed and kept at a right angle to the leg. If a compound fracture exists, the malleolus must be nailed in place or sutured by silver wire or chromic gut. In a reported case the wire was passed through the joint and around the fragment, and the result was good.[1] Nailing seems a better plan.

Fig. 437.—Fracture of both bones of leg. Bad position.

Fracture of both bones of the leg is a very common injury, is often compound, and is not unusually comminuted. Fractures by direct force, such as blows or kicks, are commonest in the upper half of the leg. Fractures by indirect force, as by falls, are commonest in the lower half of the leg. In fractures from indirect force the tibia breaks first, and then the fibula breaks at a higher level. The point of greatest liability to fracture from indirect force is the junction of the lower and middle thirds. Fractures of the leg are usually oblique, but they may be transverse if arising from direct force. Spiral, torsion, or V-shaped fractures and longitudinal breaks, sometimes occur. In oblique fractures, as a rule, the line of fracture runs from behind, downward, inward, and a little forward.

Symptoms.—Fracture of both bones of the leg is easy of recognition. The fibular fracture is detected as before described. By running the finger along the crest of the tibia displacement will be found, except in transverse fractures, when it may not occur. The common displacement is for the lower fragment to ascend and pass behind the lower end of the upper fragment and to rotate a little outward, and for the upper fragment to project in front. The ascent of the lower fragment is due to the action of the gastrocnemius and soleus muscles. If the line of fracture is in a direction the reverse of that which is usual, the lower fragment ascends in front of the lower end of the upper fragment. In fracture of both bones of the leg there are marked mobility and crepitus, severe pain, and inability to walk. In fractures from direct force there is more or less damage to the soft parts. A fracture of the shaft of the tibia near the ankle is

[1] "Rev. de Chir.," vol. viii, 1888.

distinguished from a dislocation by the fact that the deformity is easily reduced, but tends to recur in the fracture, and, further, that in a fracture the relations of the malleoli to the tarsus are unaltered, whereas in a dislocation they are altered.

Treatment.—If the fracture is near the ankle-joint, the action of the tendo Achillis may maintain deformity, and in such cases the tendon should be divided. All fractures of the lower third are difficult to reduce and often require extension by the pulley. In very few will perfect apposition of the fragments be brought about, and the best we can usually attain is good alignment (Jones). In treating a simple fracture of the lower two-thirds of the bones reduce by extension and counterextension, and use a fracture-box (see Figs. 433, 434). The compresses used in Pott's fracture are not required. If the soft parts are bruised, use evaporating lotions for a day; if they are abraded, apply antiseptic dressings. The fracture-box should be swung upon a gallows. After three weeks apply a plaster-of-Paris or silicate of sodium dressing and let the patient sit up in a chair during one week; at the end of this time the patient may get about on crutches. At the end of six weeks after the accident remove the plaster, and let the sufferer go about on crutches for two weeks and with a cane for two weeks more. Brinton was accustomed to dress a fracture of both bones of the leg for two weeks in a fracture-box, for two weeks in side-splints made of metal, and for two weeks in an immovable dressing, allowing the patient to get about on crutches as soon as the plaster was put on. Instead of the fracture-box we may use a posterior splint, two lateral splints, and a swing. The Thomas bed-splint is a very useful dressing. So is the Balkan frame with traction (Fig. 400). Nathan R. Smith's anterior splint is used by some in the treatment of fractures of the leg. Some surgeons apply plaster-of-Paris in the form of an ambulatory dressing. In this dressing a solid apparatus reaches to the lower third of the thigh and below the sole of the foot. When the patient walks the weight is transmitted to the thigh. In fractures of the upper third of the leg the McIntyre splint or the double inclined plane is used. If the fracture is *compound*, asepticize thoroughly, make a counteropening, insert a drainage-tube, dress with bichlorid gauze, apply a plaster bandage, and cut trap-doors over the openings of the tube (see Fig. 317), or dress with the bracketed splint and plaster of Paris (see Fig. 318). Remove the tube, as a rule, in about forty-eight hours; but the patient's temperature is the guide not the time of retention.

In many fractures of the lower third operation is indicated to accomplish reduction and fixation.

Fractures of the bones of the foot are rather rare accidents, although not so unusual as we once thought, for the *x*-ray has taught us that a considerable number of supposed sprains are, in reality, fractures. Owing to the number of the bones and to the elasticity of their connections the force of blows and falls is spread and dissipated. The bones most often broken are the astragalus and the os calcis. Fractures from direct force are often compound. The *cause* of fracture of either the scaphoid, the cuboid, or one of the cuneiform bones is direct force. Simple fractures of the os calcis and astragalus may arise from crushes or twists of the foot, but result, as a rule, from falls. The calcaneum may be broken by a direct blow. A fractured os calcis is usually much crushed. In rare instances the os calcis has been broken by contraction of the great calf-muscles. Forcible dorsal flexion of the foot may fracture the neck of the astragalus (Eisendrath). Compound fractures may result from gunshot-wounds, crushes, and falls.

Symptoms.—The history of the nature of the accident is of great importance. In fracture of the os calcis there are severe pain, tenderness, swelling, crepitus, mobility, often an apparent widening of the bone, and not unusually a loss of the longitudinal arch of the foot (Pick). The widening can be detected under the outer malleolus, lateral motion in the calcaneo-astragaloid joint is

interfered with (Cotton, in "Annals of Surgery," 1916, lxiv). In some cases the posterior fragment is drawn up by the calf-muscles, and in other cases there is no deformity. In fracture of the astragalus displacement may occur which resembles that of a dislocation. Crepitus may or may not be detected. It can be elicited, as a rule, by rotating the foot while the heel is firmly held. If crepitus cannot be detected we are not certain that a fracture is present, even though the patient may be unable to stand and there are swelling and pain on pressure. The malleoli may seem on a lower level than normal if the astragalus and os calcis have been crushed. Sometimes the foot is shortened and perhaps the fragments have been dislocated (Eisendrath, in "Annals of Surg.," March, 1905). The *x*-rays will make the diagnosis certain. Fractures of the other bones of the tarsus are difficult of detection except by the *x*-rays. There may or may not be crepitus, which, if it exists, is difficult to localize; there is pain on standing and on pressure, and there is bruising of the soft parts.

Treatment.—In simple fracture of the os calcis and astragalus without displacement the usual plan is to place the foot at a right angle to the leg and apply a plaster cast. This is cut down the front so that it may be removed easily. On the third or fourth day follow Eisendrath's advice and begin massage to reduce swelling and prevent muscular atrophy (Ibid.). The cast is worn for eight weeks, when the patient may begin to put weight upon the extremity. The results are often poor. If a flat-foot has resulted from the accident, a support must be worn (see page 833). If there is displacement in a simple fracture of the os calcis or astragalus it is wisest to operate. Perfect correction is not possible otherwise and no apparatus is satisfactory. The fragments are restored after incision and may be sutured, nailed or wired in place. A fragment may require removal or the badly splintered bone itself may have to come away. If the tendo Achillis is torn loose, it should be sutured to the os calcis. In fracture of the os calcis alone Cotton anesthetizes the patient, pulls down the heel, and by lateral pressure and the use of a pad and mallet creates an impaction ("Annals of Surgery," lxiv). Another plan is to cut the Achilles tendon, and while the heel and ball of the foot are being held with a pull toward each other to create the arch, plaster of Paris is applied as high as the knee (Lounsbury, in "Surgery, Gynecology, and Obstetrics," 1916, xxii). Fractures of the other bones of the tarsus are almost always compound, and the injury may require drainage and immovable dressing, excision of bones, or even amputation. If they are not compound, they may be treated by a plaster-of-Paris dressing or may require incision and fixation or removal.

Fig. 438.—Fracture of metatarsal bones.

Fractures of the metatarsal bones are almost invariably due to direct force and are almost always compound. Robert Jones has published skiagraphs of a fracture of the fifth metatarsal bone from indirect force. Crepitus may be absent because of impaction or fixation by interosseous ligaments. Jones says such a fracture may be produced by the pressure of the body weight on an inverted foot the heel of which is raised ("Annals of Surgery," June, 1902). When only one bone is broken, displacement is slight, there is severe pain on motion and pressure, and crepitus can generally be obtained. Pain is produced by flexing the toes, putting weight upon the toes, as in walking, and by inverting or everting the foot. Fracture of the third metatarsal is apt to destroy the arch of the foot. A simple fracture of a metatarsal bone is treated by an immovable dressing for four weeks. Fractures from crushes usually demand excision or amputation.

Fractures of the phalanges of the toes are due to direct force and are often compound. They may require immediate amputation.

Treatment.—In a compound fracture where amputation is unnecessary, drain with strands of catgut for forty-eight hours and dress antiseptically, at the end of this time apply over the bichlorid gauze a gutta-percha or a pasteboard splint extending from beyond the end of the toe to well up upon the sole of the foot, and fix the splint in place with a spiral bandage of the toe and instep. The splint is to be worn for four weeks. In a simple fracture fasten the injured toe to an adjacent toe or toes by a plaster bandage and wear the dressing for three weeks.

Diseases of the Joints

Synovitis is a primary inflammation of the synovial membrane alone. If other structures besides the synovial membrane are involved the condition is known as "arthritis." Two forms of simple synovitis exist—namely, *acute* and *chronic*. Some surgeons speak also of *subacute* cases.

Acute Simple Synovitis.—The *causes* of acute simple synovitis are contusions, sprains, twists, and overuse. The causative influence of exposure to cold or damp has been much debated. It seems probable that in some cases cold produces vasomotor paresis of the vessels of the synovial membrane, a condition which may be followed by inflammation. In synovitis the synovial membrane is red and swollen, and the joint contains an excess of turbid fibrinous fluid. If the inflammation advances, arthritis arises and sometimes blood is effused.

Symptoms.—A prominent symptom of acute synovitis is pain, which is increased by motion of the joint, by pressure upon the articulation, and by a dependent position of the limb. The pain is worse at night. Pressure upon the edge of the cartilage does not cause pain, but friction of the synovial membrane at once develops it. The patient places the limb in the position which gives the greatest ease, and the part becomes more or less fixed in this position because the muscles about the joint are rigid. A fluctuating swelling is noted in a superficial joint, most marked between the ligaments, which swelling bulges out the synovial area and hides or obscures the articular heads of the bones. The swelling is due early to excessive secretion of synovia, and later to effusion of liquor sanguinis. Bulging takes place at points where the capsule is thin, and at such points fluctuation may be detected. Fluctuation in the elbow is sought for posteriorly. Fluctuation in the knee is sought for on either side in front. A large effusion in the knee floats the patella up from the condyles (*floating patella*). A small effusion in the knee can be detected by Fiske's plan, which is as follows: Tell the standing patient to bend forward at the hips, resting each hand on the front of the corresponding thigh. The anterior structures of the joint are thus relaxed, and, by tapping the patella, even a small effusion can be discovered. Bulging cannot be distinctly recognized in the hip or shoulder unless effusion is great. The skin over the joint is rarely reddened, but feels hot to the hand of the observer (over superficial joints, but not over the shoulder and hip); the joint is partly flexed; fever exists, varying in degree with the size of the joint, the acuteness of the attack, and if infection occurs fever is a striking feature. Suppuration rarely follows simple synovitis, but it may do so, the area of synovitis being a point of least resistance to organisms carried by the blood or lymph. If suppuration takes place, rigors occur, there is a septic temperature, and the joint soon gives evidences of containing pus. These evidences are violent pain, increased tenderness, dusky discoloration if the joint be superficial, greater muscular spasm, periarticular edema, and constitutional symptoms of sepsis. Traumatic synovitis without infection tends toward cure without suppuration if the patient is healthy, and after it ankylosis is rare.

Treatment.—In treating acute synovitis immobilize the joint. In severe cases place it in such a position that the limb will still be useful even if ankylosis occurs. In mild cases immobilize in the position of rest, apply leeches, and use the ice-bag or the Leiter coil for a few hours. After a day or two apply gentle pressure, intermittent heat, and iodin and ichthyol. If the effusion is very great and persistent, and pressure, heat, and sorbefacients fail to remove it, aspirate with aseptic care. If effusion recurs after aspiration, use massage and the hot-air oven, or apply plaster-of-Paris dressing or use flying-blisters. If there is any evidence of infection, follow Murphy's advice, that is, aspirate the joint and inject a mixture of formalin in glycerin (2 per cent.). As a rule this treatment will rapidly bring about a cure. The mixture of formalin and glycerin should have been made at least twenty-four hours before use. A rubber bandage is often useful toward the termination of a case of acute synovitis.

Chronic synovitis follows acute synovitis or it may be chronic from the start. Many cases called chronic synovitis are, in truth, tuberculous disease. The synovial membrane looks nearly natural, but is edematous, and the joint contains an excess of fluid. If the quantity of fluid is large, the disease is called *hydrops articuli*, or *dropsy*. A large amount of fluid in the knee-joint "floats" the patella upward. Tuberculous infection may occur in very prolonged cases. In prolonged tuberculous synovitis the synovial membrane may thicken in some places, soften in others; it is often adherent, and the villous processes hypertrophy. If the membrane becomes extensively softened (*pulpy degeneration*), the softened areas bulge and caseation eventually occurs. In the knee-joint a traumatic synovitis is sometimes linked with *inflammation of the semilunar cartilages*. Roux tells us that this inflammation may be produced by a squeeze, a twist, or a direct force, but a squeeze is the common cause. Hyperextension of the knee may squeeze the cartilage, and so may attempting to rise from a stooping posture.[1] If this injury has taken place, the disability will be prolonged.

Symptoms.—In chronic synovitis pain may be absent or may be present only during exercise or from pressure, and be slight even then. There may be seizures of pain; there is some limitation of movement; passive motion may develop creaking or joint-crepitus; fluctuation is apparent and there is atrophy in the muscle about the joint. The atrophy of the muscles associated with an inflamed joint is a reflex atrophy and is named after Charcot. The aspirating needle will give exit to a viscid straw-colored or bloody fluid unless the material is gelatinous.

Treatment.—Rest and pressure are of great service. Pressure may be obtained by the application of Martin's rubber bandage. A plaster-of-Paris dressing is probably the best way to combine rest and compression. Massage, douches, frictions, passive movements, and flying blisters should be used. Painting the joint with iodin and spreading over it blue ointment, and rubbing in ointment of ichthyol (50 per cent. with lanolin) may do good. Counter-irritation by the actual cautery is a valuable expedient. The Bier treatment (see page 122) is often of benefit. Injections of dilute carbolic acid in the parts about the joint rapidly relieve the pain (see page 727). Some surgeons advise aspiration, washing out with salt solution, injecting a 5 per cent. solution of carbolic acid or formalin-glycerin (2 per cent.), and immobilizing. Incision and drainage constitute a radical but proper plan in cases in which simpler methods have failed. If pulpy degeneration exists, perform an excision or an erasion. If pus forms, incise at once and drain. Internally, treat any existing diathesis and give nutritious food, tonics, and stimulants. Chronic synovitis is often greatly benefited by the use of a hot-air apparatus. The limb is wrapped in flannel and is placed in an oven. The oven is heated by Bunsen burners. The temperature is raised to 250° or even 300° F., and the limb is subjected to

[1] "Gaz. des Hôp.," No. 125, 1895.

this for one hour. The oven should be used daily, and as the patient becomes accustomed to it even a higher degree of heat can be tolerated. This high degree of heat can be borne only when it is perfectly dry. Any moisture scalds the patient. The Lentz oven has in it ventilation openings to get rid of moisture and the sweat is taken up by the flannel. The flannel must not be applied so thickly as to keep the heat notably from the joint, nor must so little of it be used as to permit of its soaking with sweat. Fig. 439 shows the Sprague hot dry-air apparatus. Dr. H. A. Wilson inserts in the oven humidin, a product obtained in the purification of salt, which absorbs the moisture entirely. Cotton should not be used to wrap the limb, because, if the bottom of the oven becomes very hot, the cotton may ignite and burn the patient. A physician or nurse should constantly watch the apparatus during its employment.[1] Bier's box is of wood lined with asbestos. It is heated through a flue by gas or alcohol lamps. Aspiration and the subsequent use of a plaster-of-Paris bandage may be tried in lingering cases of chronic synovitis.

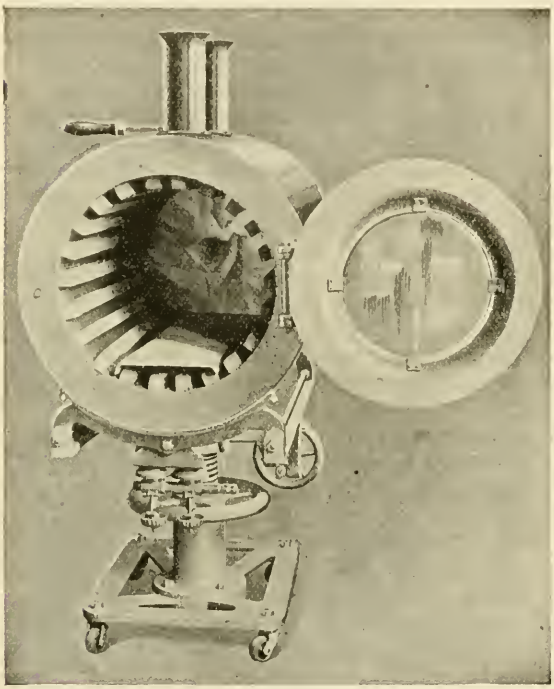


Fig. 439.—Sprague hot dry-air apparatus.

Arthritis.—By this term is meant not only inflammation of a synovial membrane, but also of other structures composing and surrounding a joint. It may follow traumatic synovitis; it may be due to pus-organisms, to tubercle bacilli, to infectious diseases (gonorrhea and typhoid fever), to rheumatism, to gout, to syphilis, and to lesions of the spinal cord. Arthritis may be either acute or chronic.

Poncet's Tuberculous Arthritis (*Tuberculous Articular Rheumatism*, see page 275).—It was pointed out by Grocco in the early 80's that tuberculous patients may develop joint disease without tubercles, cold abscesses, or destruction of the joint. Poncet, of Lyons, has written extensively on this subject. He maintains that joint inflammation is often the first evidence of extra-articular tuberculosis or of a distant latent lesion of tuberculosis. The joint inflammation is due to toxins, the joint fluid does not contain bacilli, and tubercles do not develop in the joint structures.

Such a joint may eventually develop into a true tuberculous joint with bacilli and tubercles. In many cases the joint recovers, with some stiffness or perhaps even ankylosis. The process may be acute, subacute, or chronic. One joint only may suffer. Several or most of the joints may be simultaneously involved. It is most apt to arise after an operation on tuberculous glands or bone. Fever exists in Poncet's arthritis. Matas ("Southern Med. Jour.," Oct., 1911) thus describes tuberculous rheumatism:

"It may be a flitting arthralgia, a mere soreness, a dropsical synovitis, or

[1] H. A. Wilson, in "Annals of Surgery," Feb., 1899.

it may persist as a hypertrophic or atrophic arthritis. It may present itself as a progressive polyarthritis deformans or as a dry senile arthritis (morbus coxarius senilis). The acute, as well as the chronic, form of this type of rheumatism may end in ankylosis. Many cases of spinal rigidity, spondylosis, scoliosis, painful flat-foot, genu valgum, coxa vara, and even certain cases of dry otitis media with ankylosis of the ossicles of the ear, and, in fact, all the osteo-articular affections of childhood and adolescence associated with defective osteogenesis, may owe their origin to the disturbing influence of a latent or obscure tuberculous toxemia.

"The most benign of the tuberculous rheumatic affections is a simple arthralgia—a sore or painful joint. There is pain without any objective signs, and yet this is often the precursor of a manifest visceral tuberculosis. The acute and subacute forms of the disease are usually confused at the bedside with the manifestation of ordinary acute rheumatism. Nevertheless, the clinical picture of acute tuberculous rheumatism is distinctly graver; there are fever, rapid pulse, profuse sweats, and frequent attacks of dyspnea. This is brought about by associate general infections involving the serous cavities, the pleura, peritoneum, pericardium, and the meninges. But in the majority the evolution of the disease is slow and more benign. The joint symptoms appear in successive stages separated by intervals of rest more or less long, and are distributed over various joints, ending ultimately in ankylosis. The disease is more often chronic, and many patients either recover altogether or remain permanently crippled or deformed; others die of marasmus or complications from associate visceral disease. Therapeutically, this form of rheumatism is not relieved by any of the usual antirheumatic remedies, and is improved or cured solely by treatment which aims at the cure of the tuberculous infection."

Fig. 440.—Tuberculous arthritis of wrist.

Tuberculous Arthritis (*White Swelling*, so christened by Richard Wiseman; *Strumous Joint; Pulpy Degeneration*). *Pathology and Symptoms.*—The predisposing causes of tuberculous arthritis may be strains, blows, twists, or cold (see page 247). The real cause is the tubercle bacillus. A single joint is attacked. Other joints may subsequently become involved so that several suffer simultaneously, but it is rare that the process is active in more than one joint at the same time. During the course of tuberculous disease of a joint (except of the shoulder-joint) phthisis is not common, although it may develop after the joint gets well. The same is true of tuberculous glands. During the existence of

phthisis or tuberculous glands, tuberculous arthritis does not frequently arise. The primary infection with tubercle bacilli is usually in the bone, though it may be in the synovial membrane, the joint-capsule, or the structures about the joint. The frequency of the bony origin of tuberculous arthritis is shown by John B. Murphy's statement that in 128 cases of tuberculosis of the knee it was demonstrated in all but 2 that the condition originated in the bone ("Jour. Am. Med. Assoc.," May 20–27, June 3, 1905). If the primary infective focus is in the bone, a portion of the cartilage undergoes destruction and the joint is opened, or a sinus forms and perforates the synovial membrane. When tuberculous inflammation attacks the synovial membrane granulation tissue is formed, and the capsule and periarticular structures soon become involved in the process; the parts thicken and soften from caseation, and they may be covered with tubercles, though but little fluid is usually effused into the joint. Some few cases present large joint effusions, but in most cases fluctuation is absent. Capsular thickening may or may not be manifest. Soon after tuberculous arthritis begins the joint becomes rigid, irritation having induced muscular spasm. This reflex rigidity fixes the joint more or less completely, and atrophy of the rigid muscles soon begins. There is usually some pain in tuberculous arthritis; it is seldom marked except on motion or when the epiphysis is involved, and it may be referred to a distant part. For instance, in hip-joint disease the pain is often referred to the inner side of the knee, and in Pott's disease of the spine the pain may be referred to the abdomen. A cardinal symptom of tuberculous disease of a joint is localized tenderness. In other types of infection the tenderness is widespread. Attempts at motion demonstrate the limitation of movement due to muscular rigidity and also produce pain. A child that suffers from a tuberculous joint is apt to be restless in sleep, moaning and tossing, and to wake at times crying out in terror (*night-cries* and *night-terrors*). In the ordinary form of tuberculous arthritis there occurs what is known as *gelatiniform degeneration;* the granulation tissue is formed in large amount as fungous growths; the structures are markedly edematous and softened; the relaxed ligaments yield under pressure; the natural contour of the joint is lost and it becomes spindle shaped; all the structures, articular and periarticular, are glued into one mass; the skin about the joint is white, thick, and adherent, and in it one or more large veins are seen; fluctuation or pseudofluctuation is noted when caseation has occurred; pain is not often severe, but it can usually be elicited by certain motions or by firm pressure, but the pain will always be severe when the epiphysis is involved; the temperature of the part is seldom elevated; deformity results from destruction of bone, cartilage, and ligament, from muscular spasm, and from the habitual assumption of certain attitudes to secure relief from pain. There is soon impairment of joint motions. When the products of a tuberculous arthritis caseate the thick liquid seeks exit by forming sinuses, and from them caseous pus flows. If a sinus becomes infected with pyogenic cocci, and the joint itself becomes their prey, acute suppuration arises in the joint, and constitutional involvement is pronounced and perilous to life.

In *pannous synovitis* a large effusion is formed, there is but little granulation tissue, though the tubercles are present in large numbers, and the ligaments and structures about the joint are slightly or not at all implicated.

Diagnosis and Prognosis.—Tuberculous chronic synovitis produces great swelling and distinct thickening of the capsule with obliteration of the outlines of the joint, no severe pain, and no tendency to early subluxation. Tuberculous arthritis rarely causes distinct fluctuation, does not thicken the capsule, causes reflex muscular spasm, rigidity of the joint, muscular atrophy, severe pain on movement, and eventually subluxation (Shaffer). In syphilitic arthritis there is usually some fluctuation, distinct enlargement of the joint, limitation

of motion, no reflex spasm, trivial atrophy, but distinct pain on motion (James K. Young, "Therapeutic Gazette," June 15, 1902). Acute rheumatism attacks more than one joint, is very rare in children under five, and produces high fever. The *x*-rays aid in the diagnosis of tuberculous arthritis and enable us to tell the extent of bone involvement.

The diagnosis of a tuberculous joint is often difficult, and sometimes impossible, and the prognosis is always grave. In only a very few cases, even when recognized early, is a cure obtained without some impairment of joint function. The best that can usually be accomplished is a cure with more or less ankylosis, fibrous or bony; and often ankylosis is complete. Long after the disease is apparently cured, it may break forth anew. Tuberculous lesions may arise in a distant organ or general tuberculosis may occur. Caseation is apt to produce severe constitutional disorder. Infection by pus organisms gives rise to grave danger of septicemia. Death is not unusual from exhaustion, from septicemia, from disseminated tuberculosis, from tuberculosis of an important organ, or from amyloid disease.

Treatment.—No serum or vaccine is of any proved value. Many surgeons believe in small doses of tuberculin but Ridlon says: "Tuberculin in harmless doses is useless; administered in larger doses it is both dangerous and harmful." It seems to do harm in articular cases with fever, in very late cases and in very early cases. Conservative treatment is especially successful in children. According to Hoffa, in 75 per cent. of cases in children non-operative treatment will produce cure ("Die Bekampfung der Knochen- u. Gelenktuberculose in Kindesalter Tuberculosis," iv, 1, 1905). The conservative treatment consists in open-air life, if possible in a sanatorium, the following of the plans outlined under Tuberculosis, heliotherapy, immobilization and extension of the joint, and injections of iodoform emulsion or formalin-glycerin (2 per cent.). Even when tuberculous pus forms, the same treatment may be followed unless there is violent pain or elevated temperature which does not quickly abate, in which case operation must be performed. Cases treated early by conservative methods may get well with a movable joint, but in most cases there is a stiff joint when the disease is arrested. Constitutionally, the treatment is directed against the tuberculous diathesis. The patient should be placed under good hygienic conditions. A change of climate is often of the greatest importance. Many cases do well at the seaside; others require high altitudes, and all should live in the open air. The value of sunlight is set forth on page 256. It causes local hyperemia which is bactericidal, stimulates oxidation and metabolism and produces lymphocytosis of the peripheral blood after one hour's exposure (Taylor, in "Internat. Abstract of Surgery," July, 1915). Personally I have only used local exposure beginning with a few minutes and reaching three or four hours a day taking care that the skin is not hurt and avoiding burning by using talcum powder freely for the first week (Taylor, in "Internat. Abstract of Surgery," July, 1915). A hat should be worn and if necessary goggles. Electric light has been used instead of sunlight. The Finsen light, too, is of service. The Röntgen rays may prove of great value in synovial tuberculosis and in very chronic sinuses. Treatment by tuberculin is considered on page 258. Locally, rest is of the first importance, and fixation is maintained for many weeks. Rest is best secured by immobilization and traction, and traction is applied or maintained by splints, by plaster-of-Paris bandages, or by extension appliances. The hot-air apparatus may be of some benefit. If it is employed, it should be used daily, the limb being immobilized during the remainder of the twenty-four hours. Fixation must be maintained as long as pain exists or muscular spasm is present. Fixation must be abandoned gradually, and mobility is to be slowly regained. During restoration to mobility, if pain arises, the part must be immobilized temporarily. Movements should never be violent, prolonged, or repeated at too

close intervals. Forcible breaking up of an ankylosis is never advisable in the knee, ankle, or hip; it is seldom advisable in the wrist, elbow, or shoulder. Such an attempt may be followed by a fresh outbreak of the disease. Osteotomy or resection will more safely correct a faulty and disabling deformity. In a tuberculous joint injection of formalin-glycerin, as advised by Murphy, is a valuable procedure. Several or a number of injections may be made. The joint is aspirated and the mixture introduced. About 4 drams are used in the knee, about 2 drams in the ankle. After injection extension is applied. The mixture used must be at least twenty-four hours old. In tuberculous joints intra-articular injections of iodoform are often of the greatest value. This drug strongly stimulates the formation of fibrous tissue. If sufficient fibrous tissue is formed the tuberculous foci will be firmly encapsuled and the case will be cured. Iodoform is particularly called for when no bone disease is shown by the *x*-ray or discovered by incision. The joint is incised, adhesions are gently broken up, the capsule is sutured except for a small space, the nozzle of a syringe is inserted and a mattress suture draws the capsule tightly about the nozzle (Brackett's plan). The emulsion is injected under tension and then the capsule is closed tightly. In a large joint a 4 per cent. emulsion is used; in a small joint a 10 per cent. emulsion. The part must not bear weight for six months. Bier's plan of inducing passive hyperemia is often of great service (see pages 122–125). Aspiration or incision can be used for fluid accumulations. Caseous masses are often let alone, or an aspirator is used and the joint drained, washed out with saline solution, and injected with an emulsion of iodoform and glycerin (10 per cent.). From 1 to 2 drams are injected into the joint of a child, from 2 to 5 drams into the joint of an adult. Even surface lesions are not curetted. Bier's treatment should be associated with immobilization and systemic treatment. It is more serviceable in tuberculosis of the small joints than in disease of the large articulations. There are certain contra-indications to Bier's treatment, viz.: serious pulmonary involvement, extensive amyloid degeneration, and the existence of such an unfavorable position of the parts that cure by ankylosis would mean a less useful limb than cure by resection (Bier at Internat. Surg. Congress of 1905). One advantage of this treatment is that we can employ active and passive motion early, except, according to Bier, when the foot or knee is diseased. Even in very serious cases cure may be obtained without any limitation of activity, and as the patient can get about it is not necessary to restrain him long in a hospital. Bier advocates his suction apparatus to empty sinuses. The enthusiasm for Bier's hyperemia has largely waned. It finds its best field in elbow and wrist cases (Taylor, in "Internat. Abstract of Surgery," July, 1915). Personally I believe that fixation should be the basis of treatment in most cases, and that passive hyperemia, compression, counterirritation, heliotherapy, radiotherapy, and intra-articular injections may be used as additions to fixation. Injections of balsam of Peru or of iodoform emulsion about the joint once a week are efficient in some prolonged cases, but are not to be used early. It is not wise to attempt to correct faulty position until the focus is well.

Fistulæ are frequently treated by the method of Beck, of Chicago, that is, by the injection of a paste containing bismuth. In early cases a bismuth-vaselin paste is used, in late cases a bismuth-wax-paraffin paste.

Beck described his method in the "Illinois Med. Jour.," April, 1908. The vaselin paste is composed of 30 parts of subnitrate of bismuth and 60 parts of vaselin, mixed and well stirred while boiling. The paste for later cases is composed of 30 parts of subnitrate of bismuth, 5 parts of white wax, 5 parts of soft paraffin, and 60 parts of vaselin, mixed while boiling. One per cent. formalin is often added to these pastes. The paste is injected before an *x*-ray picture is taken, and the picture shows all the ramifications of the fistula. The paste is left in for treatment. If a sequestrum exists it should be removed before

the paste is injected. It is not necessary, but is advisable, to dry the fistula before injecting.

The paste is sterilized before using. It is sucked up into the syringe while still liquid and is cooled to the requisite temperature and hardened to the proper consistency by running cold water over the syringe. It is injected very slowly and the injection is continued until a sense of pressure annoys the patient. Then the syringe is laid aside, a bit of gauze is held for a time over the outlet of the fistula to keep the paste from running out, and an ice-bag is put over the region to harden quickly the injected material. There is no pain from such an injection. Beck employs the first paste until pus disappears and then uses the second.

The value of this paste is that it distends and fills the abscess-cavity and sinus, and affords a trestle or frame for granulations to grow upon. A considerable amount of the paste may run out of the fistula during the first twenty-four hours. In shallow sinuses it all runs out. In deep and tortuous fistulæ much of it remains for weeks and is slowly absorbed. In empyema and bone-cavities it is slowly absorbed. Beck holds that the paste is bactericidal, astringent, and non-toxic. Cases of pigmentation of the lips, gums and cheeks, and cases of ulceration in the mouth from absorption of bismuth have been recorded, and at least 8 deaths are on record (Reich, in "Beiträge zur klinischen Chirurgie," Nov., 1909). Beck limits the first dose to 100 gm., but increases the amount later. Because of possible danger of poisoning Blanchard uses a paste of white wax and vaselin without bismuth. Not over 4 oz. of bismuth paste should be injected. As Bell points out, if a large quantity is injected an opening must be left. This precaution may prevent poisoning. Some think the poisoning is due to bismuth, others believe it is due to arsenic held as an impurity. David and Kauffman ("Illinois Med. Jour.," Oct., 1909) point out that there may be acute cases of poisoning which are liable to be fatal, and chronic cases which tend to recovery. In an acute case of bismuth-poisoning there is pigmentation of the gums, ulcerative stomatitis, dyspnea, delirium, and albuminuria. David and Kauffman regard pigmentation of the gums, lips, or cheeks as an indication of toxic action and a sign to discontinue the drug. The use of bismuth paste is undoubtedly a valuable method. I have seen sinuses heal under it after they had resisted various other plans of treatment. It may be used in sinuses, cold abscesses, empyemata, tuberculous joints, and other conditions. Ridlon and others have obtained with plain vaselin results as good as have been obtained by the use of Beck's paste.

If these means fail, if the patient gets worse, if there is persistent fever or violent pain, if sequestra exist, if there is mixed infection, or if the condition of the sufferer renders dangerous the prolonged conservative course, operate, removing the entire diseased area by erasion, by excision, or possibly by amputation. If the *x*-ray picture shows extensive sequestrum formation, operation is indicated. If amyloid degeneration exists, conservative treatment is contra-indicated and so is resection. Amputation must be done. Always remember that an incomplete operation or a partial removal, unless it consists of simple drainage, is worse than no operation, as it opens the portals to systemic infection, and may be responsible for the development of general tuberculosis, septicemia, or pyemia. Simple drainage, as previously stated, is seldom advisable. Garré is of the opinion that the hip, wrist, and shoulder do best by conservative treatment; the knee, elbow, and ankle, by operative treatment (John W. Churchman, in "Am. Medicine," April, 1906). Many mobilizing operations have been done for stiff joints and in many cases the results have been imperfect and disappointing. Certain it is that no tuberculous joint should be subjected to this operation until the disease is soundly cured.

It is small advantage to substitute a movable and painful for a stiff and painless joint. The results are far better in cases of traumatic ankylosis.

Tuberculosis of Special Joints; Tuberculosis of the Vertebræ (see page 951).—**Tuberculosis of the Sacro-iliac Joint** (*Sacro-iliac Disease*).—This is an uncommon affection, and is especially rare before the age of fifteen. The disease may begin in the joint, may arise in adjacent bones, or may result from a cold abscess burrowing into the joint. In some cases it is associated with extensive disease of the pelvic bones. The disease, if undetected, may lead to dissemination of tubercle, to abscess, or even to death.

Symptoms are often obscure. The disease is frequently confounded with vertebral caries, hip-joint disease, or sciatica. The patient limps on walking, the joint has a feeling of insecurity, especially on ascending stairs or carrying a weight, but can stand on either leg. There is pain in the sacro-iliac joint, about the hip, and down the back of the thigh and occasionally also along the front of the thigh. Pain may be complained of about the knee. Pain may be increased by a jar, a misstep, perhaps by coughing or sneezing (Howard Marsh, on "Diseases of the Joints and Spine"). Tenderness is manifest on pressure over the joint and on pushing the ilia together; there may be fulness over the sacro-iliac joint, but the hip is not flexed unless iliac abscess exists.[1] The thigh is usually extended. There may be apparent lengthening. Muscular wasting, especially of the gluteal region, is apparent. Frequently a diagnosis of sciatica is made. I have known appendicitis mistaken for sacro-iliac disease. Sometimes a diagnosis of hip-joint disease is made, sometimes of lumbar caries.

Treatment.—Rest in bed for months, using also a felt case for the pelvis. Counterirritation by blisters and the actual cautery. In some cases injection of formalin-glycerin or of iodoform; in others, incision and curetting. I have operated on 9 cases, with 1 death. In 1 case in the Jefferson Medical College Hospital the abscess was pointing in both the back and groin. Both areas were incised, the diseased bone was removed, and the boy ultimately recovered. In another case the abscess pointed in the groin. The treatment was as previously set forth, and the patient, a woman, recovered. The best way to reach the joint is to chisel or bore through the ilium above the great sacrosciatic foramen.

Tuberculosis of the Hip-joint (*Hip Disease; Morbus Coxarius; Morbus Coxæ; Hip-joint Disease*).—The primary lesion may be in the synovial membrane, but it is more often in the bone. It may begin in the acetabulum; it may begin in the femur. In 95 per cent. of cases it begins in the head of the femur. If it begins in the femur, it usually arises on "the distal side of the epiphyseal cartilage" (Senn). Sometimes primary tuberculosis arises in the trochanter major, and never involves the joint. When the synovial membrane becomes involved at any point, spread throughout the joint is rapid. In many cases the articular cartilages are attacked, and in some cases the epiphyseal cartilage is destroyed. It is commonest in children, but it may arise in adults and even occasionally in those of advanced years; 62 per cent. of cases arise in children under ten years of age and 80 per cent. of cases occur before the twentieth year (Bryant). Traumatism and cold may be predisposing causes. The disease strongly tends to caseation and the formation of sequestra.

Symptoms.—It has been usual to divide the disease into three stages: (1) the stage of microbic deposition and multiplication, the products of the bacilli causing irritation and new growth; (2) the stage of progression, with formation of masses of granulation tissue and effusion into the joint, and (3) the stage of caseation, with destruction of the joint and often of the structures about it. Bradford and Lovett[2] protest against this. They say: "It has been customary to divide hip-disease into stages, and to ascribe to these stages certain definite symptoms. Neither from a clinical nor a pathological point of view is it

[1] See A. G. Miller, "Edinburgh Med. Jour.," May, 1895.
[2] "Orthopedic Surgery."

desirable to attempt such a division." As H. Augustus Wilson says: "Tuberculous bone and joint disease should be considered as the primary invasion or incipiency, and all other symptoms should be regarded as results and not as an integral and necessary part of the trouble."

The symptoms of incipient coxalgia are slight and may be overlooked entirely. In a child there are night-terrors; on getting about in the morning the child shows no lameness, but a limp develops during the day, and the little one soon grows tired while playing and lies down to rest. There is a slight limp; some muscle spasm may be noted, and pain may be complained of at night in the hip, in the front of the thigh, or at the inside of the knee. Tapping the sole of the foot, the thigh and leg being extended, may develop pain, just as it will develop pain in any inflammatory involvement of the joint, but the employment of this method is objectionable. It may injure a joint already damaged by the tuberculous process, and it gives no information which cannot be obtained by a safer mode of investigation. After all, pain on tapping the sole of the foot means only what muscular rigidity means, and muscular rigidity is always present and is easily demonstrable by careful manipulation. The diagnosis of incipient coxalgia is more or less problematical.

As the disease progresses more positive symptoms are observed. The limp grows worse; the hip is broadened by an effusion into the joint, and fluctuation may possibly be detected; the thigh muscles atrophy; the extremity is pushed forward, abducted, and everted. The position is described as flexion, abduction, and outward rotation (Fig. 441). This position may not be obvious; in fact, the limb may be extended by the side of the companion extremity. When it is, there is a forward curve of the lumbar spine (lordosis) and a lateral curve of the lumbar spine, which raises the pelvis on the sound side and depresses it on the diseased side. These lumbar curves serve to bring the femur toward the middle line, give the extremity the appearance of being lengthened, enable the sufferer to walk (Fig. 441), and cause him to rest his weight on the sound limb. Apparent lengthening means abduction. In some few cases adduction exists rather than abduction. The abduction, which is usual, releases tension of the fascia lata, and thus abolishes pressure upon the joint through lessening of pressure upon the great trochanter, and also relaxes the outer portion of the Y-ligament and the ligamentum teres. The flexion relaxes the anterior portion of the capsule and the psoas muscle and prevents pressure of its tendon upon the front of the joint. Outward rotation relaxes the inner portion of the Y-ligament and the posterior portion of the capsule. Pain exists, often sudden or starting, and is located in the joint, on the front of the thigh, and to the inner side of the knee in the course of the obturator nerve; the pain is aggravated at night, and full extension and complete abduction are not possible. The gluteal muscles waste, and the gluteal crease is on a lower level than is that of the sound side. The gluteal crease may be nearly or quite effaced because of hypertrophy of the subcutaneous layer (Alexandroff), or from slight flexion of the leg (McClellan). As the disease progresses adductor spasm causes adduction, and the limb is flexed, adducted, and apparently shortened. This apparent shortening is accomplished by a lateral curvature of the spine, which keeps the limb from crossing its fellow and being useless. It does so by raising the hip of the diseased side and drawing the femur outward (Fig. 441). This causes apparent shortening (Howard Marsh, in Treves's "Manual of Surgery"). The above symptoms arise chiefly from unconscious efforts to obtain ease, from joint-effusion, reflex irritation, and involuntary or spasmodic muscular contractions. There is an appearance of lengthening or shortening, but it is only apparent, not real. The real position is shown on Plate 8, Fig. 4. The fluid effusion may be absorbed or may find its way externally by means of sinuses. The latter condition is known as *abscess of the hip*. The absorption of the exudate or the rupture of the capsule permits the con-

tracting muscles to bring the head of the femur into firm contact with the acetabulum or its brim; the bones are worn away and destroyed, real shortening results, there is adduction, and flexion is increased as shortening becomes more marked.

In advanced cases of coxalgia the head of the femur passes upward and outward upon the rim of the acetabulum, the thigh is flexed and fixed, and attempts at extension when the patient is recumbent cause the pelvis to tilt forward and occasion a marked lumbar curve (lordosis) (Pl. 8, Fig. 2), which is due to the pelvis moving with the femur as if ankylosed, and which disappears on flexion. In this condition adduction occurs because of the ascent and movement outward of the head of the bone. Shortening is marked. After a hip abscess finds an external outlet pyogenic infection is very apt to take place and suppuration arises, which is followed by that state which is designated as "hectic." If a cure follows advanced coxalgia, partial or complete ankylosis takes place; if death ensues, it may be due to septicemia, tuberculosis of the viscera, exhaustion, or amyloid degeneration.

Diagnosis is very easy in well-established cases of hip-disease, but very difficult when the disease is incipient. Always make a systematic and thorough

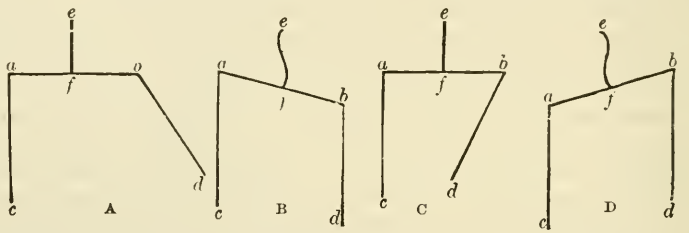

FIG. 441.—Positions in hip-joint disease. A: *e–f*, lumbar spine; *b–d*, limb fixed in flexion and abduction, useless for walking. B: *e–f*, lumbar spine. Patient corrects the condition in Figure A by curving the lumbar spine forward and rotating the pelvis on its transverse axis, thus making the femur point downward. The lumbar spine is curved laterally, the pelvis ascending on the sound side and descending on the affected side (apparent lengthening). C: *b–d*, limb fixed in flexion and adduction. D: *e–f*, curve of lumbar spine to correct condition in Figure C (apparent shortening). (After the plan of Howard Marsh and Treves.)

examination. Undress the patient and place him recumbent with his legs extended upon a table or a hard mattress. Note if the heels are level and if the iliac spines are on the same level (a depressed spine on the affected side means abducted extremity, the degree of which is determined by carrying the limb out until the spines are horizontal; elevation of the iliac spine on the affected side means adduction, the amount of which is determined by adducting the limb until the spines are horizontal, Fig. 441). The amount of flexion is ascertained by lifting the knee until the curved spine has become straight. Try all the movements belonging to the joint, to detect any limitations; observe if bringing down the knee produces lordosis; look for swelling and for muscular wasting; feel if the head of the bone is enlarged; determine if motion produces pain or if pressure develops tenderness; and always carefully elicit the history of the attack, of the person, and of the family.

Hip disease may be confounded with spinal caries in which a psoas or a lumbar abscess has formed, with sacro-iliac disease, with infantile paralysis, with congenital dislocation of hip, with lordosis from rickets, with gluteal abscess, and with bursitis of the gluteal bursæ. In hip disease there is always some lameness; pain may be severe, may be trivial, or may be absent entirely, and may be in the hip or be referred to the front of the thigh or the inner side of the knee. Always remember that the pain is not characteristic, and that pain in the same localities may arise from aneurysm of the femoral or iliac arteries, from abscess in Scarpa's triangle, from caries of the lumbar vertebræ,

from sacro-iliac disease, and from cancer of the rectum. Altered position of the limb, limitation of movement in the hip-joint, muscular wasting, and swelling soon arise in hip-joint disease.

In disease of the sacro-iliac joint examination shows that the movements of the hip-joint are unlimited and produce no pain, and that pain is developed by pressure over the sacro-iliac articulation and by pressing the ilia together. In infantile paralysis there is no pain, but there is paralysis with great muscular atrophy, which comes on with considerable rapidity. In spinal caries with psoas abscess the evidences of disease of the vertebræ are clear and a collection of fluid is located in the groin external to the femoral vessels. The tuberculous pus of hip abscess generally gathers under the tensor vaginæ femoris muscle, but it may reach Scarpa's triangle by passing through the cotyloid notch or through the bursa under the psoas muscle; it may even appear under the glutei. Matter from a caseating acetabulum may reach the interior of the pelvis and appear above Poupart's ligament.

Fig. 442.—Thomas's posterior splint.

In gluteal bursitis the symptoms last for many months, and do not remit as the symptoms of early hip disease are apt to do. The pain is but moderate, and is aggravated by exercise, but passes away on going to bed, and is felt back of the hip and back of the knee. There is a certain amount of limitation of motion and there is a positive limp, which arises early. In marked cases fluctuation can be detected in the upper gluteal region.[1]

Prognosis.—If the case of hip disease is seen early the chances of cure are excellent in children, in whom the disease may be arrested at any stage. The longer the duration of the disease and the older the subject, the more unfavorable is the prognosis. Many months will elapse before a cure can be effected, and advanced cases only get well by means of ankylosis with shortening and deformity. Hip disease may recur years after apparent cure, and a person who has or has had hip disease runs a chance of developing visceral tuberculosis.

Complications.—The complications that may accompany hip disease are the following: *Abscess*, as above noted. *Tuberculous meningitis*, or the condition known as "acute hydrocephalus" or "water on the brain," may arise during the progress of the case or after apparent cure, and is apt to ensue upon incomplete operations. It is almost inevitably fatal. *Phthisis pulmonalis* is a rare complication, but a not uncommon sequence, perhaps arising, sooner or later, after the hip disease has been cured *Amyloid*, *lardaceous*, or *waxy degeneration of viscera* (see page 265) follows upon profuse and long-continued suppuration and is apt to arise in the liver, spleen, kidneys, or intestinal mucous membrane. Tuberculosis is not the only cause of amyloid degeneration, syphilis being responsible for at least 30 per cent. of all cases. In amyloid disease of the liver the organ is much enlarged, smooth, painless, and of increased consistency; there is no jaundice, the spleen is apt to be enlarged, and albuminuria is the rule. In amyloid kidney large amounts of pale urine of low specific gravity are voided; albumin is usually present in large amount, but may be absent; globulin may often be found, as may also hyaline, fatty, or granular casts; the patient is anemic and dropsy usually exists. Test the hyaline casts with iodin for amyloid material. Amyloid changes are usually slow in onset, but they may be rapid; they are commoner in men than in women, and are

[1] See E. G. Brackett's important paper on "Gluteal Bursitis" in the "Transactions of the American Orthopedic Association," vol. x.

most frequently encountered in individuals between the ages of ten and thirty. Slight amyloid change may be recovered from, but an extensive degeneration brings about a fatal result.

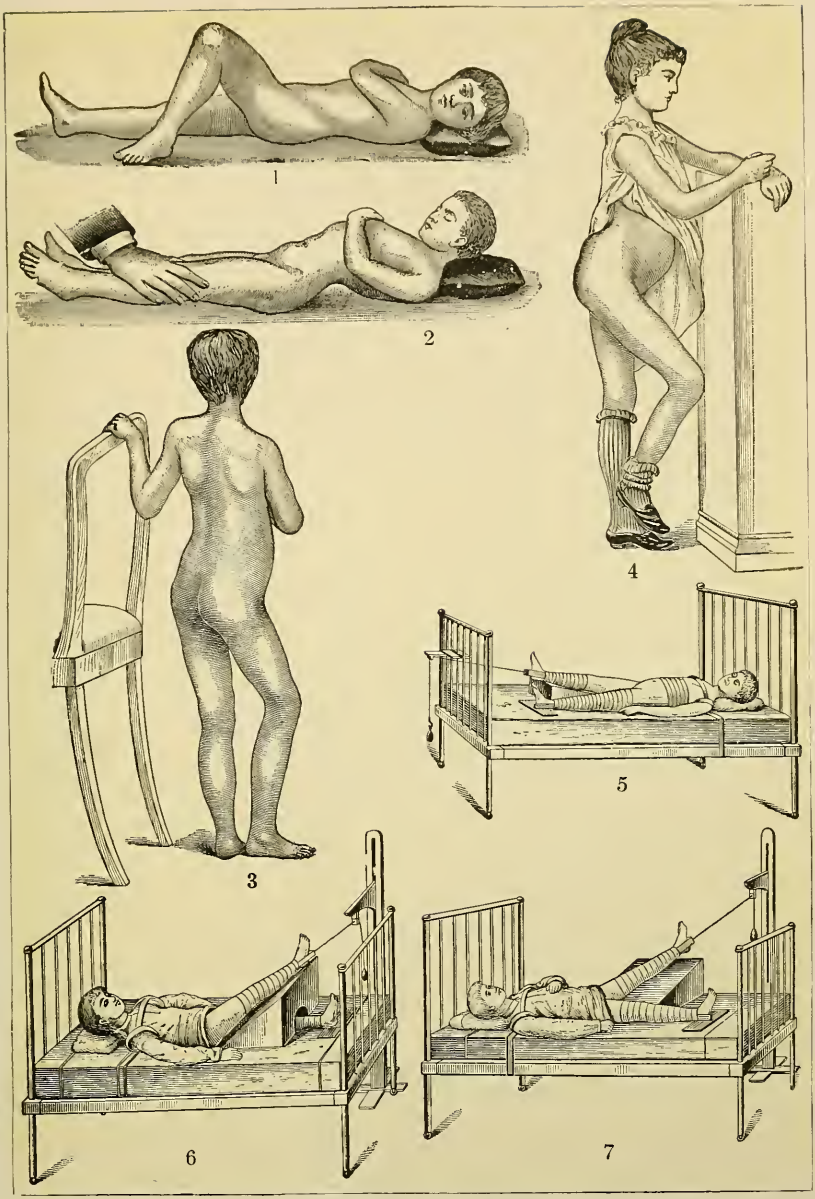
Treatment.—In most of these cases conservative treatment is advisable. Antituberculous treatment is used in all cases. In incipient hip disease the treatment usually advocated is rest. The patient is placed upon a solid mattress and extension is applied. In children under ten years of age a weight of from 3 to 5 pounds is used; in individuals between ten and twenty a weight of from 5 to 8 pounds is used. A long splint is often applied to the sound side to keep the patient recumbent and horizontal. A cradle is employed to hold up the bed-clothing. The extension is applied in the long axis of the limb, the extremity being placed in the line of the deformity due to disease and being properly supported. Lordosis means that there is flexion of the thigh, and when lordosis exists the limb is to be raised until the lumbar spine flattens out on the bed and extension is to be applied (Pl. 8, Fig. 5). If the anterior superior spine of the ilium is depressed on the affected side and there is apparent lengthening abduction exists. The limb is to be moved until the anterior superior spines of the ilia are on a horizontal level and then extension is to be applied (Pl. 8, Fig. 6).

If the anterior superior spine is elevated and there is apparent shortening, adduction exists. The limb should be moved inward across its fellow until the spines of the ilia are on the same horizontal level, and the extension is to be applied (Pl. 8, Fig. 7). The object of extension is to overcome muscular spasm and so put the part in a condition of physiological rest. Muscular spasm is a great factor in destroying structures. Spasm presses the parts together, and as a result of pressure plus bacterial action destruction occurs. The extension and traction tire out the muscles and cause spasm to cease. Extension will remove flexion in two weeks in a recent case and in the course of some months in an older case. As flexion is relieved the pillows are removed and the leg lowered, but extension is maintained in the long axis of the thigh. Abduction and adduction cannot be removed by simple extension in the axis of the limb.

Abduction demands no special treatment. In a movable joint it will disappear, and in an ankylosed joint it is an advantage, compensating by apparent lengthening for the shortening due to bone-absorption or to stunted growth of the limb. Adduction requires an addition of several pounds to the extension weight, the use of a long splint on the sound limb, and the drawing up of the sound side by a rope and pulley toward the head of the bed. The weight used to pull the sound side toward the head of the bed is equal to that used to pull the diseased side to the foot of the bed. This expedient is used for a month or six weeks. In old cases, in which the weight will not bring about extension, the patient is anesthetized, the limb is gently straightened a very little, and the weight is reapplied.

Extension in a mild case must be continued for three months after the symptoms have disappeared, and in a severe case the period must be six months. The weight is gradually taken off; if symptoms recur, the weight is reapplied; if they do not recur, apply a traction splint or a plaster dressing, put a high-heeled boot on the sound limb, and send the patient out on crutches. In young children extension can be made while the child is in a wheeled carriage, thus enabling the patient to go out in the fresh air and sunlight. The general treatment is tonic and restorative. The joint is so deeply placed that external applications are useless. In the treatment of hip disease Thomas's splint (Fig. 442) is used by many, and it may be combined with weight extension; or Sayre's splint (Fig. 443) may be employed. Wyeth's apparatus (Fig. 444) is a favorite with many American surgeons.

If the limb is in good position, or has been brought into good position, either



1, 2. Effects on the Lumbar Spine of Flexing and Extending the Diseased Leg in Hip Disease (Albert). 3, 4. Positions in Coxalgia (Albert). 5. Extension in Hip Disease (Treves). 6. by weight extension or straightening under ether, plaster of Paris is a useful dressing. It is applied from the toes up, and includes the entire extremity and also the pelvis. A patient wearing plaster may get about on crutches when the sole of the foot of the sound extremity is raised by the wearing of a thick-soled shoe.

Treatment by Weight-bearing and Fixation by Hip Spica of Plaster of Paris (Lorenz's Method).—This plan is based upon the principle that ankylosis is to be secured in every instance. To keep the patient in bed is to keep him from the open air and sunlight, which are so necessary in tuberculosis. Such confinement favors muscular atrophy, leads to anemia, and lessens vital resistance. The hip is placed in 20 degrees of flexion,

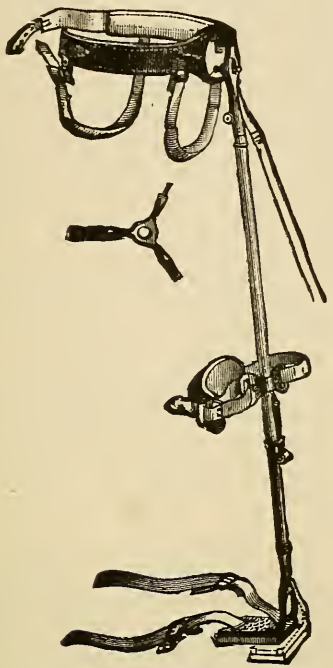

Fig. 443.—Sayre's long splint.

Fig. 444.—Wyeth's combination method.

20 degrees of abduction, and 5 degrees of external rotation, and is fixed by a short plaster spica of the hip. The patient walks and so antagonizes muscular spasm. The joint surfaces bear weight, which leads to a useful increase of blood supply (curative hyperemia), but do not grind upon each other, hence, the spread of the disease is not favored. That muscles increase in size is shown by the fact that the cast gets tight and must be changed from time to time. The open-air life and exercise are of the greatest benefit to the patient and a gain in weight is the rule. Cases in a debilitated condition or those with discharging sinuses must not be treated by this plan "without the temporary use of crutches" (H. A. Wilson, in "Southern Med. Jour.," Dec., 1908). The plan is more suitable for incipient than for advanced cases. The average duration of treatment is claimed to be about ten months (H. A. Wilson, Ibid.). It is true that the method affords easier access to the open air than does the bed treatment, but why should every patient be doomed to ankylosis when we know that in many cases joint function may be retained by treatment looking to that end?

Intra-articular Injections and Operation.—If in spite of treatment the condition does not improve or if it becomes worse, use intra-articular injections of formalin-glycerin or iodoform. Always try these injections before doing a

resection unless the *x*-rays show a large sequestrum. Sometimes they succeed and if they do, resection is unnecessary. Asepticize the surface; carry a small aspirating needle into the joint, irrigate the joint with salt solution, and inject a sterile emulsion of iodoform and glycerin (see page 708). In one week, if reaction has ceased, repeat the injection. In another week again use the injection. It may be necessary to give from ten to twenty injections. The proper spot for puncture is thus determined: Draw a line from a point ½ inch outside of the middle of Poupart's ligament to the outer edge of the great trochanter. Puncture at the middle of the outer half of this line (De Vos). I have not attempted to remove the disease surgically early in any case and greatly doubt the wisdom of doing so. Huntington and some other surgeons advocate early operation in children instead of simply fixation, extension, and rest. Huntington ("Amer. Jour. Med. Sciences," July, 1905) recalls that when the lesion is in the head of the femur it tends to perforate into the joint, and he advises trephining at the lower border and outer aspect of the great trochanter and tunnelling the neck and head of the femur with a curet Bradford objects to this method in most cases on the ground that unless the disease is localized and the cavity is well walled off and unless injury to the localizing barrier is avoided, the operation may be responsible for dissemination of the bacteria.

If an abscess forms, incise it with the most thorough antiseptic care, let the fluid drain away, irrigate the cavity with salt solution, remove any sequestra, inject with iodoform emulsion, sew up without drainage, and dress antiseptically. In some cases the sequestrum is extra-articular. In many cases no sequestrum is found. If this method fails, drainage must be employed. The old plan of not operating until rupture was seen to be inevitable would be wrong to-day. To open early and antiseptically often means rapid healing, the prevention of burrowing, a lessened danger of visceral infection, and an earlier cure. In contrast to what happens when a very large cold abscess is opened, hectic fever will rarely arise when a tuberculous joint is opened and drained with aseptic care.

Excision of the hip is to be performed when there is a large sequestrum or severe fistulæ (Garré, "Deutsch. med. Woch.," 1905, Nos. 47 and 48); when the head of the femur is detached and lies loose in the joint; when profuse suppuration continues for a long time, and other methods fail to arrest it; when amyloid disease is threatening; or when very faulty position is inevitable without operation. Excision is an operation of considerable danger, and the older the person, the greater the danger. Schede advocates arthrectomy in some cases as a substitute for resection. Senn tells us that opinion as to resection has greatly changed of late, and it is now taught that the operation is advisable in all cases where fixation, extension, intra-articular and parenchymatous injections have failed to arrest the disease (Senn, on "Tuberculosis of Bones and Joints"). Resection of the hip does not give a very satisfactory functional result. When there is extensive disease of the femur, when excision has been tried and has failed, when the patient has not the recuperative power to withstand the long siege of illness following excision, or when there is amyloid disease, amputate.[1] Amputation of the hip-joint for tuberculous disease is a very successful procedure.

Knee-joint Disease (*White Swelling*).—After the hip, the knee is, of all joints, the commonest site of tuberculous disease. Knee-joint disease can begin as a synovitis, but oftener begins as tuberculous inflammation of the femoral or the tibial epiphysis. Tuberculous disease rarely attacks the bone on the diaphyseal side of the epiphyseal line; a single focus only exists, as a rule, and a sequestrum is seldom formed. In very rare instances the patella or the semilunar cartilage is primarily attacked. It may begin at any age, but is most common in children and young adults. If an acute synovitis

[1] See the admirable article by Howard Marsh in Treves's "Manual of Surgery."

ushers in the case, there may be a large effusion into the knee-joint and partial flexion, but swelling is usually slight in knee-joint disease. Pulpy degeneration of the synovial membrane occurs; the joint enlarges; the ligaments soften; the skin becomes edematous, and muscular spasm exists. The leg becomes flexed; the tibia displaced backward and outward; the foot is everted; and lameness arises, due chiefly to deformity. Muscle atrophy is marked above and below the joint. Pain may be absent, is often slight, and is rarely severe. Local tenderness is very common. When the disease begins in the bone or an epiphysis there are pain, tenderness, lameness, swelling, inability to extend the limb completely, sudden spasmodic muscular contractions, and final involvement of the joint. When an abscess forms, it may destroy the joint very rapidly or it may break externally.

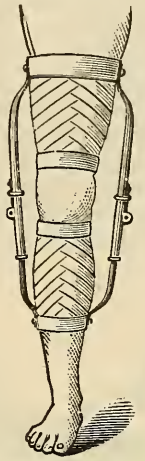

Fig. 445.—Sayre's knee splint applied.

Fig. 446.—Hutchinson's knee-joint splint.

Treatment.—In treating knee-joint disease conservative treatment is usually tried, but often fails. A plan of doubtful value is to make a mixture of guaiacol and olive oil (1:4). Once a day the surface of the knee is exposed by removing dressings, is painted with this mixture, and the painted surface is covered with cotton-wool. Rest is of the first importance, and may be secured by the application of splints (Figs. 445, 446), the use of extension (Fig. 447), or the employment of a plaster-of-Paris bandage. In any case the patient must be kept in bed for a few weeks; he may then be permitted to go out upon crutches, wearing a high-heeled shoe upon the foot of the sound limb. In cases in which treatment is begun early the disease may often be arrested in from eight to twelve months. If the symptoms do not abate after a number of weeks, or if the condition grows worse and caseation occurs, aspirate, irrigate, and inject iodoform emulsion or formalin-glycerin. Intra-articular injections are not unusually curative. Insert the needle in the angle between the outer edge of the patella and the ligament of the patella (De Vos). Repeat the injection in one week if reaction has abated, and continue as directed for the injection of the hip-joint. If this plan fails, incise the capsule, remove all fragments and tuberculous foci, irrigate with normal salt solution, inject iodoform emulsion, and sew up without drainage (Neuber's plan). A more severe case requires drainage. If these means fail, or if the case is too far advanced to permit of their use, open the joint and perform an excision or an erasion (see pages 787 and 793). Excision gives a satisfactory result in most cases, although it leaves a rigid knee and marked shortening. Garré considers any shortening over 5 cm. a bad result, and he got such a bad result in 7.5 per cent. of his 117 cases. In children shortening follows even conservative treatment, and the shortening which follows excision is due in part to removal of bone and in part to impairment of the nutritive power of the epiphyseal cartilage. In most cases in children conservative treatment should be tried. In most adult cases resection is indicated. Some cases demand amputation, which, if the patient's health is much impaired or if amyloid disease exists, is to be preferred to excision. Amputation is preferred to excision in very young children and aged people.

Ankle-joint disease may begin in the synovial membrane, in the tibial epiphysis, or in the tarsus. The origin is frequently synovial.

The *symptoms* are pain, swelling, lameness, limitation of joint-move-

ments, and atrophy of the calf muscles. Caseation often occurs and sinuses form.

Treatment.—Conservative treatment with injections of iodoform or of formalin-glycerin will cure many cases. Rest is obtained by means of splints or plaster-of-Paris bandages. Caution the patient to avoid standing upon the diseased extremity. In making an intra-articular injection insert the needle below the outer malleolus. When caseation occurs, it is advisable to open the joint, wash out with normal salt solution, inject iodoform emulsion, sew up the incision, and put up the ankle-joint in plaster. When there is considerable bone disease, when fistulæ exist, when adjacent joints or tendons are diseased, or when joint-disorganization occurs, perform an excision or an erasion. Some cases demand amputation (Syme's amputation being preferred by some, amputation above the ankle being approved by many). Osteoplastic resection is sometimes advised (Wladimiroff-Mikulicz operation). Operative treatment is more satisfactory in children than in adults (Garré).

Shoulder-joint disease is not common; it is rare in children but is less rare in adults; it may begin in the synovial membrane, but usually begins in the head of the humerus. The glenoid cavity is rarely attacked. Pain is slight, atrophy

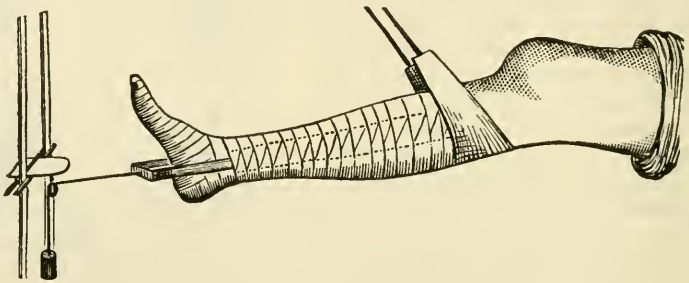

Fig. 447.—Sayre's double extension of the knee-joint.

of the deltoid and other muscles is noted, the joint is stiff, and the scapula follows the motions of the humerus. Caries sicca is the usual cause of destruction. In many cases swelling is not obvious, the joint shrinking because of destruction of the head of the bone and contraction of the capsule (Senn). Abscess-formation is unusual. If an abscess forms, it may open in the axilla, through the deltoid muscle, or at some far distant point. Shoulder-joint disease is frequently complicated by pulmonary tuberculosis.

Treatment.—A majority of cases recover by the use of conservative treatment, a stiff joint resulting. Put on a shoulder-cap, apply the second roller of Desault, and hang the hand in a sling. Maintain rest for at least four months. Arthur Gillette's plan is very efficient. It consists in placing in the axilla a wedge-shaped pad with the base up. The arm is allowed to hang. Aspiration and injection of iodoform emulsion or of formalin-glycerin are of great service in synovial tuberculosis. In making an intra-articular injection the needle is entered below the acromion, while the arm is held against the side and the forearm is at right angles to the arm and across the front of the chest (De Vos). If caseation occurs, open the joint, remove tuberculous foci, wash with hot saline fluid, inject iodoform emulsion, and close without drainage. In a decidedly severe case, drain. Caries sicca may occur. In rare instances dead bone will have to be gouged away. Excision is sometimes required, but the results are seldom satisfactory.

Elbow-joint disease may begin in the humerus or the ulna. The head of the radius is rarely the primary focus. In some cases the synovial membrane is first attacked. The disease is most frequent in young adults. The joint is

swollen, its movements are somewhat limited, muscular wasting is pronounced, and pain is generally slight. Tuberculous pus may form.

Treatment.—In treating early elbow-joint disease, especially in young children, conservative treatment is very successful. Rest is secured by means of an anterior angular splint (Fig. 448) and a triangular sling or a plaster-of-Paris dressing. Splints are to be worn for from four months to a year. Injections of iodoform emulsion or formalin-glycerin are usually employed. Insert the needle close to the outer side of the olecranon. In a cure by conservative methods a stiff joint will usually result. It may be necessary to perform resection because of extensive bone disease. Resection gives an excellent functional result.

Wrist-joint disease may arise at any age, and is sometimes met with in late middle life or even in old age. The joint presents a puffy swelling, loses its normal contour, and becomes spindle shaped. Hand-movements are impaired, pronation and supination cannot be performed completely or satisfactorily, the joint is stiff and partly flexed, the grasp is enfeebled, pain may be severe or slight, the skin is sometimes, but seldom, hot, and muscular atrophy is marked. This form of tuberculosis may begin in the synovial membrane,

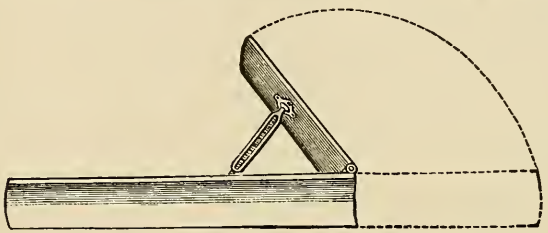

Fig. 448.—Stromeyer's anterior angular splint.

in the bones, or in the tendon-sheaths. The prognosis is better than in tuberculosis of any other joint. There is usually preservation of considerable function on recovery.

Treatment is usually conservative and very successful, giving, as a rule, a functionally useful joint and movable fingers. Garré recommends a trial of the method even when there are fistulæ and when there is necrosis of the carpus. Apply a Bond splint and sling or put on a plaster-of-Paris bandage and maintain strict rest for from four to six months. Aspiration and injection of iodoform emulsion of formalin-glycerin may be practised. Enter the needle at the dorsal edge of the radial styloid process, and again at the upper edge of the pisiform bone (De Vos). In some cases it is well to incise, wash with salt solution, inject iodoform emulsion, and close without drainage. Severe cases demand incision and drainage with the maintenance of rest. Resection is to be avoided if possible. It gives a bad functional result, the amount of bone removed leaving the tendons too long and contractures of muscles being common (Garré). It may be demanded because of extensive caries or sequestra formation. Amputation is occasionally necessary.

Non-tuberculous Arthritis.—Most of these cases, acute and chronic, are of infectious origin. Some of them are non-infectious. Among the non-infective forms are the joint lesions of locomotor ataxia and syringomyelia—constitutional conditions, as gout, purpura, hemophilia, and scurvy—functional derangements expressed by articular neuralgia or intermitting hydrops and traumatic states (Hoffa, in "Zentralbl. f. Chir.," xxxiv, 1907; and Bloodgood, in "Progressive Medicine," Dec. 1, 1907).

Osteochondritis Deformans Juvenalis (Quiet Hip Disease. Legg's Disease. Perthes's Disease).—Legg, of Boston discovered this condition in 1909 ("Boston Med. and Surg. Jour.," 1910, clxii). Perthes of Tübingen described it in 1910. (See Leonard V. Ely, in "Annals of Surgery," Jan., 1919.) In this disease there is

atrophy and rarefaction of the head of the femur and if weight-bearing is continued the head of the femur will be almost destroyed. In many cases a diagnosis of tuberculous hip has been made. The cause is unknown. Legg considers trauma causal in 67 per cent. of cases ("Boston Med. and Surg. Jour." Feb. 7, 1910). Taylor and Freider consider trauma a possible but very doubtful cause ("Am. Jour. Orthop. Surg." Vol. xiii, 1915). Kidner suggests infection of the tonsils as causal ("Am. Jour. Orthop. Surg.," Vol. xiv, 1916). Others regard the lesion as nutritional. The latter explanation gains much in probability from Blanchard's observation that there is also "decreased bone density and some atrophy of the pelvis of the diseased side in the acute cases." ("Jour. Am. Med. Assoc.," Sept. 29, 1917). It is probably a nutritional disease of growing bone and muscle. The first symptom is a limp. There may be some pain running down the thigh. Fever is absent. There are no night cries. There is some limitation of rotation, and atrophy of the hip and buttock. If the case is untreated shortening will occur. After about a year the head of the femur may be largely destroyed. The neck will be shortened and in a coxa vara or coxa valga position (Blanchard, Ibid.). There are 2 or 3 cm. of shortening. "Abduction is partly lost and movements of the hip in other directions are slightly limited"(Blanchard, Ibid.). In a year or more the disease ceases to progress and the bone begins to harden and to undergo repair. If weight-bearing is prevented during the existence of the disease the head of the femur will never lose its rotundity and by the end of the second year will have become hard again. Even if the head of the femur has been destroyed proper mechanical treatment for a year or two will cause almost complete regeneration. A limp remains after recovery.

The plan of letting these cases walk about without treatment is to be condemned. Treatment is highly successful. A plaster-of-Paris spica running from the foot nearly to the axilla is an excellent plan of treatment. It is associated with a high shoe on the sound side and crutches.

Some use the abduction splint as in tuberculosis of the hip and guard the patient from treading on the diseased limb (Sever, in "Jour. Am. Med. Assoc.," Sept. 29, 1917).

Traumatic Arthritis.—This may be due to a single injury (a sprain or a bruise) or to some continuing cause (genu valgum may cause arthritis of the knee; flat-foot may be responsible for arthritis of the knee or hip).

If a contusion or sprain causes relaxation of the capsule or fixing tendons, the joint becomes loose and injures itself again and again during movement. It does the same thing when there are loose bodies or enlarged synovial fringes. Traumatic arthritis usually involves but one joint. Recent traumatic arthritis is treated by protecting the joint, massage, hot air, and passive motions.

If a continuing cause is present it is to be removed. Distant causes may be removed by orthopedic apparatus or by operation. Causes within the joint may be sought for by arthrotomy, and when found they should be removed. For instance, in the knee, *inflamed synovial fringes* may be responsible for chronic inflammation. They get caught between the joint surfaces, are squeezed, and trip the victim. They should be removed. Lockwood ("Brit. Med. Jour.," July 3, 1909) points out that an overgrowth of fat may get between the tibia and femur and be squeezed. This surgeon calls attention to the fact that there are "adipose pads immediately above the articular surface of the femur, and on either side of the upper end of the patella" (Ibid.). He calls them the *pads of Malgaigne*, after the French surgeon who described them in 1859. If they are subject to repeated traumatism they should be removed.

Infective Arthritis.—In this condition the inflammation is due to bacteria. Various forms of bacteria may be responsible. A streptococcic arthritis begins in from one to five days after the primary infection, a typhoid joint many days or even weeks after. In some cases pus forms and pyogenic bacteria are

demonstrable in fluid removed by aspiration. In other cases, perhaps exhibiting symptoms as acute, no pus forms and no bacteria are demonstrable in the fluid removed by aspiration. The latter cases are due to toxins or to bacteria of attenuated virulence. Secondary infection may occur. In most cases the disease is polyarticular, but if a wound is causal the arthritis will be monarticular. The bacteria may reach a joint by way of a wound from an adjacent focus of osteomyelitis, from a near or distant area of infection, from the genito-urinary tract, the teeth, or by way of the tonsils. Bacteria not directly introduced into the joint reach it by way of the blood or lymph.

The disease may arise during the course of gonorrhea, scarlatina or any infectious process. The source of the bacteria may be oral sepsis, chronic appendicitis, prostatic inflammation or some other focal infections. It may arise when no area of infection can be discovered. It may arise in the course of an acute infectious disease (such as erysipelas, cerebrospinal fever, bronchopneumonia, typhoid fever, pneumonia, influenza, mumps, dysentery, diphtheria, measles, scarlatina, variola), and may be due to pyogenic cocci, to the specific micro-organism of the acute infectious disease, or to microbic products. Arthritis may follow empyema. Infective arthritis may be followed by pneumonia. Rosenau claims that streptococci can be converted into pneumococci. So too, he asserts, pneumococci may be converted into streptococci ("Illinois Med. Jour." 1914, xxv). Joint inflammation arising in the course of or as a sequel to an acute infectious disease may or may not suppurate.

Symptoms.—If no suppuration takes place, the *symptoms* of the attack resemble those of rheumatism; if suppuration occurs, the symptoms are the same as those of acute suppurative arthritis, with which disease this form of infective arthritis is identical. Suppuration rarely occurs. Ashby has well described the arthritis which sometimes follows *scarlatina.* It involves the wrists, finger-joints, tendons of the forearms, the knees, ankles, or spine. The joints are painful, but are rarely much swollen or discolored (Howard Marsh). We can distinguish infective arthritis from rheumatism by the fact that it does not migrate and is uninfluenced by antirheumatic remedies. Dislocation may follow the acute manifestations of infective arthritis. In the hip it may simulate congenital misplacement.

Treatment.—In every early case in which we suspect the condition, diagnostic aspiration is performed. If the fluid obtained contains bacteria Murphy's formalin and glycerin should be injected (2 per cent.). An injection is followed by the application of an extension apparatus. The mixture must be at least twenty-four hours old. In many cases this treatment is of the greatest value. If aspiration and injection fail, arthrotomy and irrigation are indicated. In all clinically severe cases and in all prolonged cases, open and irrigate, first with corrosive sublimate solution (1 : 1000), then with normal salt solution. If the joint contains pus Dakin's fluid may be used every hour. Recent cases which are not very acute and are free from pus may have the capsule closed without drainage of the joint. The soft parts above the capsule are not sutured (Cotton, in "Boston Med. and Surg. Jour." 1915, clxxiii).

Pyogenic or Acute Suppurative Arthritis.—This condition is a form of infective arthritis and is usually due to the Staphylococcus pyogenes aureus or to the Streptococcus pyogenes, which finds entrance by means of a wound, by the spontaneous evacuation into a joint of the products of an osteomyelitis, by extension of suppurative inflammation through contiguous structures, or by the blood-stream. It is necessary to remember that causative bacteria may have entered the blood or lymph at a point near to or distant from the joint (tonsils, ethmoid cells, urethra, a focus of osteomyelitis, puerperal sepsis, etc.). Of course, a wound into a joint may be the open gateway for infection. A traumatism may create a point of least resistance and bacteria may be derived from the blood or lymph. It is not very unusual for traumatic arthritis

to eventuate in pyogenic arthritis. Particularly in youths and young children the symptoms of arthritis may overlie and hide a causative osteomyelitis. Sometimes gonorrhea is the cause and in rare cases septicemia is causal. In pyogenic arthritis all the joint-structures are involved and suppuration rapidly appears. Synovial membrane is converted into granulation tissue and cartilage is destroyed by pus. The greater the intensity of the inflammation, the larger the amount of granulation tissue, hence, ultimately, the greater the amount of scar tissue and the greater impairment of joint function.

The *symptoms* of acute suppurative arthritis are usually a chill followed by fever and a rapid pulse. There are severe pain, which is aggravated by motion and is worse at night; discoloration, heat, and edema of the skin, partial flexion of the joint; fluctuation, and marked constitutional symptoms of sepsis. The joint tends to rapid disorganization, and fatal septicemia is very apt to occur. In pyemic arthritis several joints become infected.

Treatment.—In every suspicious case immediately aspirate. If bacteria are found in the aspirated fluid, at once open the joint (*arthrotomy*) and irrigate it with corrosive sublimate solution (1 : 1000) and then with salt solution. In early cases which are not very violent formalin-glycerin may be injected, the wound closed, and the joint immobilized or subjected to extension after the operation. In a late case or a violent case treatment consists of incision, drainage, immobilization and antiseptization. We introduce Carrel's tubes and instil Dakin's fluid at proper intervals. Always be sure whether or not arthritis is the result of osteomyelitis. If osteomyelitis exists the area of bone disease must also be operated upon. Arthritis due to staphylococci and streptococci is often secondary to bone suppuration. If a periosteal abscess exists the joint condition is almost certainly secondary. If osteomyelitis exists it requires prompt and radical treatment (see page 579). In advanced cases involving the knee Allen and Alden ("Surg., Gynecol., and Obstet.," July, 1909) open the joint by a transverse incision below the patella, disinfect with pure carbolic acid followed by alcohol, and pack with iodoform gauze. I would only regard this as justifiable in advanced and very severe cases, as it is sure to be followed by ankylosis. Although in late cases which recover after arthrotomy and irrigation there is aways more or less ankylosis, many cases treated early recover without serious impairment of joint function. Early arthrotomy is of the utmost importance, and if the aspirated fluid contains bacteria we should never postpone operation or hold it in reserve while we employ Bier's hyperemic or any other conservative method. Radicalism is here the course which promises the greatest safety, and the surest retention of joint function. If we decide that the best we can get will be ankylosis and if that is what we seek every care must be taken to place the joint at the angle which will be most useful. Sir Robert Jones advocates the following positions:[1]

Shoulder.—Fixed in abduction of 50°.

Elbow.—Fixed at an angle of 110°.

Wrist.—Dorsiflexion.

Hip.—Fixed in extension.

Knee.—Fixed in extension.

Ankle.—Fixed at a right angle.

Free drainage, immobilization and antiseptization are imperative. It is thought best not to remove loose pieces (Osgood,[1]). Resection or amputation may be required. In some cases ample or partial resection is indicated. In some amputation is necessary. Septic joints following gunshot fractures constitute a special group (page 734).

Typhoid Arthritis.—This disease is a form of infective arthritis. That the bacteria of typhoid may inflame the joints is proved, and it seems certain that they can cause suppuration, although their pyogenic power has been

[1] See Lt.-Col. Osgood, in "Am. Jour. Orthop. Surgery.," Oct., 1918.

disputed. Some claim that mixed infection is the real cause of pus formation in a typhoid joint. The typhoid bacilli enter the bones in many typhoid cases and sometimes cause osteomyelitis. Joint-disease is more common than bone-disease. Bone cases are apt to occur in older, joint cases in younger persons. One joint, two joints or several joints may be involved. Typhoid disease of a joint begins when the fever is abating, and more than one joint may be involved. Typhoid joints may recover permanently, may become ankylosed, may dislocate, or the joint-disease may lead to fatal sepsis. In most cases the joints recover. In slight cases the synovial membrane only is involved; in more severe cases capsule, cartilages, ligaments, and even bones are involved. Some cases suppurate. Septic typhoid arthritis may result from a mixed infection with typhoid bacilli and pyogenic bacteria, and is identical in symptoms and progress with ordinary septic arthritis. Typhoid arthritis proper may be monarticular or polyarticular, the monarticular form being the most common, and the hip-joint being the articulation most liable to be attacked. In most cases typhoid arthritis causes little pain. The swelling is marked, although in the hip it is concealed. Pus rarely forms. Keen calls attention to the fact that in the 84 cases of typhoid arthritis which he collected spontaneous dislocation occurred in 43, nearly all in the hip.[1] Fluid from a typhoid joint may be sterile (bacteria having died), may show mixed infection, or may give a pure culture of typhoid bacilli (A. G. Ellis, in "Jour. of Infectious Diseases," April 1, 1909).

Treatment.—A mild case is treated as a simple synovitis. If diagnostic puncture obtains fluid free from bacteria, no more radical method than aspiration and irrigation is required. If the fluid contains bacteria, inject formalin-glycerin. If this fails, incision and drainage are demanded. In some cases an autogenous vaccine appears to be of service, in others it fails utterly.

Typhoid arthritis may be responsible for spontaneous dislocation. If, for instance, the hip becomes painful and the limb assumes an abnormal position, weight extension should be used and aspiration should be practised to relieve effusion (J. B. Murphy, in "Surgery, Gynecology and Obstetrics," August, 1916). If luxation has occurred Murphy insists on aspiration, but reduction should not be made until well into convalescence and then should be by the method Lorenz teaches for congenital dislocation (Murphy, Ibid.). If a luxation is found in advanced convalescence it should be reduced promptly.

Gonorrheal Arthritis or Gonorrheal Rheumatism.—During the progress of gonorrhea the development of a painful joint does not of necessity prove the existence of gonorrheal rheumatism, for ordinary rheumatism is just as likely to arise when a man has clap as when he has not this malady. Furthermore, the term is inaccurate, as gonorrheal rheumatism is not rheumatism at all, but is an infective disorder of the joints or of the synovial membranes, the infective material being contained primarily in the urethral discharge. Gonorrheal arthritis is one of the forms of infective arthritis. Occasionally this form of arthritis arises from gonorrheal ophthalmia (Heiman's case); it sometimes, though rarely, arises during the height of a gonorrhea, but it is more frequently met with in chronic cases or when the intensity of the inflammation is abating in acute cases. Men suffer from gonorrheal arthritis far more frequently than do women, and the seizure is very apt to recur again and again. In some cases many joints are involved, but in most cases only a few joints suffer. Osler states that the knees and ankles are most apt to be involved in gonorrheal rheumatism, and that this form of arthritis is peculiar in often attacking joints that are usually exempt in acute rheumatism ("the sternoclavicular, the intervertebral, the temporomaxillary, and the sacro-iliac"). There are two forms of gonorrheal rheumatism—an acute and a chronic form. The poison reaches the joint by way of the blood. In some cases gonococci are found in the joint fluid; in other cases they are not found. I am inclined to believe that in the milder

[1] Keen on "The Surgical Complications and Sequels of Typhoid Fever."

cases, which recover without genuine pus formation, only toxins are present in the joint. In the severe cases the organisms themselves exist in the articular fluid. Osler suggests that the non-suppurative cases are due to the action of toxins taken up from the area of primary infection, and that the suppurative cases are due to infection with pyogenic bacteria. Endocarditis may occur, and it is due to micro-organisms and not to toxins.

Changes In and About the Joint.—The inflammation of gonorrheal arthritis may be located around rather than in the joint, and especially in the tendon-sheaths. Suppuration is unusual, but it may occur in joints and in tendon-sheaths. Cultures of the exudate may or may not show the gonococci. Cover-glass preparations carefully stained may or may not show gonococci.

Symptoms.—The acute form attacks, as a rule, but a single joint, but may attack several joints. The joint trouble begins with great suddenness, and is often ushered in by chilly sensations or by a distinct chill. Moderate fever arises. The pain in the joint, severe from the first, becomes excruciating. If superficial joints suffer, the skin over them becomes red and hot, and peri-articular edema soon presents itself. The fluid in the joint is in most cases serous, but may become purulent. If pus forms, the fever becomes very high and chills may occur.

A chronic condition may follow the acute, but the condition may be chronic from the start. The symptoms resemble those of the acute form, but are far milder, although acute exacerbations may occur. The joint fluid is usually serous.[1] In gonorrheal arthritis there may be transitory, intermittent, and wandering pain in and about the joint, without any other symptom; one or more joints may become swollen and painful, and moderate fever may develop. One joint, especially the knee, may swell to an enormous extent, pain, peri-articular edema, redness, and fever being absent (hydrarthrosis, or dropsy of the joint). Suppuration in this form of the disease seldom occurs. The tendons, the tendon-sheaths, the bursæ, and the periosteum may inflame. Whether the joints are inflamed or not inflamed, the tendon-sheaths about the wrist and ankle and the retrocalcaneal bursæ may suffer. In some cases numerous bursæ are involved. It is often difficult and is perhaps impossible to check gonorrheal arthritis. It may last for a long period, and tends to recur again and again. Iritis, periostitis, pleuritis, endocarditis, and pericarditis have been observed as complications.

The *diagnosis* between gonorrheal arthritis and acute rheumatism rests chiefly on the great chronicity, the lesser degree of fever, the excessive tendency to recurrence, and the absence of profuse acid sweats in gonorrheal arthritis; and on the shorter course, the higher fever, the profuse acid sweats, the lesser tendency to rapid recurrence, the greater proneness to symmetrical involvement, and the great liability to cardiac and visceral complications in rheumatic fever. Furthermore, in gonorrheal arthritis a gonorrheal infection (urethral or ocular) certainly exists or recently existed; in ordinary rheumatism a urethral discharge may, of course, happen to be present. Gonorrheal arthritis is apt to affect certain joints which acute rheumatism seldom attacks. Gonorrheal rheumatism of the spine comes on suddenly, causes elevation of temperature, pain but no tenderness.

Treatment.—Because of the lingering character and dangerous nature of gonorrheal arthritis and because if unchecked it is liable to produce grave impairment of function, treatment should be prompt and radical, as advocated by Halsted many years ago. The joint should be aspirated and if the fluid obtained contains gonococci or any pyogenic bacteria, formalin-glycerin should be injected. If this fails, the joint should be opened and irrigated. If pus is absent and the case not very violent, the joint may be injected with formalin-

[1] See Schuller, in "Aertztl. Pract.," No. 17, 1896.

glycerin and the wound can be closed without drainage. If pus is found by incision, irrigate, drain, and immobilize. In cases free from pus Bier's treatment is of value (see page 122). Drug treatment is of little value in gonococcal arthritis. The salicylates, the alkalis, and salol are useless; iron, arsenic, and strychnin are possibly of some benefit. Quinin is thought to be helpful in some cases. Large doses (1 dram) of syrup of iodid of iron are given by some clinicians, associated with tonic doses of corrosive sublimate. Iodid of potassium seems to be of a certain amount of value. The inflamed joints are usually wrapped in cotton and bandaged, and every day a little blue ointment is rubbed into the skin about them. If the inflammation lingers, it is customary to use the hot-air oven, massage, and gentle passive motion, to apply blisters, or to counterirritate with the hot iron. The object in this stage is to absorb infiltrations and adhesions and thus lessen stiffness. Early passive motion allays reflex muscular contractures, combats atrophy, and prevents adhesion (see Bier and Baetzner, in "Practitioner," June, 1912). It is thought by some competent clinicians that antigonococcic serum possesses distinct value, greatly alleviating pain and favoring the restoration of joint mobility. My experience with it is as yet too insignificant to justify me in expressing an opinion.

The value of vaccine treatment is estimated highly by some, but many have obtained no beneficial results.

Arthroplasty for ankylosis caused by gonorrheal rheumatism is usually followed by re-ankylosis but sometimes by a flail-joint. Gonorrheal ankylosis gives a worse prognosis for this operation than ankylosis of another origin because of the amount of exudate in the tissue about the joint. Operation may be tried and even if it fails ankylosis in a more useful position may be obtained. Cases of anchoring of the patella give a very good prognosis after arthroplasty. Cases of ankylosis of the knee are very unfavorable. A painful partial ankylosis calls for resection and the creation of a firm, and hence painless ankylosis (see Okinczyc, in "Jour. de Chir.," 1914, xiii)

Pneumococcus Arthritis.—This is a rare condition, although Bulkley has collected 172 cases from literature and added one of his own ("Annals of Surgery," 1914, lix): Examination of the blood may or may not discover pneumococci, and pneumococci may be found in the blood during pneumonia, when the joints are free from disease. The inflammation may attack any joint, but is most apt to arise in a joint weakened by previous injury or damaged by rheumatism or gout. In three-fourths of the cases but one joint suffers. In one-fourth of the cases the disease is polyarticular. Infants are most liable. Alcoholics are prone to suffer. In a great majority of cases the disease is associated with lobar pneumonia, but Cole's case proves that the lung may be free ("American Medicine," May 31, 1902). Seventy-five per cent. of cases are associated with pneumonia, about 93 per cent. following and 7 per cent. preceding the lung lesion (Bulkley, Ibid.). Bulkley points out that the most common date of occurrence is within two weeks after the onset of pneumonia. As a rule, a single large joint is attacked, and the knee is most liable to suffer. The synovial membrane alone may be involved or cartilages may suffer and bone may be attacked. The fluid may be serous, but is usually purulent. I have seen 2 cases: in 1 case the knee only was involved; in the other, both knees, one elbow, and one shoulder were attacked. In Cole's series of 41 cases, 13 exhibited involvement of more than one joint. The inflamed joint is frequently completely destroyed. Pneumococcus arthritis develops, as a rule, soon after the crisis of pneumonia, but Herrick says it may arise as late as three weeks after the crisis.

The diagnosis is made by the history of pneumonia, the development of septic symptoms, and the signs of joint inflammation. It is confirmed by aspiration and examination of the fluid. The disease is very fatal. In Herrick's series of cases over 65 per cent. were fatal ("Am. Jour. Med. Sciences,"

July, 1902). In Cole's series of cases there were 28 deaths and 13 recoveries. Even if the patient recovers, the convalescence is prolonged and more or less ankylosis is to be expected.

Treatment.—A non-purulent effusion may be treated by aspiration if bacteria are not found in the fluid. If the aspirated fluid contains bacteria, formalin-glycerin is injected. If this fails, or if pus is present, the joint should be opened and drained.

Syphilitic Arthritis.—(See pages 376 and 380.)

Acute Rheumatic Arthritis; Rheumatic Fever or Acute Rheumatism.—Acute rheumatism is a self-limited febrile malady whose characteristic features are polyarthritis, profuse acid sweats, and a tendency to heart involvement. There is some evidence to indicate that acute rheumatism is a form of infective arthritis, the bacteria being deposited in the synovial tissues and later perhaps entering into the joint cavity. Arthritis of many joints has followed intravenous injection into animals of diplococci obtained from the throat of a man suffering from rheumatic angina (Poynton and Paine at Manchester meeting of the "Brit. Med. Assoc.," 1902). Rosenau in 14 out of 16 cases of acute rheumatism was able to isolate organisms from joint fluid, in 4 out of 7 cases from the blood and in 2 cases from the stools. These organisms were similar to those described by Payne and Poynton (Rosenau, in "Illinois Med. Jour.," 1914, xxv). When the virulence of these bacteria is in different stages they produce different effects when injected into animals. In one stage of virulence they produce endocarditis, arthritis, and fever. In another stage they cause myositis. John O'Conor[1] believes that acute rheumatism is a condition "something similar to gonorrheal arthritis and pyemia, the germ or toxin gaining admission to the body through the tonsil or other microbic trap-door, and that the joint invasion is promptly followed by a form of infective arthritis accompanied with general toxemia; and, furthermore, the infected joints serve as incubators, where the poison is elaborated and passed into the circulation and thus conveyed to other articulations and to the heart."

Symptoms of Acute Rheumatism.—In acute rheumatism the case begins with malaise and fever, and one or more joints become affected. The inflammation spreads from joint to joint, is apt to be symmetrical, and when it arises in fresh joints, usually disappears quickly in those previously affected. The temperature is high, the skin sweats copiously, the joints are red, swollen, hot, and excruciatingly painful, and the structures about the joints are edematous. After a short time the inflammation subsides in one joint and passes into another, the joint first attacked regaining its functions. Suppuration does not take place. Anemia is pronounced, exhaustion is profound, the sweat is sour, the saliva is acid; the urine is acid, scanty, high colored, often contains albumin, and is deficient in chlorids. Cardiac disease is apt to be produced (endocarditis, pericarditis, or myocarditis). Nodules may form upon fibrous structures, hyperpyrexia is not unusual, and cerebral or pulmonary complications may occur.

The *treatment* of acute rheumatism comprises the use of alkalis, salicylates, etc. (See a book upon practice of medicine.) O'Conor is a believer in incising and draining the inflamed joints; and if the theory of an infective origin is correct, this treatment is rational. I have never ventured to do it, but would consider the advisability of doing so if the ordinary treatment proved futile. O'Conor operates early and believes that this is the real way to arrest the disease and prevent complications, but his views have not met with general acceptance.[2]

Chronic rheumatism sometimes follows repeated attacks of acute rheumatism, but oftener arises insidiously in people who have been exposed to cold and damp, who have suffered from poverty, hardship, and privation, or have

[1] "Lancet," Jan. 24, 1903. [2] Ibid.

had much worry. The capsule and tendon-sheaths thicken, and there is usually but little effusion into the joint, but the articulation becomes stiff and painful. The joint-cartilages are occasionally eroded. Muscular atrophy occurs.

Symptoms of Chronic Rheumatism.—In chronic rheumatism the affected joints are stiff and painful and are a little swollen, but not red. Dampness and cold aggravate the symptoms. One joint or many may be affected, but usually several are involved. Passive movements cause the joint to creak and develop crepitus in the tendon-sheaths. The muscles are wasted. Anemia is usually pronounced. The smaller blood-vessels become surrounded by fibrous tissue which progressively contracts and lessens the blood-supply of the synovial structures. The joints may ankylose. There is no fever and no tendency to suppuration, and the disease is incurable.

Treatment.—In chronic rheumatism maintain the general health of the patient, give courses of iron, arsenic, and strychnin, and an occasional course of iodid of potassium or a salt of lithium, and, if possible, send him every winter to a warm climate. Turkish baths give considerable temporary relief. The waters and regimen of Carlsbad and Vichy are of positive though temporary benefit, and the sufferer may obtain relief at the hot springs of Virginia. The patient must avoid damp and must wear woolens. Frictions, the douche, massage, flying blisters, counterirritation with the hot iron, ichthyol ointment, and mercurial ointment are of benefit. Subjecting the diseased joint to a very high temperature by placing it daily in a hot-air apparatus often does great good. The pains of chronic rheumatism may be greatly benefited by the plan communicated to me by Dr. J. T. Rugh. He makes a mixture of 14 min. of glycerin, 14 min. of sterile water, and 1 gr. of crystallized carbolic acid. This is injected at two points, about the articulation and in the extracapsular structures. As soon as an injection has been made the area must be vigorously rubbed to diffuse the fluid and prevent sloughing. The joint must be kept at rest for three days. Injections can be repeated at intervals of five days. In partial ankylosis it is proper in some cases to give ether and break up the adhesions.

Gouty arthritis, which appears especially in the smaller joints (as the fingers and the metatarsophalangeal joints of the great toes), is due to a deposition of urate of sodium in the joint and in the periarticular structures. The irritant urate of sodium causes inflammation, inflammation leads to the formation of granulation tissue, granulation tissue is converted into fibrous tissue, and the fibrous tissue contracts and thus deforms the joint and limits its mobility. A great mass of urates clinging to a joint constitutes a *chalk-stone.*

Symptoms.—The premonitory symptoms may be observed for a day or so, but the acute seizure usually occurs early in the morning, the patient, as a rule, being aroused by excruciating pain in the metatarsophalangeal articulation of one of the great toes. The joint swells, and the skin over it feels hot to the touch and becomes red and shiny. There is often considerable fever. After a few hours the intensity of the seizure abates, only to recur again with renewed violence early the next morning, these remissions and recurrences taking place during six or eight days, until the attack subsides. In patients with *chronic gout* many joints are stiffened and deformed as a result of repeated attacks. Chalk-stones form, and the skin above them may ulcerate. Such patients are chronic dyspeptics, have high-tension pulses, their hearts are hypertrophied, and their urine contains albumin and casts.

The *treatment* of gouty arthritis belongs to the physician, and not to the surgeon, although to the latter the symptoms of the disease should be known, so that it may be diagnosticated from other maladies.

Osteo-arthritis (*Rheumatoid Arthritis; Arthritis Deformans; Rheumatic Gout*).—In this disease, which is not a combination of gout and rheumatism, the synovial membrane and cartilages are affected, the periarticular structures are involved, and masses of new bone are formed.

Osteo-arthritis possibly has in certain cases, as John K. Mitchell long ago pointed out, a nervous origin. It arises especially in persons who have been worried, driven, and harassed. There is apt to be muscular atrophy, trophic lesions of the hair and nails are likely to appear, and the symptoms are disposed to be symmetrical. The causative lesion has not been determined. The condition is now generally regarded as of toxic origin. The suspected cause is streptococcic infection (Payne and Poynton, quoted by Rosenau, in Illinois Med. Jour., 1914, xxv). The foci of infection may lie in any part of the body, but are most frequent in the teeth, tonsil, accessory sinuses of the nose and nasopharynx, the middle ear, the bronchial glands, the mesenteric glands, and the intestines, especially the large intestine. The disease is commoner in women than in men. The greatest liability exists between the ages of twenty and forty, but children may acquire the disease, and it may also be developed in people far beyond middle life. Apes in captivity may develop it. Arthritis deformans may attack the rich or the poor; it does not result from gout, nor does it often follow rheumatism; it is not caused by damp and cold, and only in rare cases does it arise after traumatism of a joint.

Osteo-arthritis differs from gout in the entire absence of urate deposit, and it differs from chronic rheumatism in the extensive alterations in the joint structures. The changes begin in the cartilage; the cartilage-cells multiply, the intercellular substance degenerates, the pressure of the bone causes thinning, and at length the cartilage is entirely destroyed and the bone exposed. The exposed bone is altered in shape, is hardened, and is worn away in the center, the periphery increasing in thickness by ossific deposit, the center deepening by absorption. The margins are not only thickened, but are bulged and lengthened by deposit. The fringes of the synovial membrane hypertrophy and multiply, and some of them are apt to break off (*loose cartilages*). Muscular atrophy arises and contractures occur. It is usually taught that these are due to nerve influence. It seems probable that they are caused by myositis (Billings, in "Illinois Med. Jour.," 1914, xxv). The capsule and the ligaments of the joints, as a rule, become fibrous and contract; but they may soften, relax, and permit of dislocation. The joint usually contains no effusion, but in some cases there is great effusion (*hydrarthrosis*). The tendons about the joint may become fibrous and contracted, they may ossify, they may be separated from the bone, or they may be destroyed entirely. Deformity is marked and motion is limited. The fingers, when involved, show nodules on the sides of the joints (Heberden's nodules). The vertebræ may be involved. Almost all the joints may suffer. Suppuration does not occur.

Symptoms.—Charcot divides osteo-arthritis into three forms, and gives their symptoms, as follows:

1. *Heberden's nodosities*, which are commoner in women than in men, usually begin between the ages of thirty and forty, and are especially common in neurotic subjects. The interphalangeal joints become the victims of attacks of moderate swelling and of some tenderness, and these attacks are not severe, but recur again and again. After a time small hard swellings (nodosities) appear upon the sides of the dorsal surface of the second and third phalanges, remain permanently, and slowly increase in size. The joints become stiff and creak on movement, the cartilages are destroyed, and contractions and rigidity develop, but there is no fever and the larger joints are not involved. The malady is incurable.

2. *Progressive rheumatic gout*, which may be acute or chronic. The *acute* form begins as does rheumatic fever. There are moderate fever and swelling, without redness, of a number of joints, of bursæ, and of tendon-sheaths; the joints are stiff and crepitate, and are apt to be symmetrically involved; muscular atrophy begins early and rapidly becomes decided; pain is slight. This acute form is apt to arise in young women after pregnancy, but is not unusual at

the climacteric and in children. Anemia always exists. The case is apt to advance progressively until a number of joints are firmly locked, when it may become stationary. Another pregnancy will develop anew the acute symptoms. In the *chronic* form swelling and pain on movement are noted in certain joints. The involvement is apt to be symmetrical. Attacks of swelling and pain alternate with periods of apparent quiescence, but the disease does not cease its advance. Articulation after articulation is attacked by the malady until almost all the joints are involved; deformity and stiffness become pronounced, and pain may or may not be severe. There is no fever. Muscular atrophy is marked.

3. *Partial rheumatic gout* or *monarticular rheumatism* attacks one articulation, and it is most often met with in old men. It may fix itself on the vertebral column, on the knee, on the shoulder, on the elbow, or on the hip. The joint grates and becomes stiff, swollen, and deformed; the muscles atrophy; there is usually pain, but fever is absent.

Still's disease is a form of arthritis deformans in which the spleen enlarges greatly and in which the joint changes cause permanent disability early in the case.

Osteo-arthritis or **partial rheumatic gout of the hip-joint** seldom occurs before the age of forty-five, but is occasionally, though very rarely, met with in persons under twenty-five. If the disease arises in an elderly person, it is often called *morbus coxæ senilis*. In some cases the hip-joint only is attacked; in many cases other joints are also diseased. Osteo-arthritis of the hip may follow an injury. Usually the disease is unconnected with traumatism, begins very gradually, and advances slowly. There is pain, often mistaken for sciatica, in and about the joint, and there is increasing stiffness. The pain and stiffness are worse when the patient first moves after resting. Lameness becomes noticeable, and grating can be detected in and about the joint. The symptoms become gradually worse, although at times they may seem to improve for brief periods. The lameness and the stiffness are greatly aggravated, and the pain becomes very severe, even when at rest. Shortening takes place, the great trochanter ascends above Nélaton's line, the limb is usually abducted, but in very rare cases is adducted, and finally ankylosis occurs.

Partial rheumatic gout of the vertebral articulations causing fixation is called *spondylitis deformans* (see page 955).

Treatment.—Osteo-arthritis cannot be cured, but in some cases it remains stationary for many years. I have seen one case apparently arrested by removal of a diseased appendix. Diseased tonsils should be removed. Billings (Ibid.) has cultures grown from them and from the cultures obtains autogenous vaccines. It is claimed by some that Lane's operation of extirpation of the large intestine may arrest it. Bottomley ("Jour. Am. Med. Assoc.," Sept. 9, 1916) believes that in all cases the operation has some beneficial influence, but that it is disappointing. If an intestinal cause is suspected the operation is justifiable but if we are to obtain benefit it must be done early. In far advanced cases it can do material good. Bottomley thinks the risks and uncertainties should be set forth to the patient. The same surgeon prefers colectomy to ileosigmoidostomy in spite of the greater risk of the former procedure. As yet I would not feel justified in recommending a theoretical operation with the idea of directly benefiting osteo-arthritis. I would, however, remove if possible, any *obvious* area of infection. The usual plan of medical procedure is to treat the anemia by iron, arsenic, nourishing food, and have the patient out in the fresh air as much as possible. Debility is met by the administration of strychnin. Hot baths of mineral water do good. It is claimed that the hot-air apparatus is of service. Douches improve these cases, but electricity is useless. Counterirritants are usually regarded as useless. I am sure that blisters and the actual cautery are sometimes of benefit. Injection

of 2 per cent. formalin in olive oil followed by immobilization for 2 to 8 weeks may prove of service (Porter, in "Am. Jour. Orthopedic Surg.," 1915, xii). Massage retards the progress of the case, relieves the pain, aids in the absorption of effusion, and delays fixation. During an acute exacerbation the joint should be put at rest for a time and evaporating lotions applied for a few hours. In an exacerbation in disease of the hip the patient should be put to bed and have extension applied. The patient is, unfortunately, liable to develop the opium-habit. If dropsy of a joint arises, try compression by Martin's bandage, and, if this fails, aspirate and wash out the joint with a 2 per cent. solution of carbolic acid. Patients with rheumatic gout do best in a warm, dry climate. Cod-liver oil does good, as it improves nutrition and hence retards the progress of the disease. Do not be tempted to immobilize the joints in an early case beyond a day or two: fixation only hastens ankylosis. Howard Marsh[1] maintains that, as a rule, but little good comes from manipulation. He makes the following exceptions; when one joint only is affected; when the joint is very stiff but not very painful; when the patient is in good general health and is not beyond middle age. If ankylosis is inevitable the surgeon should endeavor to have it take place in the position of greatest usefulness. If only one joint is involved it may be proper to produce ankylosis by operation. When ankylosis occurs all symptoms subside. Albee describes an operation for osteo-arthritis of the hip-joint. He removes a thin layer from the top of the head of the femur and a similar amount of bone from the roof of the acetabulum. The two surfaces are held in contact until union occurs. In the knee-joint Hibbs bridges the front part of the joint with the denuded patella.

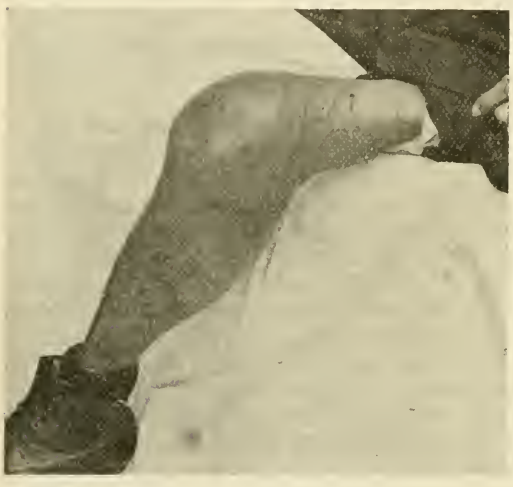

Fig. 449.—Charcot's joint.

After ankylosis osteotomy may be advisable to correct deformity. In children the deformity can usually be corrected by manipulation. After ankylosis arthroplasty may be advisable, fascia, fat, muscle, or chromicized pig's bladder being interposed between the bony surfaces. The best results are in the elbow and hip. Knee cases are not satisfactory. Jones ("Brit. Med. Jour.," 1914, ii) says that arthroplasty is contraindicated in children, if there is active disease, in cases in which the muscles have been destroyed or if scar tissue about the joint would put the flaps in danger.

Trophic Joint Affections (*Arthropathies*).—It is well known that certain diseases and injuries of brain, cord, and nerves may be responsible for arthritic changes (hemiplegia, injury of the cord, locomotor ataxia, neuritis).

From three to six weeks after an apoplexy the joints of the palsied side are apt to suffer from inflammation. The condition following apoplexy is one of synovitis. Any joint may suffer, but the hip seldom does. A well-known arthropathy is Charcot's joint (Figs. 449, 450).

Osteochondritis Dissecans.—This disease of the knee was first described by Koenig in 1888. It is one of the causes of foreign bodies in a joint. It follows a single severe traumatism or many acts of slight traumatism, usually occupa-

[1] "Diseases of the Joints and Spine."

tional, brought about by kneeling (Brackett and Hall, in "Amer. Jour. of Orthopedic Surg.," Feb., 1917). If a violent traumatism causes it the symptoms of the disease begin after the acute symptoms of the injury clear up. The ordinary case which follows repeated and trivial traumatisms comes on gradually with weakness and slight disability but no pain. After a time the joint begins to catch or perhaps lock as it does in an ordinary case of joint-mice. The catching suggests the squeezing of a synovial fringe. The locking is not followed by anything like the customary amount of synovitis and disability which are apt to follow locking in the ordinary case of movable cartilage, and there is a rapid return to the usual functional level. The *x*-rays show an area of bone defect on the outer part of the internal condyle and perhaps movable bodies in the anterior chamber of the joint. There is no osteo-arthritis. Exploration through a median patella incision proves the absence of general arthritis and discloses irregular elevations of thinned and frayed cartilage to the outer side of the inner condyle near the attachment of the posterior crucial ligament, a depression in the condyle, and cartilage hanging or separated (Brackett and Hall, Ibid.). The nature of the lesion has been much disputed. Ludloff ("Archiv f. klin Chir.," 1908, Bd. lxxvii) says the exfoliation of the cartilage is due to trauma occluding a terminal artery. Brackett is convinced that traumatism is causal. A median patella incision, permits free exposure of the anterior chamber of the joint and removal of a loose or a partially separated cartilage. This operation is followed by cure with little or no impairment of function.

Fig. 450.—Charcot's joint.

Charcot's disease (*Tabetic Arthropathy; Charcot's Joint; Neuropathic Arthritis*).—This condition is an osteo-arthritis due to trophic disturbance, arising in a sufferer from locomotor ataxia, and is anatomically identical with osteo-arthritis, which was described above. The knee is most apt to be attacked, and the hip suffers more often than any joint but the knee. The condition may develop in the shoulder or elbow. The smaller joints sometimes, though seldom, are involved. More than one joint may suffer. Vertebral arthropathy has been observed. Ochsner ("Practical Medicine Series," vol. i, 1917) sets forth the joints selected by the disease in 947 cases: Knee, 394; hip, 210; shoulder, 128; foot, 89; ankle, 50; elbow, 39; hand, 16; jaw, 2; various, 19. The disease in most cases begins acutely, often as a sudden effusion, which after a time may

disappear. In most cases, however, the joint becomes rapidly disorganized. The swelling is usually very marked and is sometimes enormous. In the earliest stages it is due to periarticular edema and to articular effusion. Pain is slight or is absent, there is no constitutional involvement, and the condition is unconnected with injury. Some cases begin without this preliminary acute swelling, disorganization being manifest from the beginning. When disorganization has once begun, it continues inexorably. Bony masses form around the articular cavity, in the ligaments, and in the cartilages. The bones and cartilages are rapidly destroyed and absorbed; fracture is apt to occur; the joint creaks and grates; the softening and relaxation of the ligaments permit an extensive range of movement; great deformity ensues; dislocation is apt to occur; muscular atrophy is decided, and pus occasionally, though very rarely, forms. There is sometimes, but seldom, repair. Charcot's joint differs from rheumatoid arthritis in the usual acute onset and the painless course. The complete or nearly complete freedom from pain is one of the most striking features of the condition. In saying there is freedom from pain we mean freedom from pain in the joint, from the pain and tenderness in the regions in which we expect to find them in an inflamed joint. Usually these patients, though free from pain in the joint, suffer much from the lightning pains of locomotor ataxia. Gastric crises are not uncommon (Bramwell). The Wassermann reaction is usually positive. Charcot's joint is more common in female than in male tabetics. In saying that Charcot's joint is often of sudden origin, we mean that in a single night, as Charcot pointed out, swelling of a joint may arise. In a day or two the joint swelling becomes great, and if aspiration is performed, yellow serum is obtained. In a week or two the joint begins to creak on movement.

The *treatment* of Charcot's disease consists in the wearing of an apparatus to sustain the joint. Resection is recommended by some, but most surgeons do not advise its performance. Southam advocates amputation for certain cases of Charcot's joint. He has performed the operation on 4 patients. He amputated twice for ankle-joint disease and twice for disease of the tarsus. In every case the stumps healed quickly and without suppuration. Southam was led to perform amputation on his first case by the report of Jonathan Hutchinson's case of amputation of the leg for perforating ulcer and disease of the bones of the foot in a tabetic.

Osteo-arthropathie Hypertrophiante Pneumique (*Marie's Disease*).—A condition associated with, and possible springing from, pulmonary disease, and characterized by widespread enlargement of joints, thickening of the finger-ends, and the formation of a dorsolumbar kyphosis. The joints are painful, the skin undergoes pigmentation, and profuse perspiration is often present. The head entirely escapes in this disease, and this immunity marks a distinction from acromegaly. The disease is probably a toxemia caused by a focus of tissue destruction especially if the focus be purulent, but it may be due to alteration of bodily metabolism (Gilman in "Edin. Med. Jour.," 1914, xii).

Hysterical joint (*Brodie's joint*) is a condition mostly encountered in young women. The disease occurs most commonly in the knee and the hip, and often follows a slight injury which acts as an autosuggestion, a latent hysteria being awakened into action and localized, though severity of the injury does not determine the severity of the symptoms. The disease may ensue upon synovitis or arthritis, or may arise without apparent cause. The patient complains of pain in and stiffness of the joint, resists passive motion strenuously, and claims that it causes much pain. There is occasionally some muscular atrophy from want of use, and the joint is a little swollen. The skin is hyperesthetic, and a light touch causes more pain than does deep pressure. The muscles may be rigid. The joint may be maintained either in flexion or in extension, but it is rarely in the exact degree of flexion assumed for ease in a true joint inflammation, and the position is apt to be changed

from day to day or from hour to hour. The skin is usually pale and cool, but may be red and hot, because of hyperemia. A periodically developed heat may be observed, especially at night, accompanied apparently by much pain. The alleged pain in some cases is neuralgia, but in most cases is a pain hallucination. There is no effusion into the joint, and swelling does not exist, although occasionally there is slight periarticular edema. In some rare cases organic disease arises in a hysterical joint.

Hysterical phenomena are seldom isolated, but are associated with certain stigmata which may be latent. These stigmata, some of which may be absent, are concentric contraction of the visual fields, pharyngeal anesthesia, convulsions, hysterogenic zones, globus hystericus, clavicus hystericus, zones of anesthesia, especially hemianesthesia, and hyperesthetic areas. Such patients are predisposed by inheritance, and have had previously, as a rule, nervous troubles. Hysterical phenomena, be it remembered, lack regularity of evolution, and are produced, altered, or abolished by mental influences and physical sensations which are without effect in causing, modifying, or curing organic disease. The general health, as a rule, is good, but neurasthenia may coexist. In examining these patients the observer will note that the symptoms disappear when the attention is diverted; that they are out of all proportion to the local evidences of disease; that there is no sign of joint destruction, and that a light touch may cause more pain than does firm pressure. If the patient is anesthetized, perfect joint mobility will be found without any evidences during movements of joint changes.

The *treatment* for a hysterical joint comprises attention to the general health, the employment of nourishing and easily digested food, the prevention of constipation, and the administration of tonics if they are needed. The surgeon must dominate his patient's mind and make her realize that he is master of the case. He is to be an inexorable but just ruler—never a brutal or a cruel one. If possible, send the patient away from the harmful sympathies of her home and let her have the rest treatment of S. Weir Mitchell. Local remedies applied to the joint do harm, as a rule, by concentrating afresh the patient's attention upon the articulation, although the hot iron sometimes does good. Suggestion in the hypnotic state may be tried. The use of morphin should be avoided as being the worst of enemies. Never immobilize the joint, and always use massage, passive motions, and frictions.

Neuralgia of a joint as an independent, isolated affection is extremely rare, though as a complication of other diseases it is by no means uncommon. Neuralgia is more common outside of the joints than in them, and periarticular neuralgia is especially frequent about the knee and the ankle. Joint-neuralgia may arise in any person, but it is more commonly present in young neurotic females. The pain may be persistent, or it may occur in periodic storms, and it is often associated with neuralgia in other parts. The pain may be dull and aching, but it is more often sharp and shooting. Joint-neuralgia is associated with tenderness on pressure, soreness on motion, often with transitory swelling without redness, and sometimes with numbness of the extremities. The *diagnosis* depends on the temperament of the patient, the sudden onset of the pain, the absence of constitutional symptoms, and the free mobility of the joint, especially under ether. Articular neuralgia may depend upon disease or injury of the central nervous system, upon malaria, syphilis, neurasthenia, rheumatism, gout, hysteria, or neuritis, and may be due to reflected irritation, especially from the ovaries, the uterus, or the rectum.

The **treatment** to be observed in joint-neuralgia is to maintain the general health. Examine for a possible exciting cause, and, if found, remove it. Give a long course of iron, quinin, strychnin or arsenic. In rheumatic or gouty subjects administer suitable drugs and insist upon the use of a proper diet.

During the attack use phenacetin. Morphin must occasionally be given in severe cases, but be sparing of it, and never tell the patient she is taking it, as there is a possibility of her forming the opium-habit. Locally, employ frictions, ointment of aconite, heat, and keep upon the part a piece of flannel soaked in a mixture of soap liniment, laudanum, and chloroform (Gross). Never allow the joint to stiffen; any tendency to stiffness should be met by daily massage, frictions, passive motion, and hot and cold douches. In some rare cases nerve-stretching or neurectomy becomes necessary.

Articular Wounds and Injuries.—A *penetrating* wound is very serious, and it may be due to a compound fracture, to a compound dislocation, to a gunshot-wound, or to a stab. If a bursa near a joint be opened, secondary penetration may occur as a result of suppuration. In a penetrating wound, besides pain, hemorrhage, and swelling there is a flow of synovial fluid. A small amount of synovia flows from an injured bursa, a large amount from an open joint.

Treatment.—If a joint is opened aseptically (as when incised by the surgeon) the wound heals nicely under rest and asepsis. If a joint is opened by a septic body, suppurative arthritis is apt to arise, and the surgeon endeavors to prevent it by antisepticizing the surface, irrigating the joint, draining, applying antiseptic dressing, and securing rest. Normal salt solution is the best agent for irrigation, as it does not injure joint endothelium. Active antiseptics may lessen tissue resistance, and thus may actually favor infection. In gunshot-wounds inflicted by pistol bullets or sporting rifle bullets, if antisepsis is not employed, suppuration is inevitable; hence military surgeons in the past, as a rule, have advocated amputation or excision in gunshot-splinterings of large joints. We now know that the wound of a large joint produced by a hard-jacketed and small-caliber bullet may heal with little trouble. This statement is true in open fighting. It is not true in trench fighting. If we are able to regard the wound as probably aseptic the surface is sterilized, and usually the wound is enlarged, the finger is introduced to discover and remove foreign bodies, through-and-through drainage is secured, a tube is inserted, the joint is irrigated, antiseptic dressings are applied, and the extremity is placed upon a splint. In trench warfare every joint wound is regarded as infected, be it bullet wound (with or without fracture), shrapnel wound, or wound by a shell fragment. At the front the skin about the wound or wounds is painted with iodin, a field dressing is applied, the part is immobilized, and the patient is taken to the rear as soon as possible. Radical operation should be done at the first possible minute. It is done at the field hospital, the evacuation hospital, or the base hospital in accordance with grim *military* necessities.

In many cases the track of the wound is moistened with iodin, the wound is excised to the joint capsule, or synovial membrane, the projectile if lodged, is removed, bone fragments loose or hanging are taken away, the joint is irrigated with salt solution, the wound is sutured (a drainage-tube being inserted down to the synovial membrane), dressings are applied and the part is immobilized. If in spite of this treatment infection occurs, or if pus exists when operation is performed, make free incisions and use continuous irrigation or Dakin's fluid. In severe wounds arthrotomy, the usual operation in civil practice, is usually a failure, and is employed only when a missile is not retained or when it is well within reach. When it is done the synovial membrane should be removed (Taddei). The Carrel treatment is most disappointing. When the articular head is damaged a partial resection is performed by many, but a typical subperiosteal resection is usually the preferable procedure, and drainage should be secured (Taddei in "Chir. d. organ di mov.," Bologna, 1918, ii).

After operation the limb should be mobilized. Place the parts in the position indicated by Jones (pages 642 and 674).

If the temperature mounts and suppuration persists, especially if albuminuria develops, amputate (Taddei, Ibid.).

In some cases it is necessary to remove considerable bone. Very severe joint injuries demand resection or even amputation. Ankylosis, more or less complete, often follows a gunshot-wound of a joint. Because of the likelihood of ankylosis Robt. Jones lays down rules for the best position in which to dress each joint ("Brit. Med. Jour.," 1916, I).

They are as follows:

1. Shoulder-joint: Arm abducted to 50°. Elbow slightly in front of body's coronal plane. When forearm is in supination and elbow at right angles the palm looks toward the face.

2. Elbow-joint: Fixation at 100°. If both elbows have been wounded fix one at 80° and the other at 100°.

3. Wrist-joint: In dorsiflexion.

4. Hip-joint: Very slight abduction, extension of thigh and a little external rotation.

5. Knee-joint: Extension and fixation.

6. Ankle-joint: Foot at right angles to leg, sole in position of slight varus.

If the joint suppurates, the drainage must be made more free, sinuses must be slit up and packed, sloughs must be cut away, dead bone must be gouged out, and the patient must be placed upon a stimulant and tonic plan of treatment. A plan found to be valuable is the introduction of a drainage-tube into the subcrural pouch and placing the patient prone (Kellogg Speed, in "Jour. Am. Med. Assoc.," March 30, 1918).

Sprains.—A sprain is a joint-wrench due to a sudden twist or traction, the ligaments being pulled upon or lacerated and the surrounding parts being more or less damaged. A sprain is often a self-reduced dislocation (Douglas Graham). The joints most liable to sprains are the knee, the elbow, the wrist, and the ankle. The smaller joints are also often sprained, but the ball-and-socket joints are infrequently sprained, their normal range of free movement saving them; they do occasionally suffer severely, however, as a result of abduction. In a severe sprain the ligaments are torn; the synovial membrane is contused or crushed; cartilages are loosened or separated; hemorrhage takes place into and about the joint; muscles and tendons are stretched, displaced, or lacerated; vessels and nerves are damaged; the skin is often contused; and portions of bone or cartilage may be detached from their proper habitat, though still adhering to a ligament or tendon (sprain fractures). Very often a case is diagnosed as a mere sprain when a fracture also exists. The wrist is a common seat of such a lesion. Ross and Wilbert ("Amer. Med.," Jan. 25, 1902) caution us to remember that when a patient comes to us a week or ten days after an accident, displaying "a wrist which is much swollen and rather painful," all ordinary remedies having failed, we should suspect a fracture of "one or more of the bones of that joint." This article of Ross and Wilbert is very valuable and considers so-called sprains in various regions. George Ross and L. F. Stewart ("Annals of Surgery," Oct., 1912) believe that all dislocations are "permitted by the primary occurrence of sprain fracture," the bony tissues giving way more easily than tendons or ligaments. This article is a comprehensive study of sprain-fracture. Sprains are commonest in young persons and in adults with weak muscles. They happen from sudden twists and movements when the muscles are relaxed. A large part of the support of joints comes from muscles, and when muscles are suddenly caught unawares they do not properly support the joint, and a sprain results. A joint once sprained is very liable to a repetition of the damage from slight force. Sprains are common in a limb with weak muscles, in a deformed extremity in which the muscles act in unnatural lines, and in a joint with relaxed ligaments.

Symptoms.—There is severe pain in the joint, accompanied by general

weakness. Nausea, vomiting, and even syncope may occur. There is impairment or loss of ability to move the joint. The above-described condition is succeeded by a season of relief from pain while at rest, numbness being complained of, and pain on motion being severe. Swelling arises very early if much blood is effused. In any case swelling begins in a few hours. Extensive effusion, by separating joint surfaces, produces slight lengthening of the limb. Movements of the joint become difficult or impossible; the tear in the ligament may sometimes be distinctly detected by the examining fingers; pain and tenderness become intense; joint-crepitus will be manifested, and in a day or two discoloration becomes marked. Moullin and others have pointed out that when a muscle is strained the skin above it becomes sensitive, especially at tendinous insertions over joints. As muscles are invariably strained when a joint is sprained, there is always some cutaneous tenderness. There is also tenderness over a sprained joint due to capsular injury, bands of adhesions, etc. Tenderness is apt to arise at certain reasonably fixed points: in a hip-joint injury it is found behind the great trochanter, in a knee-joint injury by the side of the patella, in an ankle-joint injury to the inner side of the external malleolus (Culp). When the vertebral articulations are sprained the muscles of the back are rigid, the skin is often sensitive, pain may be awakened by pressure or by certain movements, but there is no sign of cord injury in an uncomplicated case.

Diagnosis and Prognosis.—Sprain-fractures can be diagnosticated with certainty by the *x*-rays only. In the *diagnosis* of a sprain, fracture and dislocation must be considered. In fracture, crepitus and mobility exist; in dislocation, rigidity. The diagnosis of sprain should be made by a consideration of the joint involved, of the age, of the nature of the force, of the length of the limb, of the fact that the patient could use the joint for at least a short time after the accident, and of the local feel and movements of the part. In some cases examine under ether, in some apply the *x*-rays. Many injuries about the ankle which we would have formerly regarded as sprains, are shown by the *x*-rays to be fractures. The *prognosis* depends on the size of the joint, on the extent of laceration, on the amount of intra-articular hemorrhage, and on the age of the patient. The danger is ankylosis. A sprained joint is a point of least resistance to tubercle bacilli. In rare cases after a sprain of the hip-joint osteo-arthritis arises. In some few cases after a sprain of the hip the head of the bone undergoes absorption.

Treatment.—In a mild sprain apply at once a silicate, rubber plaster, or plaster-of-Paris dressing. The first indication after the infliction of a severe sprain is to arrest hemorrhage and limit inflammation. For the first few hours apply pressure and an ice-bag. Wrap the joint in absorbent cotton wet with iced water, apply a wet gauze bandage, and put on an ice-bag. After some hours place the extremity upon a splint and to the joint apply flannel kept wet with lead-water and laudanum, iced water, alcohol and water, or a solution of chlorid of ammonium. These evaporating lotions produce cold. Instead of them an ice-bag may be used for a day. Leeches around the joint do good. Constitutionally, employ the remedies for inflammation. Morphin or Dover's powder is given for the pain. Judicious bandaging limits the swelling.

After twenty-four hours, if the symptoms continue or if they grow worse, use hot fomentations, the hot-water bag, plunge the extremity frequently in very hot water, or apply heat by Leiter's tubes. When the acute symptoms begin to subside rub stimulating liniments upon the joint once or twice a day and employ firm compression by means of a bandage of flannel or rubber. Frictions should be made from the periphery toward the body. Many cases do well at this stage under the local use of ichthyol and lanolin (50 per cent.), tincture of iodin, or blue ointment. Later in the case use hot and cold douches,

massage, frictions, passive motion, and the bandage. Passive motion and massage are begun a day or so after swelling ceases. If they cause the swelling to return, abandon them for several days and then try them again. Blisters are used when tender spots persist and stiffness is manifest. If stiffness becomes marked, move the joint forcibly. Give iodid of potassium and tonics internally, and insist on open-air exercise. If the person is gouty or rheumatic, use appropriate remedies. Van Arsdale treats sprains by massage almost from the start. Gibney treats them by strapping with adhesive plaster. Gibney's dressing is of great service in a sprain of the ankle (Figs. 451 and 452). Many sprains may be put up in an immovable dressing the first day or two after the accident. If the joint contains much blood, aspiration should be practised before the dressing is applied.

The hot-air oven is a very valuable method for treating recent sprains, and the swelling, pain, and stiffness which follow sprains of the extremities. The sprained extremity is placed in an oven, and the part is subjected to heat for an hour. The next day the treatment is repeated, and on as many subsequent days as may be necessary. In an acute sprain the pain often disappears during

FIG. 451. FIG. 452.

FIGS. 451, 452.—Gibney's method of strapping in sprains of the ankle.

the first application of heat. In the intervals between the use of the oven the extremity should be at rest, perhaps upon a splint.

Schlatter's Sprain (Schlatter's Disease. Osgood-Schlatter Disease).—This condition of partial functional incapacity is due to thickening, separation or partial separation of the tibial tuberosity. Some think the condition is due to inflammation, others that it is a dystrophy. In view of the fact that many cases are bilateral, and that other muscular and ligamentous insertions may show periosteal thickening, the view that the condition is systemic would seem probable, the systemic trouble being manifested by weakening of connective tissues and thickening of periosteum. That attention is usually called to this condition by traumatism is certain. For instance, in a reported case a boy threw a stone and fell to the ground because of a disabling pain in the right knee. He walked home but the pain and partial disability continued. A month later examination made clear that there was swelling over the tuberosity of the tibia and great tenderness of the tuberosity, but neither ecchymosis nor crepitus. The *x*-rays showed that a small fragment of bone had been partially torn off. In such a case we would infer that a sprain-fracture had occurred in the diseased area (Costa's case. See "Abstract of Surgery," Jan., 1917).

Some suggest that the bone trouble is due to staphylococcic infection. Perhaps Basseta's view of the condition is that pull by the ligament of the patella causes chronic irritation and excessive ossification ("Arch. di ortop.," 1913. See "Abstract of Surgery," June, 1914).

R. Connell ("Practitioner," 1914, xciii) believes that Schlatter's sprain is a purely traumatic condition, most common in those under seventeen years of age, and predisposed to by imperfect union of the tibial tubercle.

In some marked cases the tubercle should be nailed in place. In partial separation treatment by a posterior splint is indicated.

Sprain of the Sacro-iliac Articulation.—This condition was first described by Goldthwait. A fall, lifting a heavy weight, a blow, or a twist may injure the articulation. Normally slight motion is possible at the joint. Rupture or stretching of ligaments may lead to increased motion, and any considerable range of motion at the synchondrosis means lack of solidity and want of support. A sprain may arise from long-continued standing, bending, lying, or sitting. A sprain of this articulation may be caused by parturition, and also, as shown by Dunlop, it may develop during anesthesia because of obliteration of the normal lumbar curve by lying on a flat table without a support under the lumbar region ("New York Med. Jour.," July 10, 1909). Dunlop thus explains, and I think truly, the severe backache which is so common after anesthesia.

A sprain causes severe pain, greatly aggravated by standing, by rising up from recumbency, by movements of the ilia which jar the joint, and frequently by direct pressure upon the synchondrosis. There is often lateral spinal curvature due to spasm, and the concavity is toward the injured side.

There is pain in the injured articulation, but there may be a general backache, and, just as in sacro-iliac tuberculosis (see page 710), there may be pain in the sciatic nerve, in the groin, and in the hip-joint.

When some of the sacro-iliac ligaments are ruptured or relaxed we get the chronic condition described by John Dunlop (Ibid.) and which he calls *sacro-iliac relaxation*. When this exists the individual may injure the articulation again and again because of its unsteadiness, he may now and then have trouble, he may be in a constant condition of helplessness, with backache, groinache, pain in the hip and over the ischial tuberosity, lumbar rigidity producing lateral curvature, etc. I believe in the reality of the condition.

Treatment.—A recent sprain is treated by rest in bed and adhesive-plaster strapping, reinforced by a canvas roller around the pelvis. In a chronic case (sacro-iliac relaxation), after securing by manipulation normal relations in the articulation, insist on rest and apply a spica bandage of plaster of Paris or a brace. If there is marked tendency to displacement, ankylosis may be secured by operation. Fixation by a bone-graft from the tibia should give the most rapid and permanent result.

Rupture of the Crucial Ligaments of the Knee.—This is a rare injury. Rupture of both ligaments is unusual except in very grave injury, such as complete dislocation, and then other ligaments are also torn or destroyed.

The anterior crucial ligament instead of rupturing from force may cause avulsion of the tibial spine (see page 695). A bit of bone may be torn from a femoral condyle. In most cases the *x*-rays show small bits of separated bone. When a portion of bone is not torn off, the ligament itself tears off from the femur rather than from the tibia. Bits of cartilage may be torn off. The posterior ligament, too, tends to tear off from femur rather than tibia. Pagenstecher ("Deutsch. Med. Wochenschrift," Bd. xxix) believes that the anterior ligament may be ruptured by forced flexion of the knee and by blows applied to the posterior part of the head of the tibia when the knee is flexed. The same surgeon maintains that the posterior ligament may be ruptured by blows applied to the front of the head of the tibia when the knee is flexed. Pringle ("Annals of Surgery," August, 1907) maintains that the anterior ligament

may be ruptured by "flexion, abduction, and internal rotation of the leg at the knee." If the ligaments are ruptured there will probably be abnormal freedom of anteroposterior movement between the femur and tibia.

Pringle (Ibid.) states that if, after an injury, the knee-joint becomes distended with blood, the inference should be that one or other crucial ligament has been injured or that the tibial spine has been torn off, unless some other lesion is obviously present; that if internal rotation of the extended leg is possible at the knee, or if the head of the tibia can be brought forward on the femur, or if there is unnatural abduction, the indications are that the anterior crucial ligament has been injured or the tibial spine torn off; that injury of the posterior crucial is suggested by the possibility of pushing the head of the tibia backward during flexion of the knee-joint.

The condition causes great disability, pain and muscular weakness. In many cases exploratory incision is required to make the diagnosis.

The **treatment** is to open the joint, remove loose bone and cartilage and suture the torn ligament. Disability, pain and weakness to a considerable degree may persist ofter operation.

Ankylosis.—When a joint-inflammation eventuates in the formation of new tissue in and about the joint, contraction of this tissue limits or destroys joint mobility, producing the condition known as "ankylosis." Ankylosis may be *complete* (bony) or *incomplete* (fibrous); it may arise from contractures in the joint (*true* or *intra-articular ankylosis*) or from contractures in the structures external to the joint (*false* or *extra-articular ankylosis*).

There are qualifying terms to indicate the extent of stiffness—viz., false, spurious, true, bony, ligamentous, partial, complete, or incomplete ankylosis. The significance of the above terms will be better appreciated if ankylosis is considered as meaning a stiff joint. It may be stiff without being rigid. Fibrous adhesions produce stiff joints and they become rigid only when bony union takes place between the bones forming a joint.

Spondylitis deformans is bony ankylosis of vertebræ due to osteo-arthritis.

Arthritis ossificans is a progressive bony ankylosis in which numerous joints are involved and are finally completely obliterated. It is an ossifying arthritis.

Etiology.—There are various causes—viz., traumatism, eruptive fevers resulting in acute or suppurative synovitis or arthritis, gonorrheal arthritis, tuberculous arthritis, syphilitic affections of joints, bony fixation when a fracture is near or extends into a joint, and osteitis deformans. Simple fixation of an uninflamed joint cannot cause true ankylosis.

Pathology.—In complete—*i. e.*, bony—ankylosis the bones forming a joint become united by callus in much the same manner as bone-fragments are united after a fracture, or osseous bridging takes place at one or more places around the joint. Osseous ankylosis is preceded by a more or less prolonged stage of fibrous or partial ankylosis. In fibrous ankylosis, bands of fibrous connective tissue unite the bones forming a joint, thereby limiting the motion. In cases of joint stiffness produced by extra-articular fibrous, tendinous, or cicatricial contracture the joint proper remains free from adhesions for years, provided it is not and has not been involved in inflammatory action.

Diagnosis of bony ankylosis is usually made without difficulty except where there are several joints near together, as the carpus, tarsus, and the spine. When there are several joints near together the limitation of motion in one joint is generally compensated for by the excess in mobility of another, thereby rendering the associated parts capable of closely approaching normal function. Fibrous ankylosis is more difficult to recognize, especially if pain accompanies manipulative measures. It is most apt to be confused with fibrous, ligamentous, or cicatricial contractures of soft parts outside of a joint, but having more or less direct functional relations therewith.

Extra-articular thickening may usually be detected by the existence of

resistance to free joint motion in one direction only, *i. e.*, that produced by the fibrous contracture while the joint moves freely in other directions. Muscular contracture, whether voluntary or involuntary, is but temporary, and is easily detected by the preternatural rigidity of surrounding parts. In bony ankylosis no voluntary muscular action can be detected, inasmuch as in the process of the formation of the callus uniting the bones the muscles have become atrophied from disuse. Conversely, voluntary muscle action about a joint always indicates that joint mobility is not entirely destroyed.

As muscular rigidity is one of the most important and reliable symptoms of joint inflammation and tuberculous invasion, it is a serious error to anesthetize a patient for examination of a joint until the full significance of the muscular action has been carefully studied.

Anesthesia removes the pain and abolishes muscle fixation and thus leaves the unguarded joint free for manipulative movements, which are generally prejudicial and rarely beneficial. Where no muscle fixation is present, much may be learned by the careful study of a joint while the patient is anesthetized. We thus determine the character of the adhesions, whether they are extra-articular or intra-articular, whether they are fibrous, cicatricial, or osseous, and if bony union exists, whether it involves the entire joint or only a portion of it.

Skiagraphs are invaluable helps in making an accurate diagnosis, especially when stereoscopic plates are made. Definite information can thus be obtained as to the character of the uniting material, its extent, and definite location. Positive information will be given as to the relationship of the bones composing the joint, whether there is luxation, subluxation, flexion, or other abnormal position that may influence decision as to the therapeutic measures to be adopted. It is important to remember that a joint very rarely becomes ankylosed in the position of extension (the elbow may if treated in extension for intra-articular fracture). The almost invariable rule is that flexion is the posture of such joints, and the tendency is toward increase of the flexion until bony ankylosis occurs. In the steady progress of the flexion subluxation is apt to be induced.

Treatment of Intra-articular Ankylosis.—It is most important to prevent the occurrence of ankylosis, or in the event of its becoming inevitable, to avoid postures that will render the parts unfit for future usefulness when ankylosed.

The most useful position for a stiff joint is a matter of individual opinion; no definite rules have been accepted. In ankylosis of the elbow the flexed position is more useful in certain occupations than the fully extended arm. In other occupations the extended arm is most useful. In walking when the knee is ankylosed and does not tend toward flexion the extended leg is more useful than the flexed leg, but it is more difficult to manage when sitting.

The hip, when ankylosed at various angles, is made useful by the increased latitude of motion of the other hip and by the compensatory motion of the lumbar spine. To such an extent is the lower spine reciprocal when one or both hips are abnormal that it has been termed the third hip-joint. For general usefulness the best position for an ankylosed hip is 10 to 15 degrees of flexion, 10 to 15 degrees of abduction, and 5 degrees of external rotation. In this position, when supplemented by reciprocal action of the other hip and by the lower spine, a gait very closely approaching normal carriage may be obtained in walking, and the sitting posture may be possible.

Each individual joint has its own peculiar requirement and must become a subject for careful study in determining the most useful posture if ankylosis is to be permanent. The trend of modern surgery is to reduce greatly the time of fixation of a fractured bone in order to avoid joint stiffness and prevent muscular wasting. Early passive motion when judiciously employed does not interfere with the efficient treatment of a fracture, but does lessen the joint stiffness that is often a serious and painful sequel.

Stereo-arthrolysis "is that branch of arthroplasty whose object is to loosen stiff joints and produce new joints with mobility, following ankylosis" (R. Tunstall Taylor, "Surgery, Gynecology, and Obstetrics," April, 1912).

Brisément forcé or *redressement* are terms applied to the use of such manipulative force as the surgeon can judiciously employ in freeing a joint from fibrous adhesions. It is important to keep constantly in mind the danger of breaking the shaft of a bone or of separating the epiphysis when unguarded leverage of the entire shaft of the bone is used. It is of paramount importance to avoid brisément forcé in all cases where the ankylosis has resulted from tuberculosis. The plan is said to have been suggested by Louvrier, of Paris. It was advocated by Langenbeck. Brisément forcé is only curative when the adhesions are limited to the synovial membrane. When portions of that membrane have been destroyed or when there are dense fibrous adhesions the ankylosis invariably recurs after manipulative force and often becomes worse than before. In bony ankylosis the method is out of the question.

In applying manipulative force it is not always advantageous to have the patient profoundly anesthetized. If he is profoundly anesthetized we may be tempted to apply too violent force. Severe lacerations of fibrous adhesions produce painful joints which necessitate fixation or rest for several days to permit the reunion of the torn structures. A little gain, care being taken to maintain the motion gained, mobility being gradually increased by short progressive steps, is always better than attempts to do a great deal at once. Of course the patient's co-operation is necessary.

When pain is great, much can be accomplished during primary ether anesthesia or while the patient is under the influence of nitrous oxid. Bromid of ethyl and chlorid of ethyl are used by many because of their rapid action and brief effect. As stated elsewhere (see page 1350), I seldom use either of these drugs.

Fixation appliances of any kind are contra-indicated during corrective manipulations, as increased freedom of motion is essential rather than fixation. Voluntary efforts are needed to maintain the joint motion already secured as well as to increase the muscle function controlling the affected joint.

Among the operative procedures applicable to intra-articular ankylosis are excision to obtain a false joint (pseudo-arthrosis), excision to obtain a better position for the usefulness of the limb, breaking the bone after partially cutting it with an osteotome (osteotomy), and breaking the bone without any incision (osteoclasis). These several procedures have special advantages in different joints.

Lexer ("Zeit. f. Chir. Med. Orth.," Oct., 1908, p. 476), after resecting a knee-joint ankylosed at a right angle, transplanted the entire knee-joint apparatus from a freshly amputated limb. Complete union resulted. Muscle training was subsequently practised to improve the weak muscular control. Three and a half years later the result was excellent.

Weglowski ("Zeit. f. Chir.," April 27, 1907) resorted to cartilage transplantation in a case of ankylosis of the elbow. After freeing and re-forming the ends of the three bones, two plates of cartilage (one-half thickness of rib cartilage) with perichondrium were taken from the sixth and seventh ribs and placed between the newly formed joint surfaces, the perichondrial surface being turned toward the humeral epiphysis. No special fixation was used. No drainage was employed. Active and passive motion was begun on the tenth day. In a month the patient had 60 degrees of free flexion and extension and full pronation and supination. Death from pleuropneumonia of three days' duration occurred in five weeks. Postmortem showed that the perichondrial surface of the cartilage was united to the humerus, while the opposite side was smooth, even shining; the cartilage was enlarging and passed without definite margin into the surface of the humerus.

Microscopic examination showed newly formed blood-vessels between the cartilage and bone; the cartilage was well preserved in its entire extent, the cells and nuclei staining well.

Huguier and Murphy revive a suggestion fifty years old. They interpose soft tissue between the bone ends after freeing the ends from ankylosing material ("Traitement des Ankyloses par la Résection Orthopedique et L'interposition Musculaire," par Le Dr. Alphonse Huguier). The plan was first suggested by Verneuil in 1860 ("Archives de Medicine," 1860). He cured temporomaxillary ankylosis by the interposition of temporal muscle and fascia. In 1899 Helferich suggested inserting a portion of the vastus internus muscle between the patella and femur, and two years later Cramer reported some successful cases. Hoffa followed this method. Helferich, in 1893, mobilized the temporomaxillary joint by the insertion of a flap from the temporal muscle. This was repeated by Lentz, Henle, and others. Mikulicz, in 1895, used a flap from the masseter muscle. Similar procedures were employed by Bilezguski, Hoffa, and Kusnetzow. Rochet and Schnudt with Glück, in 1902, used a skin-flap and had previously employed ivory joints to take the place of the excised structures. In 1901 Murphy operated by Verneuil's plan.

J. B. Murphy ("Jour. Amer. Med. Assoc.," May 20–27, June 3, 1905) reviews the literature of the attempt to produce new joints and says: "In our work we have been able, by the interposition of fascia and muscle, covered with a layer of adipose tissue, to produce normal movable joints with capsules and collagen intra-articular fluid." In cases of synovitis with adhesions he resects the capsule and replaces it by aponeurosis or muscle, and it is desirable, when possible, that the replacing piece contains fat, which, under pressure, will form a hygroma or artificial synovial cavity. In bony ankylosis he operates, separates the bones, removes adjacent bony prominences or processes, frees the soft parts, prevents the bones coming again in contact, and interposes between them tissue which will remain fibrous or will form a hygroma or artificial synovial surface. After wound healing has taken place, passive motion, active motion, and forcible extension are required.

W. S. Baer ("Amer. Jour. Orthop. Surg.," 1907, p. 234) advocates the use of sterilized oil injected into joints to prevent the formation of adhesions and thus increase the arc of motion. It may also be poured into a joint after arthrotomy. After using oil in the manner described, Baer summarizes as follows: "That injection of oil into joints under proper precautions is a harmless procedure; that the joint will apparently tolerate as much as it will hold.

"It is most useful in cases where adhesions have followed some acute infectious process, or in those stiff joints which are classified as arthritis deformans of the infectious type.

"Passive motions are made with less pain where the joint contains oil.

"It plays some part in preventing adhesions, so that the mobility of the joint is increased more rapidly."

W. S. Baer (Ibid., August, 1909) reviews the literature of the operative treatment for mobilizing joints, and advocates the use of chromicized pig's bladder as the most satisfactory material to place between the surfaces of the recently separated bones.

Chlumsky, disappointed with the results of muscle flaps, used non-absorbable materials, zinc, rubber, celluloid, silver, and layers of colloidin, but no permanent mobility was obtained. He then employed absorbable plates of decalcified bone, ivory, and magnesium, with somewhat better results. Baer's method of inserting chromicized pig's bladder followed the unsuccessful employment by him of Cargile membrane. The pig's bladder is tightly stitched by catgut sutures around the recently denuded bone and the wound is closed. A hip-joint two months after this procedure showed a voluntary flexion of 35 degrees; abduction of 15 degrees; adduction of 10 degrees; rotation of 25 degrees.

Seven months after operation the mobility was better than that recorded at two months. Similar results are recorded of the knee and elbow.

Baer emphasizes the necessity of having the pig's bladder absorbable in thirty to forty days. It should be pliable enough to be adapted to the contour of the joint. Every raw surface should be absolutely separated by it from that with which it would tend to come in contact.

Thorn, after mobilizing the joint, transplants a free flap of fascia to between the bone ends ("Zeitschr. f. Chirurgie." Bd. cviii). Bauer, of Baltimore, has also done this successfully. R. Tunstall Taylor has experimented elaborately in the endeavor to find a liquid and absorbable animal substance which, when injected by a syringe between the denuded ends of the bones, would immediately solidify and prevent contact of bone ends for six or eight weeks. He finally selected yellow wax 1 part and lanolin from 2 to 6 parts (this melts at from 120° to 135° F.). Taylor has had some excellent results from this method ("Penna. Med. Jour.," Jan., 1913). He cautions us not to operate by any method for ankylosis due to infective arthritis until joint inflammation has been quiescent for a year or more.

Surgical mobilization by interposition of flaps of fat, fascia, or muscle has not come up to our expectations. The hip and elbow show the best results, the knee the worst. Good results often follow mobilization of the patella and lower jaw. Gonorrheal ankylosis gives a poor prospect because of the thickening about the joint. In such a case ankylosis is apt to recur.

In the lower extremity we must have solidity. The surgeon may regard ankylosis in a useful position as preferable to a mobilization operation with the danger of a flail-joint. In most cases of ankylosis in the lower extremity the wisest plan, if the limb is in a faulty position, is to do an operation which will let the surgeon set it in a useful position when it will undergo re-ankylosis. Bergman opposed doing mobilization operations upon the lower extremity ("Internat. Abstract of Surgery," Jan., 1917).

Personally I am doubtful about such an operation on the hip and ankle. I would not do it at all on the knee. Even in the upper extremity when the operation succeeds there is marked loss of strength. Tubby would minimize the loss of stability apt to follow the operation on a lower extremity by having only a small space between the bones. In the upper extremity he secures a much larger space between the bones. If autoplastic flaps are employed drainage is unnecessary, otherwise it should be used ("Internat. Abstract of Surgery," Jan., 1915). A mistake that has been made after arthroplasty is too early movement of the joint. This is apt to loosen the flap, cause bleeding and spoil the result. The joint should not be moved for five or six weeks. In a few cases entire joints have been successfully transplanted. Tuffier twice transplanted an elbow-joint. In one case the elbow-joint of fresh cadaver was transplanted after having been in cold storage five days. A year and a half later there was a good functional result.

Lexer reported a knee-joint six years after transplantation. The *x*-rays showed that there was partial absorption but the functional condition was satisfactory (see "Review of Recent Advances in Orthopedic Surgery," by M. S. Henderson, in "Internat. Abstract of Surgery," Jan., 1915).

Treatment of Extra-articular Ankylosis.—The treatment of false ankylosis depends upon the case. Recently contracted muscles or tendons require motion, massage, frictions with stimulating liniments, hot and cold douches, and the use of the hot-air apparatus. Violent breaking up is not satisfactory, neither is tenotomy nor myotomy. Old contractions of tendons require tendon lengthening by tendoplasty or myoplasty. Chronic inflammation of tendon-sheaths with adhesion of tendons requires excision of the sheaths. Whenever possible, excise a cicatrix that causes false ankylosis, and fill the gap with

sound cutaneous tissue and fat. When the fixation is due to adhesive synovitis of the capsule, excise the capsule and attached ligaments; "the head and neck of the bone should then be surrounded by an aponeurosis or muscle to prevent the re-forming of adhesions" (John B. Murphy, in "Jour. Amer. Med. Assoc.," May 20–27 and June 3, 1905). Bony deposits are gouged away and tumors are removed. Contractures in cases of paralysis require electricity, passive motions, frictions with stimulating liniments, the hot-air bath, and general treatment. Constant and graduated pressure by means of splints and braces (with ratchet or screws) will, in many instances, restore function. The patient can be taught to alter the pressure frequently, making it as powerful as he is able to bear it.

Loose Bodies in Joints (Floating Cartilages).—The knee is the joint affected in 90 per cent. of cases, but the elbow, shoulder, hip, wrist, lower jaw, and ankle may suffer. There may be but one loose body in a joint, there may be two or more, there may be many, or even hundreds. More than one joint may be involved. The condition is commonest in adult men. These bodies may be free or each may have a stalk or pedicle; they may move about and occasionally block the joint, or may lie quietly in a joint-recess or diverticulum. They may be flat or ovoid, smooth or irregular, as small as peas or as large as plums, and may be composed of fibrous tissue, of cartilage, or of bone. There are numerous different modes of origin of these bodies, many being "detached ecchondroses or pieces of hyaline cartilage hanging by narrow pedicles" (Sir J. Bland-Sutton), and they result from enlargement and chondrification of the villi of the synovial membrane. Loose bodies are found in the course of osteo-arthritis and osteochondritis dissecans.

Symptoms.—Some bodies give rise to no symptoms for a long time and others merely cause synovitis. A loose body may produce pain and interfere with joint-function. The joint is weak and a little swollen, and the patient can perhaps feel the body and can even push it into a superficial area of the joint, where it may be felt by the surgeon. From time to time the body may get caught, thus suddenly locking the joint and producing intense and sickening pain, extension and flexion being impossible until the body slips out. It may slip out in a moment, but may not for hours or even for many days. A rather small body seems more apt to cause locking than a very large one, but if a large one does cause locking, it is more difficult to dislodge than is a small one. Locking of a joint by a loose body is followed by inflammation and effusion. If the loose body is dense and large, the *x*-ray may disclose it. Sesamoid bones in the gastrocnemius muscle must not be confused with loose bodies in the knee-joint. In some cases of loose body in the knee the diagnosis is impossible from dislocation of a semilunar cartilage, inflamed semilunar cartilage, and synovitis with proliferation of villi.

Treatment.—To relieve locking, employ forced flexion and sudden extension. Cure can be obtained by operation only. Let the patient bring the foreign body to a point where it can be felt by the surgeon, so that he can determine where it lodges. Asepticize the knee with the utmost care. Operate if possible under cocain; if not, give ether. If the body is felt before operating, fix it with a pin. The joint is now opened, explored with the finger, the foreign body extracted, and an exploration made to see that no other bodies are present. If a body has an attachment the pedicle is snipped through by scissors. The wound is sutured in two layers and the leg is placed upon a splint. Asepsis must be most rigid. The operation does not cure the causative process, and these bodies are apt to form again. When the knee is involved, some surgeons saw the patella transversely, open the joint widely, remove all foreign bodies, and seek to cure any causative process. Robert Jones divides the patella longitudinally.

Luxations or Dislocations

A dislocation is the persistent separation from each other, partially or completely, of two articular surfaces. A self-reduced dislocation is called a sprain (Douglas Graham). There are three forms of dislocations: (1) traumatic; (2) spontaneous or pathological; (3) congenital.

1. Traumatic dislocations are due to injury. They are divided into—*complete* dislocation, in which the two articular surfaces are entirely separated and the ligaments are torn; *incomplete* or *partial* dislocation or *subluxation*, in which the two articular surfaces are not completely separated and the ligaments are rarely lacerated; *simple* dislocation, in which there is no wound leading from the surface to the articulation; *compound* dislocation, in which a wound leads from the surface to the joint; *complicated* dislocation, in which, besides the dislocation, there is a fracture, extensive damage of the soft parts, an opening which makes the case compound, or damage of a nerve or blood-vessel; *primitive* or *primary* dislocation, in which the bones remain as originally displaced; *secondary* dislocation, in which the dislocated bone assumes a new position, for instance, a subglenoid luxation of the humerus is primary, and it may become secondarily a subcoracoid luxation because of muscular contraction or attempts at reduction; *recent* dislocation, in which the displaced bone is not firmly fastened by tissue changes in its new situation, and its old socket is not obliterated; *old* dislocation, in which the displaced bone is firmly fastened by tissue changes in its new habitat, and the old socket is to a great extent obliterated (whether a dislocation is old or new depends on the state of the parts rather than on the time which has elapsed since the accident); *double* dislocation, in which corresponding bones on each side are dislocated; *single* dislocation, in which only one joint is dislocated; *unilateral* dislocation, in which one articulation of one bone is out of place; *bilateral* dislocation, in which symmetrical articulations are dislocated; and *relapsing* or *habitual* dislocation, which recurs frequently from slight force because of relaxed ligaments or lack of complete repair after the ligamentous rupture of a first dislocation.

2. Spontaneous, Pathological, or Consecutive Dislocations.—Spontaneous dislocation arises from such very slight force that the cause may not be identified, and it acts on a joint rendered lax by disease. It may arise in the course of chronic synovitis, tuberculous joint-disease, or rheumatoid arthritis. In Charcot's joint a spontaneous dislocation will occur sooner or later. In typhoid fever spontaneous dislocation is not uncommon. The hip-joint is most often the one attacked. *Dislocation of the hip in typhoid fever* follows a severe joint inflammation, is usually upon the dorsum of the ilium, and is frequently not noticed until convalescence has set in. If a typhoid dislocation is seen early, reduction is easily effected, but if seen late, is impossible. The treatment for irreducible typhoid dislocation is the same as for any other irreducible dislocation. Dislocation may occur in the acute infectious arthritis of scarlatina, pneumonia, etc., from distention of the joint cavity with septic products or exudates. In infantile palsy muscular atrophy may be so great that a shoulder or hip may be easily dislocated.

3. Congenital Dislocations.—A congenital dislocation is due to a congenital joint malformation which renders it impossible for the bone to maintain a normal position, or is due to external violence during the period of uterine gestation. Congenital dislocations should not be confounded with dislocations produced during delivery. The hip is the joint most often involved. The shoulder suffers occasionally. Lannelongue maintains that congenital dislocation of the hip is due to atrophy of the muscles and of the acetabulum following spinal-cord disease. Verneuil thinks the dislocation is paralytic. Broca says that in view of the fact that the head of the bone is larger than the cavity in which it belongs, it is useless to attempt reduction

by manipulation or extension, but many successful cases by the Lorenz bloodless method prove Broca's condemnation to have been too sweeping. Lorenz and Hoffa have each devised an operation for this condition (see pages 800, 801). Congenital dislocation of the shoulder requires incision, possibly excision, or the paring down of the head to fit the glenoid cavity (Phelps).

Traumatic Dislocations.—In the succeeding pages the traumatic form of dislocation will be particularly considered.

The causes of traumatic dislocations are divided into *predisposing* and *exciting*.

Predisposing causes are: (1) *age;* dislocations are commonest in middle life, the usual lesion of the young being green-stick fracture, and that of the old being fracture; dislocations of the radius are not uncommon in youth; (2) *muscular development*, dislocations being commonest in those with powerful muscle; (3) *sex*, males being more predisposed than females, because of their occupations and muscular strength; (4) *occupation* predisposes as a cause according as it demands the employment of muscular force, as in the carrying of burdens; (5) *nature of the joint*, ball-and-socket joints being more liable to luxation than are ginglymoid joints, because of the wider range of motion of the former; (6) *joint-disease* predisposes by relaxing the ligaments; (7) *situation of the joint*, some joints being more exposed to injury than others.

Exciting causes are divided into—(1) external violence and (2) muscular action. *External violence* may be *direct*, as when a blow upon one of the bones forces it directly away from the other; or it may be *indirect*, as when force applied to a distant part of a bone is transmitted to its end and drives the bone out of its socket. *Muscular action* is a cause when sudden and violent muscular contraction occurs during the maintenance of a position of the joint which gives the muscles full sway, and throws the head of the bone against the weakest part of its retaining ligaments.

Pathological Conditions.—In a recent complete traumatic dislocation the ligaments are damaged, and may perhaps exhibit extensive laceration, or may show only a buttonhole laceration through which a bone projects. External force produces much laceration and little stretching of the ligaments; muscular action produces little laceration and much stretching of the ligaments. In some cases of dislocation due to external violence the structures about the joint are bruised or otherwise damaged; the old socket is filled with blood, and the bone in its new situation lies in a bloody area. Large vessels and nerves are rarely torn, though they are not unusually compressed. Sprain-fracture is certainly common, in fact almost invariable (Ross and Stewart, "Annals of Surgery," Oct., 1912).

If a dislocation is not soon reduced, inflammation arises in the old joint cavity and about the displaced bone, and the whole area becomes glued together, first, by coagulated exudate, and finally by fibrous tissue. After a time, in ball-and-socket joints, the old socket fills with fibrous tissue, contracts, becomes irregular, and may even be obliterated; the head of the dislocated bone is altered in shape, its cartilage is destroyed or converted into fibrous tissue, and the pressure of the head of the bone forms a hollow in its new situation, which hollow becomes surrounded by fibrous tissue or even by bone. A new joint may form, the surrounding tissue becoming a compact capsule, and a bursa forming between the head of the bone and its new socket. In a dislocated hinge-joint the ends of the bone alter greatly in shape and their cartilage is converted into fibrous tissue. In an unreduced dislocation the muscles shorten or lengthen or undergo atrophy or fatty degeneration, as the case may be. An unreduced dislocation of a ball-and-socket joint may give a fairly movable new joint, but an unreduced dislocation of a hinge-joint rarely allows of much motion.

General Symptoms of Traumatic Dislocation.—In general, traumatic dislocations are indicated—(1) by *pain* of a sickening, nauseating character; (2)

by *rigidity*, voluntary motion being impossible except to a slight extent in the direction of the deformity. (For instance, in dislocation of the inferior maxillary the jaw can be opened a little more, but it cannot be closed.) This rigidity brings about loss of function. When the surgeon attempts to move the joint he finds it very rigid; (3) by *change in the shape of the joint* (as flattening of the shoulder after dislocation of the humerus); (4) by *alteration in the mutual relations of bony prominences about a joint* (as the alteration of the relation between the olecranon and humeral condyles in dislocation of the elbow backward); (5) by feeling the displaced bone in its new situation; (6) by missing the head of the bone from its proper situation; (7) by alteration in the length of the limb (in dislocation of the femur into the thyroid foramen the limb is lengthened, but in dislocation on to the dorsum of the ilium it is shortened); and (8) by alteration in the axis of the bone (in dislocation upon the dorsum of the ilium the axis of the injured thigh would, if prolonged, pass through the lower third of the sound thigh); (9) by seeing the dislocation with a fluoroscope or looking at a skiagraph of it.

Diagnosis of Traumatic Dislocation.—A dislocation may be mistaken for a fracture. In dislocation there is rigidity, in fracture there is preternatural mobility; in dislocation there is no true crepitus (there may be tendon- or joint-crepitus), in fracture there usually is crepitus; in dislocation the deformity does not tend to recur after reduction, in fracture it does recur after extension is relaxed. In a sprain the movements of the joint are only limited, not abolished, by the almost complete rigidity encountered in dislocation. The change which a sprain may cause in the shape of a joint is due to effusion or to bleeding; there is no alteration in the relation of the bony prominences to one another; there is no notable alteration in the length of the limb (in a sprain a very slight increase in the length of the limb may arise from joint-effusion, or the head of the bone may subsequently be absorbed and thus produce shortening after some weeks); there is no alteration in the axis of the bone; the bony head is not felt in a new position, and it is found in its normal place. Always remember that a fracture may exist with a dislocation. In any doubtful case—in fact, in most cases—give ether, for a dislocation should be reduced while the patient is anesthetized (except in dislocation of the jaw, of a finger, of the carpus, etc.). In some cases swelling renders the diagnosis difficult or impossible. Always compare the injured joint with the corresponding joint of the sound side. The *x*-rays constitute an invaluable method of diagnosis.

Treatment of Traumatic Dislocation. *Recent Simple Dislocation.*—Reduce a simple dislocation under ether, as a rule. Try *manipulation*, a procedure which seeks to make the bone retrace its own pathway. If this procedure fails, employ extension and counter-extension. If considerable force is needed, an assistant makes counter-extension, and the surgeon fastens to the extremity a clove-hitch, which he ties about his waist, and thus secures powerful extension. Counterextension may be obtained by bands, or, in some instances, by the foot of the surgeon. The *clove-hitch* is used because it will not tighten by traction; a tightening band would lacerate the soft parts (Fig. 453). If great power is needed, compound pulleys may be employed, such as the Jarvis adjuster or some similar appliance, but at the present day pulleys are rarely used (see page 757). If these means fail, cut down upon the bone and restore it to position; operation is much safer than the application of great force. After reducing a dislocation, immobilize the joint for a time, which varies for different joints, and for the first few days combat swelling and in-

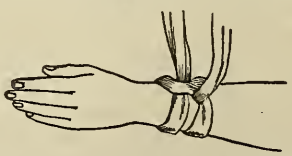

FIG. 453.—Clove-hitch knot applied above the wrist. In dislocation of the shoulder this knot is put above the elbow (after Erichsen).

flammation by rest of the part and the use of evaporating lotions or an ice-bag. If there exists a fracture of the dislocated bone, apply splints and then try to reduce by manipulations, grasping the limb and the splints with one hand below and, if possible, the head of the bone with the other hand above the seat of the fracture. Allis believes that a dislocation can be reduced even when a fracture exists. It is possible to pull the dislocated head down to the joint, because a portion of periosteum and possibly tendinous material and muscle still hold the two fragments as a strap might unite two sticks. The head may be forced into place by the fingers while traction is being made. If the fracture is near the joint and the fragments cannot be fixed, try to reduce the dislocation, first striving to press the bone into place. This attempt can be greatly aided by traction upon the lower fragment. In some cases with fracture reduction can be much aided by making a small incision, screwing a gimlet into the head of the bone, and using this tool as a handle. McBurney incises, drills a hole in each bone, inserts hooks into them, and pulls the dislocated bone into position (see Figs. 315 and 316). When the dislocation has been reduced, the bone-fragments should be wired or plated together.

Compound Traumatic Dislocation.—The opening in the soft parts may be due to external violence or to projection of a bone. Compound dislocations are very serious. Hinge-joints are more liable to these injuries than are ball-and-socket joints. Many cases require excision; some, amputation; one that does not demand excision or amputation should be treated by sterilizing the parts, restoring the dislocated bone, making a counteropening, draining, dressing antiseptically, and immobilizing. Considerable ankylosis generally ensues, except sometimes in the small joints. It is scarcely ever necessary to cut away any portion of the protruding bone to effect reduction. If a joint is badly splintered, or if the soft parts are extensively damaged, it may be necessary to excise or amputate; if the main vessels of a limb are seriously injured, amputation must be considered. If the patient is so old or so feeble that it is perilous to force him to combat a long illness, amputation should be performed.

Old Traumatic Dislocation.—The problem always presented in an old dislocation is, Shall reduction be tried or shall the bones be let alone? Sir Astley Cooper laid down this rule: "Do not attempt to reduce a shoulder-dislocation after three months, nor a hip dislocation after two months;" but this rule was put forth before the days of ether. Do not select any fixed period of time to determine what action is advisable. In dislocation of a ball-and-socket joint considerable motion may become possible and a new joint may form. If movement does not produce pain, a useful new joint may be obtained by the persistent employment of active and passive movements; if movement of the limb does produce pain, enough motion will not be attempted by the patient to produce a useful joint. In the former case it may be best to try to obtain a useful new joint, and in the latter case the surgeon should endeavor to reduce the old dislocation. Always remember that dislocation of a hinge-joint, if left unreduced, will never eventuate in a useful new joint.

In trying to reduce an old dislocation give ether, make movements to break up adhesions, and persist in making these motions until the head of the bone is felt to move; then try at once to reduce by manipulation or extension and counterextension, not waiting for two days, as some suggest. If the head of the bone cannot be made to move, the Dieffenbach plan has been advised, which is to cut the tense restraining bands with a tenotome. Lord Lister, being much impressed with the danger inevitably linked with forcibly dragging old dislocations into place, preferred to cut down and restore the bone, employing, of course, the strictest asepsis, and surgeons in general have adopted this view. In some old dislocations excision of the head of the bone is the proper operation.

Special Traumatic Dislocations.—Mandible.—A dislocation of the lower jaw, when there is no fracture, is almost invariably forward. Backward dislocation without fracture is extremely rare, and some have maintained that it cannot occur. Croker King reported a case in 1858. Theim has observed it seven times in five women. The condyle passes under the lower surface of the auditory canal.[1] The common dislocation is forward, and this is the form meant when we simply speak of dislocation of the jaw. There are two forms of forward dislocation—the *unilateral*, which is rare, and the *bilateral*, which is common. Dislocations of the jaw are commonest in women and during middle life. When the mouth is open, contraction of the external pterygoid muscle may pull the condyle over the articular eminence; this contraction may be brought about by yawning, vomiting, scolding, etc. When the mouth is open, dislocation of the lower jaw may be caused by a blow upon the chin; it may also be caused by forcing the mouth more widely open by pushing a bulky body between the teeth.

Symptoms of Lower-jaw Dislocation.—In the *bilateral* form the mouth is open and fixed, and it cannot be closed, though it can be opened a little more. The condyles are in front of the articular eminences, and are fixed by the action of the masseters and internal pterygoids, the coronoid processes being wedged against the malar bones. The lower jaw is advanced in front of the upper jaw and the face looks longer than natural. The lips cannot close, the saliva dribbles, swallowing and speech are difficult, there is a depression in front of each ear, the condyles are recognizable in their new abodes, the coronoid processes are detected by a finger in the mouth, and the masseters and temporals stand out in a state of rigidity. Pain may be severe, may be moderate, or may be absent. In the *unilateral* form the chin deviates toward the sound side, and the mouth is not so widely open as in the bilateral form, neither is the jaw so fixed. The symptoms are similar to those of a bilateral luxation, but are not so pronounced. The hollow in front of the ear and the abnormal situation of the condyle are detected upon one side only. In an unreduced dislocation the patient may after a time establish some movements of the jaw, but the power of mastication will always be seriously impaired.

Treatment of the Lower-jaw Dislocation.—In reducing a dislocation of the lower jaw the patient is usually placed with his head against the back of a chair or against the body of an assistant. The surgeon, after wrapping up his thumbs to protect them from being bitten, stands in front of the patient, puts his thumbs upon the last molar teeth, and grasps the chin with his free fingers. He now presses downward and backward on the jaw, and as soon as the condyle is loosened, closes the jaw over the thumbs by pushing up the chin, using his thumbs as levers. For the last year I have followed the excellent suggestion of W. J. Young ("Brit. Med. Jour.," March 23, 1913), which is to stand behind, the right thumb far back in the right side of the patient's mouth and grasp the chin with the left hand. The right hand easily depresses the jaw and the left guides the condyle into place. Then the procedure is reversed and the left side reduced. If reduction by the hands fails, wedges should be put between the molar teeth and the chin should be pushed up either by the hands or by a tourniquet, the band of which surrounds the head and chin. In a unilateral dislocation the wedge should be used only on the injured side. In difficult cases Sir Astley Cooper pushed a round wooden ruler between the molar teeth, used the upper teeth as a fulcrum, and raised the end of the ruler as the handle of a lever. The forceps used by an anesthetist may depress the condyle from its point of fixation, whereupon the chin may be pushed up and back. Nélaton advises that the surgeon place his thumbs in the mouth of the patient and push the coronoid processes backward. After reduction a Barton bandage should be applied and worn for over two weeks. The dressing should be

[1] Theim, in "Rev. de Chir.," vol. viii, 1888.

renewed once a day, and passive motion be begun in the second week. The bandage may be discarded at the end of the third week. Liquid diet is advisable for three weeks after the accident. In an old dislocation reduction is always attempted, at least up to a period of six or seven months after the accident. An irreducible dislocation requires osteotomy of the neck of the bone if the part cannot be restored after incision.

Dislocation of the Clavicle. Sternal End.—There are three forms of dislocation of the sternal end of the clavicle, namely: (1) forward; (2) backward, and (3) upward.

Forward Dislocation of the Sternal End of the Clavicle (Presternal Dislocation).—The *causes* of forward dislocation of the clavicle are blows, falls, or pulls which drive or draw the shoulder backward.

Symptoms and Treatment of Forward Dislocation of the Sternal End of the Clavicle.—The symptoms manifest in dislocation of the clavicle are: prominence in front of the sternum; the acromion is nearer to the sternum on the injured than on the sound side; the clavicular origin of the sternocleidomastoid muscle is rigid; movement is difficult and painful. To reduce a dislocation of the clavicle, pull the shoulders back against the knee of the surgeon, which is placed between the scapulæ. Dress with a posterior figure-of-eight bandage (Fig. 915) or a Velpeau bandage (Fig. 917), the dressing to be worn for three weeks. After removal of the dressing apply a truss, the pad of which is put over the head of the clavicle. The instrument is to be worn for a month. Dislocation of the clavicle is difficult to keep reduced, but even if it becomes fixed in deformity, the motions of the arm will not be impaired permanently. It can be reduced and fixed by incision and wiring.

Backward dislocation of the sternal end of the clavicle is very rare. The *causes* are direct violence and indirect force, such as falls or blows which drive the shoulder forward and inward.

Symptoms and Treatment of Backward Dislocation of the Sternal End of the Clavicle.—The symptoms are: pain, loss of function in the arm; inclination of the head toward the injured side; stiffness of the neck; the shoulder passes forward and inward, and often falls downward; a depression exists over the sternoclavicular joint; the head of the clavicle cannot be felt, or is found back of the sternum. The displaced clavicle may press upon the trachea, the esophagus, or the great vessels, inducing dyspnea, dysphagia, obliteration of pulse in the arm of the injured side, or great venous congestion of the head (see Pick). The usual method of treatment is to pull the shoulders backward and apply a posterior figure-of-eight bandage (Fig. 915), which must be worn for three weeks. If pressure-symptoms are urgent, it is the rule to incise, restore the bone to place and wire it, or resect the displaced head.

Upward dislocation of the sternal end of the clavicle is very rare. The *cause* is indirect force, which carries the shoulder downward, inward, and backward (Smith).

Symptoms and Treatment of Upward Dislocation of the Sternal End of the Clavicle.—The chief symptom is impaired function of the arm; the shoulder passes downward and inward, the clavicular axis is altered, and the displaced head is felt. Dyspnea may or may not exist. To treat this dislocation, put a pad in the axilla and press the elbow to the side (in order to throw the bone outward), and try to push the head into place. Apply a Desault bandage (Fig. 918) and place a firm pad over the sternoclavicular joint. The deformity is apt to recur, but a useful limb will nevertheless be obtained. The best method of treatment is to wire the bones in place.

Dislocation of the acromial end of the clavicle is almost always upward, but it may be below the acromion. The *cause* is violent force, which, if so applied to the scapula as to drive the shoulder forward, may produce a dis-

location upward. A dislocation downward is due to blows upon the upper surface of the outer end of the clavicle.

Symptoms and Treatment.—In dislocation of the acromial end of the clavicle upward there are noted: prominence of the clavicle upon the top of the acromion; impaired function of the arm (it cannot be lifted over the head); the shoulder falls downward and passes inward; there is apparent lengthening of the arm; the head is bent toward the injured side, and the clavicular origin of the trapezius is strongly outlined (Pick). In *dislocation downward* both the acromion and the coracoid are very prominent, the clavicular axis is altered, and there is depression over the sternoclavicular joint. The surgeon usually endeavors to reduce a dislocation upward by placing the patient supine on a hard table, pulling the shoulder back, and pushing the bone into place. After reduction the old method of treatment was to apply a Desault bandage, which was kept on for three weeks, and decided deformity, enduring pain, and disability were looked for as inevitable. Stimson used to apply dressings of adhesive plaster. The author has seen several cases treated by the apparatus of Thomas Leidy Rhoads. The apparatus completely corrected the deformity, and the patients made a most satisfactory recovery. The essential element

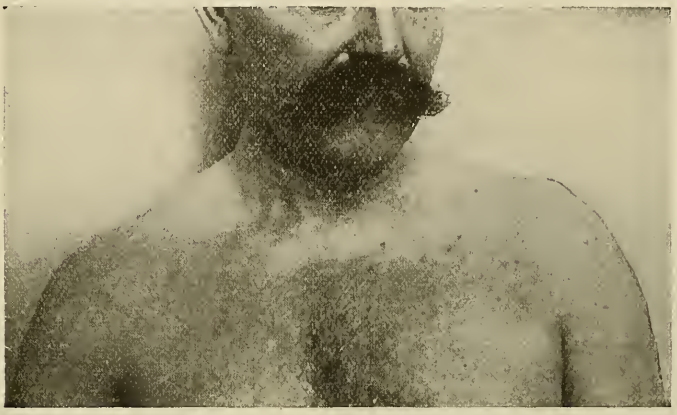

Fig. 454.—Dislocation upward of acromial end of clavicle.

of Rhoads's apparatus is a trunk-strap applied after reduction of the dislocation, as shown in Figs. 455, 456. If the deformity can be completely corrected, Rhoads's apparatus will serve a good purpose, but in many cases it is impossible really to reduce the deformity or after apparent reduction the deformity at once returns. This is due, as Moore[1] points out, to the fact that the superior acromioclavicular ligament is torn from the clavicle, but remains attached to the scapula, and when reduction is attempted, is pushed under the clavicle and nothing remains to hold the clavicle "in place but the skin and superficial fascia." I agree with Moore that the best treatment is incision, replacement, and suturing the acromion to the outer end of the clavicle. The bones are sutured with silver wire or kangaroo tendon, the acromioclavicular ligament is sutured with catgut, the wound is closed with sutures of silkworm-gut, and the patient is kept supine in bed for three weeks. I have operated successfully on 5 of these cases.

Dislocation downward is reduced and treated in the same manner as dislocation upward.

Simultaneous dislocation of both ends of the clavicle is a very rare injury. It is treated as is single dislocation.

The so-called **dislocation of the lower angle of the scapula** is not, as was long

[1] "Annals of Surgery," May, 1902.

taught, a dislocation at all. The lower angle and vertebral border deviate from the chest. This condition was thought to be due to the bone slipping from under the latissimus dorsi muscle, but it is now known to be due to *paralysis* of the *serratus magnus muscle*, the bone being acted upon by the trapezius,

Fig. 455.

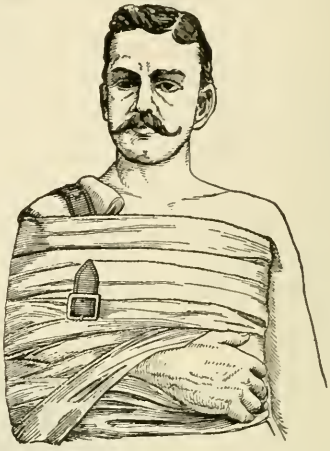

Fig. 456.

Figs. 455, 456.—Rhoads's apparatus for treating dislocation upward of the acromial end of the clavicle.

pectoralis minor, levator anguli scapulæ, and the rhomboid muscles. Examination shows that the scapula will not rotate normally forward. This is demonstrated by extending the arms in front to a right angle, the gliding forward of the scapula upon the sound side being marked, but upon the diseased side being slight or absent

Treatment of paralysis of the serratus magnus muscle comprises massage, electricity, passive motion, and deep injections of strychnin.

Fig. 457.—Subcoracoid dislocation of shoulder.

Katzenstein advocates operation for serratus palsy. He makes an incision near to the midline of the back, exposes portions of origin of the trapezius and rhomboideus major, divides them, carries the cut muscles downward and outward, and sutures them to the periosteum of the seventh, eighth, and ninth ribs and to the latissimus dorsi. He then makes an "incision along the inner surface of the arm from the middle up through the axilla to end on the thoracic wall." He divides the humeral insertion of the great pectoral and sutures its tendon to the axillary border and the anterior scapular muscles (Binnie's "Operative Surgery").

Dislocation of the Humerus (Shoulder-joint).—This injury is quite frequent because of the free mobility of the shoulder-joint, its anatomical inse-

curity, and its exposed situation; it rarely occurs in the very young and in the aged, and is oftenest encountered in muscular young adults. Shoulder dislocation is produced by throwing the arm into abduction. In this position the head of the humerus presses against the lower and front part, that is, against the thinnest and most poorly supported portion of the capsule. In almost all cases the tear in the capsule occurs between the tendon of the subscapularis and the triceps. Hence, most dislocations are *primarily* subglenoid, although the bone usually moves to some other position, being dragged or driven there by the injuring force or being pulled there by muscular action. Dislocation forward is much more common than dislocation backward because the long head of the triceps keeps the head of the bone from going posterior and because the anterior are stronger than the posterior muscles. Four chief forms of shoulder-joint dislocation exist, namely: (1) forward, inward, and downward, under the coracoid process—subcoracoid; (2) downward, forward, and inward,

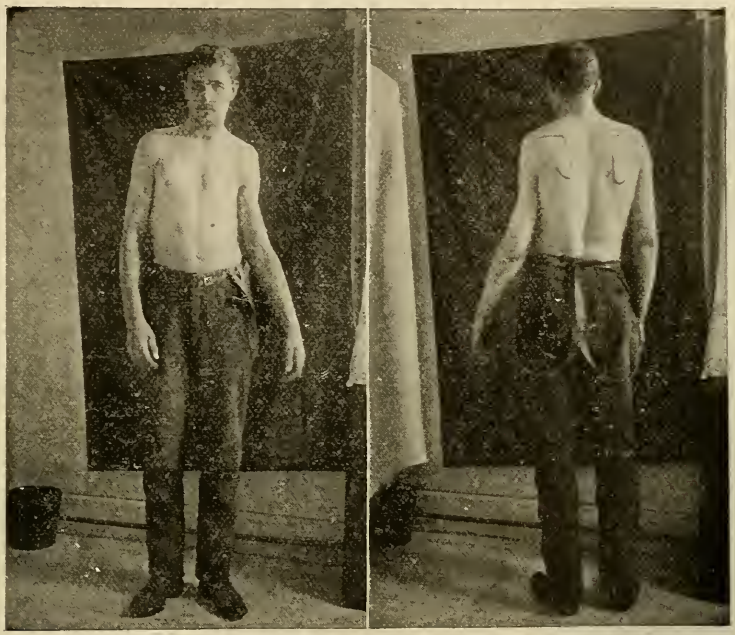

Fig. 458.—Subcoracoid dislocation of the left humerus (St. Joseph's Hospital case; photographed by Dr. Nassau).

beneath the glenoid cavity—subglenoid; (3) backward, inward, and downward, under the spine of the scapula—subspinous; and (4) forward, inward, and upward, under the clavicle—subclavicular.

A very rare form of shoulder-joint dislocation is known as the *supracoracoid*. Another rare form is the *luxatio erecta*.

Subcoracoid Luxation (Figs. 457, 458).—The subcoracoid variety of dislocation embraces three-fourths of all shoulder-joint luxations. It may be caused by direct force driving the head of the humerus forward and inward, or by indirect force, such as falls upon the hand or the elbow. In this dislocation the head of the bone lies against the anterior surface of the scapular neck below the coracoid process. A part of the anatomical neck of the humerus lies upon the anterior margin of the glenoid cavity, and the head of the bone is above the tendon of the subscapularis muscle.

Subclavicular luxation is very rare. It is caused by the same sort of vio-

lence which produces subcoracoid luxation. The head of the bone rests upon the thorax, below the clavicle, and underneath the pectoralis major muscle.

Subglenoid or Axillary Luxation (Fig. 459).—It may be produced by contraction of the great pectoral and latissimus dorsi muscles when the arm is at a right angle to the body, but it is usually due to falls upon the hand or the elbow when the arm is raised and the head of the bone is against the lower portion of the capsule. In this dislocation the head of the bone rests upon the border of the scapula, below the tendon of the subscapularis, in front of the long head of the triceps, and above the teres muscles. Most dislocations of the shoulder are primarily subglenoid, the position perhaps being subsequently altered by muscular action.

Subspinous luxation is a rare injury. Pick met with this accident in a man who, while having his hands in his pockets, fell upon the front of the point of the shoulder. The head of the bone reposes beneath the scapular spine, between the infraspinatus and teres minor muscles.

Supracoracoid luxation is seldom encountered. The head of the humerus rests upon the coraco-acromial ligament or upon the acromion process, and the acromion or the coracoid is always fractured.

Fig. 459.—Axillary dislocation of the right humerus.

Luxatio Erecta.—In this injury the arm is markedly abducted and in some cases the elbow is actually raised above the patient's head. As a rule, the forearm rests behind the occiput, sometimes on the top of the head. The patient holds the forearm to the occiput or vertex to avoid pain. It is, in reality, a form of subglenoid luxation. In such an injury the head of the bone has passed under the subscapularis muscle and also under the teres major or the lower border of the great pectoral. Judd, Hulke, Cleland, and others have reported cases.

Symptoms of Dislocation of the Shoulder-joint.—Dislocation is diagnosticated by—(1) pain of a sickening character; (2) flattening of the shoulder, the head of the bone having ceased to bulge out the deltoid muscle; (3) apparent projection of the acromion through sinking in of the deltoid; (4) hollow beneath the acromion, over the empty glenoid cavity, and the bone missing from its normal habitat. This hollow may be easily appreciated by the finger, especially when the extremity is somewhat abducted; (5) rigidity (some movement is possible in the direction especially of an existing deformity, but mobility is strictly limited and attempts at motion produce great pain); (6) Dugas's sign: the elbow cannot touch the side when the hand is placed upon the sound shoulder, and the hand cannot be placed upon the sound shoulder if the elbow is to the side (this is due to the rotundity of the chest. In a dislocation the head of the bone is already touching the chest, and the bone, being approximately straight, cannot touch the spherical surface of the chest in two places at the same time. If the elbow can be placed against the chest with the hand on the sound shoulder there cannot be dislocation; if it cannot be so placed, there must be dislocation); (7) finding the head of the bone in a new situation; (8) examining by means of the *x*-rays. Symptoms 1 to 5 inclusive may be grouped as Erichsen's list of signs. The form of dislocation is made out by a study of the direction of the axis of the limb, the existence and extent of lengthening or of shortening, and the situation of the head of the bone.

In a shoulder-joint dislocation the head of the bone may press upon the brachial plexus and produce pain and numbness, and occasionally traumatic neuritis or paralysis; sometimes pressure upon the axillary vein causes intense edema, and pressure upon the axillary artery diminishes or obliterates the pulse. The axillary vessels may be torn and the muscles may be lacerated badly. The capsule is torn and considerable blood is usually effused. Swelling is due first to hemorrhage, and secondly to inflammation. Partial dislocation sometimes, though rarely, occurs. What is usually spoken of as "partial dislocation" or "subluxation" is a condition in which the head of the humerus passes forward under the coracoid because of rupture of the long head of the biceps or because this tendon slips out of its groove, the ligaments of the shoulder-joint being intact.

The following table from T. Pickering Pick's work on "Fractures and Dislocations" makes the above points clear:

	Direction of the axis of the limb	Alteration in the length of the limb	Presence of the Head of the bone in new situation
Subcoracoid.	The elbow is carried backward and slightly away from the side.	Very slight lengthening.	The head of the bone cannot easily be felt; it is found at the upper and inner part of the axilla.
Subglenoid.	The elbow is carried away from the trunk and slightly backward.	Very considerable lengthening.	The head of the bone can easily be felt in the axilla.
Subspinous.	The elbow is raised from the side and carried forward.	Lengthening intermediate in degree between the subglenoid and the subcoracoid.	The head of the bone can be felt and be grasped beneath the spine of the scapula.
Subclavicular.	The elbow is carried outward and backward.	Shortening.	The head of the bone can readily be seen and be felt beneath the clavicle.

Diagnosis of Shoulder-joint Dislocation.—In *fracture of the neck of the scapula* the acromion is prominent, a hollow is detected below it, and a hard body is felt in the axilla; but the coracoid process descends with the head of the humerus, which it does not do in dislocation. Furthermore, in fracture there is mobility, in dislocation, rigidity. In fracture crepitus is present; in dislocation it is absent. In fracture the deformity is easily reduced, but it at once recurs; in dislocation the deformity is with difficulty reduced, but does not recur. In fracture the elbow can be made to touch the side when the hand is upon the sound shoulder; in dislocation it cannot be so manipulated. In *fracture* of the *anatomical neck of the humerus* deformity is slight; the head of the humerus is found in place, does not move when the shaft is rotated, and is not in line with the axis of the bone. Crepitus exists in the fracture if impaction is absent. In *paralysis of the deltoid muscle* there is distinct flattening, but the bone is felt in place and there is no rigidity. The *x*-rays are invaluable in diagnosis.

Treatment of Shoulder-joint Dislocation.—Reduction by manipulation is usually readily accomplished in a recent case of shoulder-joint dislocation. If a simple trial without ether fails, an anesthetic should be administered. Ether is given, but not chloroform, for chloroform seems to be particularly dangerous to life when given to enable the surgeon to reduce a dislocation of the shoulder. *Forward dislocations* (subcoracoid, subclavicular, and axillary) are reduced by *Kocher's method* (Fig. 460). This method was introduced by Kocher in 1870 ("Sammlung klin. Vorträge," No. 83). Reduction by this method can frequently be effected without the aid of ether. The patient should be recumbent. Slowly but forcibly adduct the abducted elbow and get it finally

against the side. At the same time draw it slightly backward. The forearm is flexed. If there is much muscular resistance, follow Keetley's advice, and not only bring the elbow to the side, but push it backward and inward toward the spine. Grasp the elbow with one hand, and the wrist with the other, and slowly make external rotation until the forearm points outward from the body. We thus carry the head of the humerus to the margin of the glenoid cavity. External rotation must be done slowly and gently. When we first try it there is much muscular resistance. If enough force is used to overcome the resistance the surgical neck of the bone may be broken. By gently and gradually persisting in external rotation the muscles are finally tired out and relax. Next lift the elbow anteriorly as far forward as it will go, so as to bring the head of the humerus to the glenoid margin just opposite the capsular tear (Keetley). Then throw the bone into place by gradually swinging the forearm inward across to the other side of the chest, that is, by internal rotation. The formula is, flexion of the forearm, external rotation, lifting the elbow forward, internal rotation of the arm, and lowering the elbow. The motions to unlock the bone and start it to retrace the steps it took when emerging should be gentle, not forcible, slow, not sudden, and rigid muscles should be tired out and made to relax by steady traction upon them. Sudden and violent motions increase rigidity. Adduction stretches the upper portion of the capsule and presses

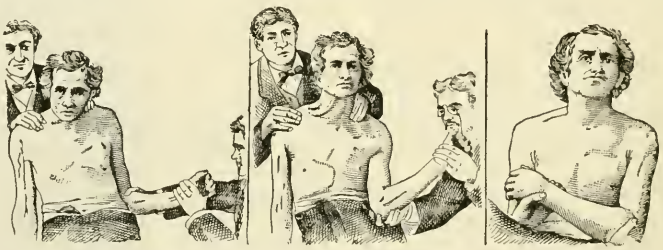

FIG. 460.—Kocher's method of reduction by manipulation: *a*, First movement, outward rotation; *b*, second movement, elevation of elbow; *c*, third movement, inward rotation and lowering of the elbow (Ceppi).

the head against the glenoid. External rotation opens the tear in the capsule. Elevation relaxes the untorn part of the capsule and coracohumeral ligament and stretches the torn portion. On this fulcrum the head, which is the end of a lever, is forced into place. If in trying Kocher's plan external rotation of the humerus does not take place, abandon the method, as persistence will fracture the humerus. Another method of manipulation is as follows: if the *right* shoulder is dislocated, the surgeon stands behind the patient (who is sitting erect); if the *left* shoulder is dislocated, he stands in front of the patient. The surgeon holds the forearm flexed upon the arm with his right hand and makes external traction and rotation, and with the fingers of his left hand he tries to force the bone into place.

In *Henry H. Smith's method* for forward dislocation the surgeon stands in front of the patient. If the *left* shoulder is dislocated, the surgeon grasps it with his left hand; if the *right* shoulder is dislocated, he grasps it with his right hand, the thumb resting on the head of the bone. With his disengaged hand the surgeon grasps the elbow, abducts it, makes traction and external rotation, and suddenly sweeps the elbow inward, aiming it at the sternum, and tries with his thumb to push the bone into place. In *subspinous luxations* reduction may be effected if the surgeon stands behind the patient, makes abduction, traction, and internal rotation, sweeps the elbow inward toward the spine, and with thumb aids the bone in its return into position. Raising the elbow far above the head and sweeping it inward will reduce some dislocations. As the head of the bone slips back a distinct jar is felt and a snap is heard, the

motions of the joint are again obtainable, and with the hand on the opposite shoulder the elbow may be made to touch the side.

Reduction by Extension.—Before attempting the reduction of a dislocation of the shoulder-joint by extension the patient should be anesthetized and placed upon a low bed or upon the floor. The surgeon then places his foot, covered only by a stocking, in the axilla. Place the sole of the foot, not the heel, against the chest high up, the instep being made to touch the humerus and the heel the border of the shoulder-blade, a towel being first put into the axilla to rest the foot against (Fig. 461). If the left arm is dislocated, use the left foot, and vice versâ. The elder Gross approved of making extension while sitting between the patient's limbs. Make steady extension, which will in many cases bring about the reduction. If it fails to cause reduction, bring the patient's arm across the chest and use the foot as the fulcrum of a lever. If the humerus is pretty firmly fixed in its abnormal position, make counterextension with a foot in the axilla and make extension by fixing a clove-hitch (see Fig. 453) *above the elbow* and fastening to it bands which go over one shoulder and under the other shoulder of the surgeon. The back may thus be used for extension, the hands being left free for manipulation (Allis's and Pick's plan). Lateral extension is used by some surgeons. The patient lies down, a large piece of canvas is split, the arm is passed through the split, and the body is thus fixed. The arm is pulled to a right angle with the body and traction is applied.

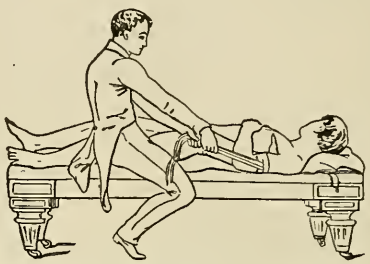

Fig. 461.—Reduction of shoulder-joint dislocation by the foot in the axilla (Cooper).

The late Prof. Joseph Pancoast favored *Sir Astley Cooper's method* of placing the unanesthetized patient in a chair and using the knee as a fulcrum, pushing the elbow to the side (Fig. 462). Brunus, in the thirteenth century, devised the method of *upward extension.* In applying this method the surgeon takes his place behind the patient, steadies the scapula with his hand, and carries the patient's arm upward and backward above his head, making extension and external rotation (Fig. 463). *La Mothe's method* is applied with the patient supine upon the floor. The surgeon places his foot upon the shoulder to make counterextension, and makes extension as in Brunus's method. It is a useful expedient, when either of these plans is applied, to have an assistant make the traction while the surgeon manipulates the head of the bone. Cock advises, when reduction fails, that an air-pad be placed in the axilla and the arm be bound to the side—a method by which reduction will sometimes take place after two or three days.

Pulleys should not be used to pull the bone into place, as they develop a dangerous force. In a dislocation irreducible by ordinary force, antiseptic incision is safer and better than the pulleys. After incision try to restore the bone to place.

In reducing a dislocation the axillary artery or vein may be ruptured, fracture of the neck of the humerus may take place, injury to the brachial plexus may occur, or the soft parts may be badly damaged. After reducing a dislocation apply a Velpeau bandage, keep the shoulder immobile for one week, then make passive motion daily, reapplying the dressing after each séance. The patient may wear a sling only during the third week, after this period he may use the arm. (For Compound Dislocations, see page 748.)

Unreduced and Irreducible Dislocations of the Shoulder.—In some cases where we find there is considerable movement without pain we can, by manipu-

lation and active motion, increase the range of movement and the usefulness of the new joint.

As a rule, in a youth or a middle-aged person we attempt bloodless reduction if the head of the bone is movable and there is no prospect of a useful new joint. Give ether, break up adhesions by forced flexion and extension, and try Kocher's method, and, if this fails, the other methods, but never use violent force. In reducing an old dislocation we may fracture the surgical neck of the humerus. I have seen this happen twice. The proper treatment is incision and pulling the head into place by McBurney's hooks. In attempting reduction of an old dislocation by force the brachial plexus may be lacerated or one or both of the axillary vessels may be torn. If an axillary vessel is torn, it must be at once exposed by incision. A larger tear in either vessel requires a ligature about the vessel on each side of the tear. A small tear may be sutured (Keetley, in "Lancet," Jan. 23, 1904). Rather than use sufficient force to endanger the vessels in attempting to reduce an old dislocation, practice incision. In some cases after incision the head of the bone can be pulled and pushed into place. In other cases the head must be resected. After reduction of an old dislocation immobilize for three weeks, and begin passive motion after seven days.

FIG. 462.—Reduction of shoulder-joint dislocation by the knee in the axilla (Cooper).

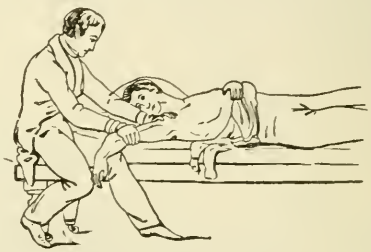

FIG. 463.—Reduction of shoulder-joint dislocation by upward extension (Cooper).

If a *dislocation* is *complicated* by a *fracture of the humerus*, try to pull the head of the bone opposite the joint. This may be possible if the two fragments are held partly together by a fair amount of periosteum and muscle. Traction is exerted upon the arm, and an attempt is made to manipulate the head into the socket (Allis's plan in the hip). McBurney incises, fixes a hook in the scapula and a hook in the head of the humerus, pulls the head into place, and wires the fragments (see Figs. 315, 316). In an emergency gimlets may be used instead of the hooks. In some cases it is necessary to excise the head of the bone.

Habitual or Recurrent Dislocation.—Habitual or recurrent dislocation of the shoulder, following an original traumatic dislocation, results usually from a slight or trivial force. It is apt to take place when the arm is in abduction, slight rotation frequently being necessary. In some cases rotation will produce a dislocation while the arm is near the side of the body. Little is known of the frequency with which these cases occur, but they are probably much more frequent than is generally supposed. The frequency of the recurrences in the individual cases varies widely. In some they occur more or less regularly every two or three years, while in others they have been known to take place daily and even several times a day. In most cases in the intervals between the recurrences the joint functionates normally without difficulty, although the patient fears abduction because of its influence in favoring a recurrence. In rare cases pain persists a long time after each dislocation, so

that if the recurrences are frequent, the patient may be compelled to give up work.

Cause.—The essential cause is a relaxation of the capsule at the site of the original tear, produced by the addition to the old or original portion of capsule of a new or cicatricial portion bridging over the gap between the margins of the tear produced by the first dislocation. The failure of these margins to unite closely is due to the repeated emergence of the humeral head forcing them apart before union is complete. The defects in the head of the humerus which have been found at autopsy and operation have, probably, only a slight and secondary causal importance, while the fractures of the greater tuberosity of the humerus sometimes occurring in dislocations of the shoulder are probably not followed by recurrent dislocations.

Fig. 464.—Dislocation of both bones of the forearm backward.

Treatment.—Excision of the head of the humerus has been abandoned in these cases. Capsulorrhaphy for the shortening of the relaxed anterior portion of the capsule has given excellent functional results. Dawbarn, of New York, did this operation in my clinic, upon a city fireman, and the result was a perfect success. I have had two gratifying results. The capsule may be exposed through the usual resection incision along the anterior margin of the deltoid. This may be modified by an additional incision outward at right angles to the first, and the insertion of the pectoralis major may be partially divided. T. Turner Thomas advocated an axillary incision along the inner border of the coracobrachialis, passing between this muscle and the axillary vessels and nerves, and avoiding particularly the circumflex and musculocutaneous nerves. The subscapularis muscle is partially divided to give a freer exposure of the capsule. This route exposes, by a small incision, the site of the original tear in the capsule. It avoids division of the deltoid and gives dependent drainage if drainage is necessary. At present he prefers a posterior axillary incision. He has operated on 18 shoulders and has had 16 complete successes ("Surgery, Gynecology and Obstetrics," 1914, xviii).

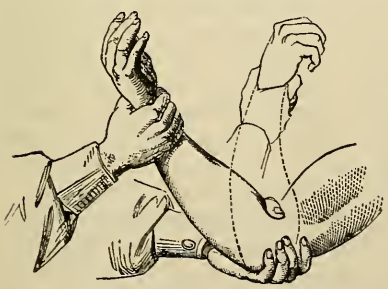

Fig. 465.—Reduction of elbow-joint dislocation.

The relaxed portion of the capsule may be shortened by taking up a reef with catgut or silk sutures, without opening and exploring the joint for loose pieces of bone; the capsule may be incised transversely to its longitudinal fibers and the margins of the incision overlapped; an oval piece may be excised and the edges united by sutures; or the margins of the original tear may be found and sutured together.

Dislocation of the elbow-joint is not infrequent, and is commonest in children. Both bones or only one bone of the forearm may be dislocated, and the dislocation may be partial or complete.

Dislocation of Both Bones Backward (Fig. 464).—The *causes* of backward dislocation of both bones of the forearm are falls upon the extended hand or twists inward of the ulna (Malgaigne). The coronoid process lodges in the olecranon fossa of the humerus.

Symptoms of Backward Dislocation.—In complete dislocation of both bones of the forearm the olecranon is very prominent. The distance between the point of the olecranon and the apex of the inner condyle is notably greater than on the sound side; the forearm is flexed, supinated, and shortened; the lower end of the humerus projects in front of the joint, below the skin-crease; the head of the radius is found back of the outer condyle; and there are the general symptoms of dislocation. Fracture of the coronoid rarely occurs with backward dislocation, but if it does occur, there will be crepitus and mobility. Fracture at the base of the condyles is distinguished from dislocation of both bones of the forearm backward by the following points: in fracture there are found the ordinary symptoms; measurement from the condyles to the styloid processes does not show shortening; there is no alteration of the normal relation between the olecranon process and the condyles; and the projection in front of the joint is above the crease of the bend of the elbow.

Fig. 466.—Forward dislocation of the radius.

Treatment of Backward Dislocation.—Reduction must be effected early in dislocation of both bones of the forearm, because it will soon become impossible, and an unreduced dislocation means a limb without the powers of flexion, pronation, and supination. The surgeon may place his knee in front of the elbow-joint, grasp the patient's wrist, press upon the radius and ulna with his knee, and bend the forearm with considerable force, the muscle pulling the bones into place (Sir Astley Cooper's plan). Forced flexion, traction and extension may be tried (Fig. 465). Put the arm in Jones's position for two weeks, and make passive motion daily after the first few days.

Dislocation of Both Bones Forward.—The *cause* of forward dislocation of both bones of the forearm is a blow on the olecranon when the arm is flexed. It is an unusual accident.

Symptoms and Treatment.—The *symptoms* of forward dislocation of both bones of the forearm are: the forearm is flexed and lengthened; some slight motion is possible; the olecranon is on a level with the condyles if unfractured, hence its prominence is gone; the humeral condyles are felt posteriorly, and the radius and ulna are felt anteriorly. The *treatment* of this injury consists in early reduction, which is accomplished by means of forced flexion, extension, and pressure, placing the part in Jones's position for two weeks, and making passive motion daily after the first few days.

Lateral dislocation of both bones of the forearm is usually incomplete.

Symptoms and Treatment of Outward Dislocation.—The *symptoms* of outward dislocation of both bones of the forearm are: the forearm is flexed, fixed, and pronated; the joint is widened; the head of the radius projects ex-

ternally and has a depression above it; the inner condyle projects internally and has a depression below it; the olecranon is nearer than normal to the external condyle and further than normal from the internal condyle. Reduction is effected by extension of the forearm and pressure inward upon the head of the radius. Apply an ascending spiral reversed bandage of the forearm, a figure-of-8 bandage of the elbow-joint, and a sling. Make passive motion after a few days. The bandages must be worn for two weeks.

Symptoms and Treatment of Inward Dislocation.—In dislocation inward of both bones of the forearm the position of the forearm is the same as that in dislocation outward; the sigmoid cavity of the ulna projects internally, and the external condyle projects externally. Reduction is effected by extension of the forearm and pressure outward on the ulna, subsequent treatment being the same as that employed in the preceding form.

Fig. 467.—Dislocation of the radius backward.

Dislocation of the ulna alone is very rare, and can take place backward only.

Symptoms and Treatment.—Dislocation of the ulna alone is indicated by the forearm being flexed and pronated. The head of the radius is found in place, and the olecranon projects posteriorly. The *treatment* of this injury is the same as that for dislocation of both bones.

Dislocation of the radius forward (Fig. 466) is the commonest form of dislocation of the elbow. This injury is caused by a fall upon the hand with the forearm in pronation and extension, or is produced by blows on the back of the joint; forced pronation alone will not cause it.

Symptoms and Treatment.—The *symptoms* in dislocation of the radius forward are: the forearm is midway between pronation and supination, and is semiflexed; attempts to increase flexion cause the radius to strike against the humerus with a distinct blow; the head of the radius is felt in front of the outer condyle and is missed from its proper abode. Reduction is effected by flexion over the knee, extension, and manipulation. The subsequent treatment is Jones's position and passive motion. Deformity is apt to recur after reduction because of rupture of the orbicular ligament. If permanent dislocation exists, resection of the head of the radius is necessary. Passive motion should be begun in two weeks after the resection. The results as to function and strength are usually excellent.

Dislocation of the radius backward (Fig. 467) is caused by falls on the hand or by blows on the front of the joint.

Symptoms and Treatment.—Backward dislocation of the radius is indicated

by the forearm being slightly flexed and fixed in pronation, by some impairment of flexion and extension, and by the head of the radius being felt behind the outer condyle. Reduction is effected by flexion over the knee, extension, and manipulation, and the subsequent treatment is the same as that given for the preceding dislocation.

Dislocation of the radius outward is very rare. In this injury the head of the radius is distinctly felt. Reduction is effected by extension and pressure; the subsequent treatment is the same as that for the above-mentioned dislocations.

Subluxation of the Head of the Radius.—This name is given to an injury which is very frequent in children between two and four years of age. It results from traction upon the hand or the forearm, and often arises when the nurse or the mother pulls upon a child's arm to save it from a fall or to lift it over a gutter. Some writers hold that pronation as well as extension is required to produce the injury; many surgeons claim that extension and adduction are the causative forces. Hutchinson asserts that supination may cause subluxation. Bardenheuer assigned falls as causes.

The *symptoms* are very characteristic. The history points to the injury. Pain and perhaps a click may be felt about the elbow, and pain and a click may also be felt in the wrist at the time of the accident. The arm hangs by the side, with the elbow-joint slightly flexed and the forearm midway between pronation and supination. Flexion to an angle of less than 60 degrees and complete extension are resisted and are very painful, but movements between 60 and 130 degrees are free and painless.[1] The movements of the wrist-joint are free and painless. The elbow-joint presents no deformity. Pressure over the head of the radius causes pain. Strong pronation is painful; strong supination is very painful, and there seems to be a mechanical obstacle to its performance. Forced supination develops a distinct click at the head of the radius, and causes pronation and supination to become natural and free from pain. The condition will be reproduced if the parts are not immobilized for a time. The nature of the lesion is not understood, and various conditions have been thought to exist by different observers. Among them may be mentioned the following: a slight anterior displacement of a head of the radius; a slight posterior displacement; locking of the tuberosity of the radius behind the inner edge of the ulna; dislocation of the triangular cartilage of the wrist; intracapsular fracture of the radial head; painful paralysis from nerve-injury; displacement by elongation, the return of the bone being prevented by collapse of the capsule; and the slipping up of the margin of the orbicular ligament over the rim of the head of the radius.

Treatment.—In order to reduce, place the forearm at a right angle to the arm and make forcible supination. Apply an anterior angular splint, and have it worn for four or five days, or put the part in Jones's position for an equal period.

Dislocation of the Inferior Radio-ulnar Articulation.—See page 763.

Dislocation of the Ulna Backward.—This is caused by forcible pronation, for instance wringing clothes. The wrist is pronated and extended, the fingers are extended or semiflexed and almost powerless, supination is impossible, the hand is adducted and the head of the bone is prominent posteriorly on the radius. This is reduced by separating the two bones with the thumbs and pushing on the ulna while an assistant supinates the hand.

Dislocation of the Ulna Forward.—This is caused by forcible supination. Pronation is impossible. The wrist is narrowed and the ulna projects anteriorly. Reduction is secured by manipulation, extension and pronation.

Madelung's deformity results from the strain of persistent heavy work upon the radius of one who has not yet reached puberty. The lower end of

[1] See the instructive article by W. W. Van Arsdale, in "Annals of Surgery," vol. ix, 1889.

the radius becomes flexed, the ulna projects posteriorly. Slight backward projection of the ulna, the radius not being flexed, may arise from overwork in childhood. In such a case the ulna is hypertrophied and full extension is impossible.

Dislocation of the wrist is very uncommon and is caused by a fall upon the hand.

Backward Dislocation of the Wrist. *Symptoms.*—The deformity in backward dislocation of the wrist (Fig. 468, A) resembles that of Colles's fracture (Fig. 468, B). The fingers are flexed, the wrist is bent backward, the radius projects on the front of the wrist, the carpus projects on the dorsal surface of the forearm, the relation of the styloid process of the radius to the styloid process of the ulna is unaltered (it is altered in Colles's fracture), there is rigidity, and crepitus is absent.

Forward dislocation of the wrist is very unusual and is caused by a fall upon the back of the hand.

Symptoms and Treatment.—In forward dislocation of the wrist the radius and ulna project posteriorly and the carpus projects in front. The *treatment*

FIG. 468.—Deformity in dislocation of the wrist backward (A) and in Colles's fracture (B) (Stimson).

in both of these dislocations is reduction by extension and manipulation, the use of a Bond splint for ten days, and the employment of passive motion after five or six days.

Dislocation at the inferior radio-ulnar articulation is rare and is caused by twisting. A fracture occurs with it.

Symptoms and Treatment.—In *forward* dislocation at the inferior radio-ulnar articulation the forearm is pronated, the space between the styloid processes is diminished, and the ulna forms a projection posteriorly. In *backward* dislocation the forearm is supinated, the space between the styloid processes is diminished, and the ulna projects in front. Reduction is accomplished by extension and manipulation. Two straight splints (as in fracture of both bones) are to be applied for four weeks, and passive motion is to be made in the third week.

Dislocation of Individual Carpal Bones.—Pick says there is one weak spot, which is "between the head of the os magnum and the scaphoid and semilunar bones," and the os magnum may be forced up. The lesion is called by some dislocation of the os magnum backward. Some surgeons believe the condition is a dorsal dislocation of the carpus over the semilunar bone. Codman and Chase ("Annals of Surgery," March and June, 1905) regard the injury as really *dislocation of the semilunar forward*, a dislocation which may be associated with fracture of the carpal scaphoid. The injury is caused by forcible overextension or by twisting of the wrist. According to Codman and Chase, the injury is most frequently met with in men between the ages of thirty and forty, results from violent force, immediately produces severe pain, soon followed by tenderness and ecchymosis. On examination a slight silver-fork deformity is observed, the posterior projection being the os magnum, this projection being separated from the radius by a groove which marks the former situation of the dislocated semilunar. The dislocated bone is felt under the flexor tendons of the wrist, the palm seems shorter than its fellow, the fingers are partly flexed,

active or passive motion causes pain, and the *x*-rays exhibit the dislocated bone (Ibid.).

A trauma, even a slight one, which damages the ligament carrying the blood supply to the semilunar, may be followed by rarefaction of that bone, and possibly fracture from slight force. Pain and swelling of the wrist persist, motion is circumscribed and strength is lessened.

Treatment.—According to Codman and Chase, recent dislocations (even after the fifth week) may be reduced by hyperextension followed by hyperflexion over "the thumbs of an assistant held firmly in the flexure of the wrist or the semilunar" (Ibid.).

If bloodless reduction fails, the author advises palmar incision and reduction, and if this fails, excision of the bone. If in excising the semilunar the scaphoid is found to be fractured, the proximal part or the entire scaphoid must also be removed. The functional result from operation is excellent.

Dislocation of a metacarpal bone is seldom encountered. The first metacarpal bone is most liable to dislocation.

Symptoms and Treatment.—Dislocation of a metacarpal bone is obvious because of projection. It is reduced by extension and manipulation, a straight splint and large pad for the palm are applied (as in fracture of the metacarpus), and the splint is worn for three weeks.

Dislocation at a metacarpophalangeal articulation is unusual. Backward dislocation is the most common. The *cause* is a fall upon the hand.

Symptoms and Treatment.—A dislocation at a metacarpophalangeal articulation is obvious. Reduction is easily effected by extension and manipulation, except in the case of the thumb. A splint must be worn for three weeks.

Dislocation of the Metacarpophalangeal Joint of the Thumb.—In this dislocation the phalanx usually passes backward. In some cases the long flexor of the thumb gets to the ulnar side of the head of the metacarpal bone and hinders reduction (J. Hutchinson, Jr., in "Brit. Med. Jour.," Jan. 15, 1898). The chief impediments to reduction, as demonstrated by Farabeuf, are the sesamoid bones and glenoid ligament, which accompany the base of the phalanx in the dislocation. It is not probable that the catching of the metacarpal bone between the two heads of the flexor brevis, which often happens, is an important impediment.

The *symptoms* of *backward* dislocation are as follows: The base of the first phalanx rests upon the metacarpal bone; the head of the metacarpal bone projects forward and buttonholes the muscles of the thumb; the first phalanx of the thumb is strongly extended, and the terminal phalanx is semiflexed. The *symptoms* of *forward* dislocation are as follows: The base of the first phalanx is felt in the palm, and the head of the metacarpal bone is felt posteriorly.

Treatment.—In treating backward dislocation of the metacarpophalangeal joint of the thumb reduction is difficult. Always give ether. Keetley's directions are to adduct the metacarpal bone into the palm (this relaxes the flexor muscles) and to have an assistant hold it; bend the thumb strongly back, extend, pull the thumb toward the fingers, and suddenly flex. To get a firm enough grasp for these manipulations use the apparatus of Charrière or of Levis (Figs. 469, 470). If the above maneuvers fail, incise freely on the dorsum and reduce. Tenotomy is seldom of service. After reduction of this dislocation a splint must be worn for three weeks. In *forward* dislocation reduction is easily effected by strong extension and forced flexion. A splint is to be worn for three weeks.

A dislocation of a phalanx may be complete or may be partial. It is most common between the first and second phalanges.

Symptoms and Treatment.—Dislocations of the phalanges are obvious. In reducing such dislocations employ extension and manipulation. Use a splint for one week.

Dislocations of the Ribs and Costal Cartilages.—The ribs may be dislocated from the vertebræ. This accident is seldom uncomplicated, and cannot be differentiated from fracture without a skiagraph. The diagnosis is rarely made, and the injury is treated as a fracture. The ribs may be dislocated from their cartilages, one or more ribs being displaced. The end of the rib forms an anterior projection, there is a depression over the cartilage, and crepitus is absent. *Treatment* is the same as that employed for fractured ribs. The costal cartilages may be displaced from the sternum, forming an anterior projection upon this bone. Reduction is brought about by placing the patient upon a table, with a sand-pillow between the scapulæ, pushing back the shoulders and chest, and forcing the cartilage into place. The dressings are the same as those used for fractured sternum. The cartilages of the lower ribs (sixth, seventh,

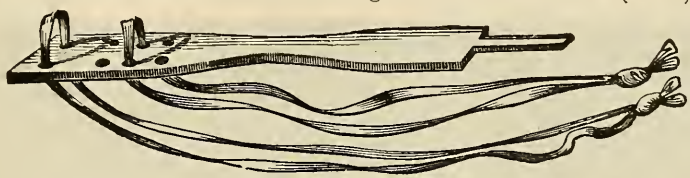

Fig. 469.—Levis's splint for reducing dislocation of phalanges.

eighth, ninth, and tenth) may be separated. The inferior cartilage goes forward and can be felt. Pick states that reduction is brought about by causing the patient to hold the chest full of air while efforts are made to push the cartilage into place. The injury is dressed as are fractured ribs (see page 624).

Dislocation of the Sternum.—In dislocation of the body of the sternum the manubrium is separated from the gladiolus. The injury is a rare one, is usually associated with fracture, and is most common in the young. It is due in most cases to violent direct force inflicted by a fall or heavy blow; it may be due to indirect force and arose in a reported case of acute tetanus. The *symptoms* and *treatment* are the same as those of fracture (see page 625). Dislocation of the ensiform process is one of the rarest of injuries. It is usually due to direct force, but Polaillon reports a case caused by tight lacing.

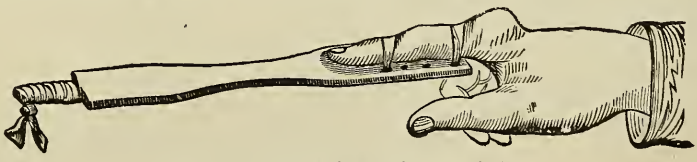

Fig. 470.—Levis's splint applied.

Pelvic dislocations are almost always complicated by fracture. A pubic bone can be dislocated by falls from a height or by the application of violent force to the acetabula. The condition may happen from accident while riding a horse. The dislocation may be up or down, front or back, and it may damage the urethra or the bladder. The patient cannot stand; there are great pain and recognizable deformity. Treat by molding the bones into place, by applying a pelvic girdle, and by rest in bed for four weeks. Pure separation or relaxation of the symphysis is seldom the result of injury and is usually due to childbirth. In this condition there is mobility, pain on pressure and movement, and pain on abduction of the thighs. The treatment is rest in bed and the application of a pelvic girdle. Occasionally in traumatic and also in post-obstetric separation it is necessary to wire the bones. Dislocation of the sacro-iliac joint is produced by falls. Movement on the part of the patient is difficult or impossible; there is violent pain, and often paralysis (from pressure upon nerves). In dislocation backward there is apparent shortening of the leg, eversion of the foot exists,

and the ilium moves posteriorly and upward. In dislocation forward the anterior superior iliac spine projects and the pelvis is broadened. Sacro-iliac dislocation is reduced by holding the pelvis firm and making extension by means of a pulley. The patient stays in bed for four weeks and wears a pelvic belt as in fracture.

Dislocation of the coccyx is considered on page 629.

Dislocation of the Femur (Hip-joint).—Dislocation of this joint is not often encountered, as the hip-joint is very strong. In 23,000 surgical admissions to the Episcopal Hospital of Philadelphia, 6000 of which were surgical injuries there were 10 dislocations of the hip (Steinke, in "Annals of Surgery," 1914, lx).

It is far more common in males than in females and is most apt to occur in a young adult. It is very rare in those beyond middle life but occasionally occurs

FIG. 471.—Thyroid dislocation of the femur eight weeks after the accident. Reduced by open section (Rugh).

in the early sixties. In forcible extension the head of the femur presses against the capsule of the joint, but the capsule here is very thick, and certain muscles, the rectus, psoas, and iliacus, are pulled tight and serve to strengthen it. The head of the bone cannot go directly upward because of the acetabulum (Edmund Owen). The weak point of the acetabular rim is below; the weak part of the capsule is also below; hence forced abduction is apt to push the head of the bone through the lower part of the capsule, a dislocation occurring primarily into the thyroid foramen. The signs of the dislocation depend upon the untorn portion of the capsule. The anterior portion of the capsule, including the Y-ligament, usually escapes laceration. Vessels are rarely injured. Muscles are often torn. In some cases the sciatic nerve is lacerated, bruised, or caught up on the neck of the femur during the circumduction of attempted reduction.

Four forms of hip-joint dislocation are usually described: (1) upward and backward, on the dorsum of the ilium; (2) backward, to the border of the sciatic notch; (3) downward, into the obturator foramen, and (4) inward, on the pubes.

All dislocations are primarily inward or outward. From these initial positions the head may be shifted to any region about the socket within reach of the remnant of untorn capsule (Oscar H. Allis). Allis rejects the old classification and suggests the following:

Low thyroid, Mid- " High " } All present abduction and outward rotation.

Reversed thyroid:

Low dorsal, Mid- " High " } All present adduction and inward rotation.

Dislocation upon the dorsum of the ilium (Fig. 472) is the commonest form. One-half of all hip dislocations are of this variety. It is *caused* by a fall or a blow when the limb is flexed and abducted (as in carrying a weight upon the shoulder), by a fall upon the knee or foot, by a weight striking the back while bending, etc. Allis says rotation inward is the chief element in its production. In this dislocation the head of the femur goes upward and backward, rests upon the ilium, and is always above the tendon of the obturator internus muscle. This dislocation is secondary to thyroid dislocation, muscular action shifting the bone from its seat of displacement.

FIG. 472.—Dislocation of femur upon the dorsum of the ilium (Dr. Ohnesorg's case).

Signs.—Dislocation upon the dorsum of the ilium is indicated by the following symptoms: the buttock appears flat and broad; the great trochanter is above Nélaton's line and is deeply placed; the head of the bone can be detected in its new situation; deep pressure in front of the joint finds a hollow; the leg is shortened by about 2 or 3 inches; the fascia lata is relaxed; in some thin people the socket can be outlined; when the patient is recumbent the injured extremity can be brought to the perpendicular without flexing the leg (Allis); the knee is somewhat flexed; the thigh is slightly flexed, inwardly rotated, and adducted (Fig. 473) (this is shown by the fact that the axis of the thigh of the injured side, if prolonged, would pass through the lower third of the sound thigh); when the capsule is extensively lacerated there may be no adduction and may be eversion (Allis); the heel is raised, and the great toe of the foot of the injured side rests upon the front of the instep or the ankle of the sound side (Fig. 473); rigidity exists; voluntary movement is impossible, though some passive motion is possible in the direction of the deformity (the deformity can be made more marked). If a patient is recumbent and the knees vertical, the foot of the sound extremity is free of the bed, but the foot of the injured extremity touches the bed (*Allis's sign*).

Diagnosis.—Examine first without anesthesia. The *x*-rays are invaluable in diagnosis. If the *x*-rays are not obtainable, examine again while the patient

is anesthetized. Dislocation is distinguished from intracapsular fracture by noting the inversion, the great shortening, the absence of crepitus, the age of the subject, and the nature of the force. The nature of the force, the inversion, and the absence of crepitus mark the diagnosis from extracapsular fracture.

Treatment.—The chief obstacle to reduction in dislocation upon the dorsum of the ilium, Bigelow states, is the untorn portion of the capsule, especially the Y-ligament. The iliofemoral, Y, or Bigelow's ligament resembles an inverted Y, arises from the anterior inferior spine of the ilium, is inserted into the anterior intertrochanteric line, and is incorporated into the front of the capsule. To reduce a dislocation this ligament must be relaxed by manipulation or be torn by extension. Manipulation makes the head of the bone retrace its steps over the same route it took in emerging. Give ether; place the patient supine upon a mattress on the floor; flex the leg on the thigh (to relax the hamstrings), flex the thigh on the pelvis; increase the adduction over the middle line; strongly abduct; perform external rotation and extension. This treatment may be summed up as flexion, adduction, external circumduction, and extension; or, as Pick puts it, "bend up, roll out, turn out, and extend." Allis's advice is to fix the pelvis to the floor, lift the head of the bone to the level of the socket, rotate outward by carrying the leg toward the pubis, and extend the femur. If extension and counterextension are employed, make extension in the axis of the dislocated limb and obtain counterextension by a perineal band. The extension band is fastened to the thigh by a clove-hitch. After reduction put the patient to bed and use sandbags (as in fracture of the hip) for four weeks. We may tie the knees together instead of using the sandbags. Passive motion is made in the third week. The pulleys must not be used in reduction. They may inflict great or even fatal injury. If the surgeon fails to reduce the deformity, there are two courses open to him. He may let it alone. He may operate. If he lets it alone, the limb will almost certainly become ankylosed, though probably useful. If he determines to operate, he must recognize that tenotomy is useless. It is necessary to make a free incision in order to restore the bone.

Fig. 473.—Hip-joint dislocation upon the dorsum of the ilium (Cooper).

Dislocation Onto the Border of the Sciatic Notch.—In this dislocation the head of the bone passes backward and a little upward, and rests upon the ischium at the margin of the sciatic notch (not in the notch), below the tendon of the obturator internus muscle. The *causes* are the same as those given for the previous dislocation.

The *signs* of dislocation into the border of the sciatic notch are like those of dislocation upon the dorsum of the ilium but they are not so marked. There are flattening and broadening of the hip; ascent of the trochanter above Nélaton's line; shortening to the extent of an inch; relaxation of the fascia lata. If the knee of the injured side is vertical, the sole of the foot touches the bed. Flexion, inward rotation, and adduction exist, but the axis of the femur of the injured side passes through the knee of the sound side, and the ball of the great toe of the injured side rests upon the great toe of the sound side (Fig. 474). Other symptoms are identical with those of dislocation upon the dorsum of the ilium, but are less pronounced. Allis's signs of this dislocation are of value: if, with the patient recumbent, the thighs are brought to a right angle with the body, shortening on the affected side is materially increased; if the dislocated thigh is extended, the back arches as in hip disease.

Diagnosis and Treatment.—The signs of dislocation on the border of the sciatic notch are similar to, but are less marked than those of dorsal dislocation,

and, being a backward dislocation, the reduction and treatment are the same as for dislocation backward upon the dorsum of the ilium.

Dislocation Downward Into the Obturator Foramen (Figs. 471 and 475).—Downward dislocation is the primary position of most dislocations of the hip, the bone rarely remaining in the thyroid foramen, but usually mounting up as a result of muscular action or of the initial violence. The *cause* is a violent abduction by falls or by stepping from a moving car.

Signs.—Dislocation downward into the obturator foramen is indicated by flattening of the hip; the head of the bone is felt in its new position and is missed from the acetabulum; rigidity exists; passive motion is only possible in the direction of deformity, and that to a slight extent; a hollow is noted over the great trochanter, which process is well below Nélaton's line and nearer than normal to the middle line. The gluteal crease is lower than is the crease of the opposite side; there is lengthening to the extent of 1 to 2 inches; the body is bent forward by the traction upon the psoas and iliacus muscles, and is also deviated to the side, thus causing great apparent lengthening; the limb is advanced partially flexed and abducted, and the foot is pointed straight ahead or is a little everted (Fig. 475); when the patient is recumbent extension is impossible, the knees cannot be pushed together without great pain, and the abductor muscles are hard and rigid. Allis's signs are absent. Unreduced dislocations do well, the patient obtaining a very useful hip-joint (Sédillot).

Fig. 474.—Hip-joint dislocation onto the sciatic notch (Cooper).

Treatment.—In treating dislocation downward into the obturator foramen give ether and effect reduction, if possible, by manipulation, and, if this fails, by extension. To reduce by manipulation, flex the leg on the thigh and the thigh on the pelvis, and then perform, in the following order, abduction, internal circumduction, and extension. Allis's rule of reduction is as follows: fix the pelvis to the floor; pull the head of the femur outward and above the socket; fix the head; push the knee toward sound knee and extend the femur. If extension is made, make traction in the axis of the limb by means of muslin fastened around the thigh by a clove-hitch. Do not use pulleys; incise rather than use them.

Fig. 475.—Hip-joint dislocation into the obturator or thyroid foramen (Cooper).

Dislocation upon the pubis is a very uncommon accident. The head of the bone usually rests just internal to the anterior inferior spine of the ilium. The primary position of the bone is in the thyroid foramen; the pubic dislocation, when it occurs, is always secondary, and is due to the initial force and to muscular action.

Symptoms.—In pubic dislocation the head of the bone can be felt and seen in its new position; the hip is flattened; there is a hollow over the great trochanter, this process being found below the anterior superior spine of the ilium; there is shortening to the extent of 1 inch; the limb is in abduction with eversion (Fig. 476), and the knees cannot be approximated without great pain.

In the *treatment* of pubic dislocation give ether and employ manipulation as for thyroid dislocation. If this fails, employ extension. The limb is well abducted, extension is made downward and backward, and the head of the femur is pulled outward "by a towel around the thigh, just beneath the groin" (Keetley). The after-treatment is the same as that for the previous forms.

Central or Internal Dislocation (Fig. 477).—By this term we mean that the head of the femur has been displaced and perhaps forced through a fractured acetabulum into the pelvis. It is not a genuine dislocation. There is neither tearing nor stretching of the capsule and the acetabular floor may remain in contact with the femoral head. Skillern and Pancoast ("Annals of Surgery," Jan., 1912) point out that "the injury varies from a light depression of the floor of the acetabulum . . . to the passage of the femoral head into the pelvic cavity." For the first injury they suggest the term *fractura acetabuli perforans;* for the second, *fractura acetabuli perforata.* This injury is due to violent force. The usual cause is a fall upon the great trochanter. The symptoms vary with the degree of depression or fracture of the floor of the acetabulum. If there is only slight depression of the floor, there may be no appreciable shortening and very slight approach of the trochanter toward the symphysis pubis. The *x*-rays may be needed to make a diagnosis. If the head has perforated, shortening will be evident, there will be marked approach of the trochanter toward the midline, and vaginal or rectal palpation will discover the displaced femoral head. In both injuries there are pain, tenderness, and impaired mobility. There may be serious damage within the pelvis. Intrapelvic hemorrhage is common. The peritoneum may be lacerated, the bowel may be damaged, the bladder injured, or the obturator nerve bruised (Skillern and Pancoast, Ibid.).

Fig. 476.—Dislocation on pubis (Cooper).

Treatment.—If complications such as are mentioned above exist, at once open the abdomen and repair the injury. Reduce the deformity by extension and counter-extension. Treat by "extension in the axis of the limb in conjunction with lateral traction upon the femoral neck" (Ibid.). After a week, if there is no contra-indication, apply a plaster-of-Paris dressing from the toes to the chest.

Skillern and Pancoast (Ibid.) state that the injury was first described by Callisen in 1788, and that, with their 4 cases, 55 have been reported.

Anomalous Dislocations of the Hip.—In *supraspinous dislocation* the dislocation of the hip is backward, the head of the femur resting upon the ilium above or even anterior to the anterior superior spine. In *ischial dislocation* the dislocation is downward and backward, the head of the femur resting on the ischial tuberosity or in the lesser sciatic notch. *Monteggia's dislocation* is a supraspinous dislocation with eversion of the limb. In *perineal dislocation* the head of the femur is in the perineum. In *suprapubic dislocation* the head of the femur passes above the pubes. In *subspinous dislocation* the femoral head rests on the horizontal ramus of the pubes.

Dislocation with Catching Up of the Sciatic Nerve During Reduction.—This accident causes severe pain. The leg is flexed on the thigh and the thigh is flexed on the pelvis. Allis tells us that the task of reduction is very unpromising. We must strive to put the neck of the femur in such a position that the nerve will "drop off," and yet often the nerve cannot drop off because it is held by adhesion to the injured muscles. Allis attempts reduction by the following plan:

1. Place the patient upon his back and redislocate the femur.
2. Extend the thigh.
3. Flex the leg on the thigh.
4. Turn the ankle out until the leg is horizontal (this causes the head of the bone to look downward).
5. "Shake, shock, jar, adduct, and abduct," to disengage the nerve.
6. Rotate into socket without flexing leg (without making nerve tense).
7. If this fails, make an incision above the popliteal space, and draw the

nerve out of the wound. Detach the head of the bone from its entanglement and rotate it into the socket.[1]

Dislocation of the Head of the Femur with Fracture of the Shaft of the Bone.—We may incise, replace, and plate the fragments. We may use McBurney's hooks as in the shoulder. We may be forced to do a resection of the head.

Allis maintains that it is possible to reduce it by manipulation. He states that the upper fragment is the entire lever, and the lower fragment "is only the agent through which we apply our force." The fragments are not completely separated, but are connected at one side by material which is "partly periosteal, partly tendinous, and partly muscular." This connecting material enables us to make traction upon the upper fragment, but does not allow "rotation, circumduction, and leverage through the agency of the lower fragment." Hence "the only agency at our command is traction." If the dislocation is inward (forward), draw the head outward and have an assistant make direct pressure upon the head of the bone. If this fails, the assistant holds the head of the bone to prevent its slipping into the thyroid depression, and

Fig. 477.—Dislocation of left hip. Fracture of acetabulum, ischium, and pubes (right), with central dislocation of hip. Separation of pubic arch.

the surgeon makes traction inward or inward and downward. If the dislocation is outward (backward), make traction directly upward to lift the head of the bone to the level of the socket, and try to place the head over the socket by traction obliquely upward and inward. During all these manipulations an assistant presses upon the trochanter to prevent the head of the bone slipping back. Traction is now made downward and inward, and the tightened ligament may drag the head of the bone into place.

Dislocation of the Knee.—It is a rare injury. There are four forms—forward, backward, outward, and inward. Any one of the four may be complete or incomplete; the commonest dislocations are lateral. The *cause* is violent force, such as a fall, or in jumping from a moving train, or in being caught by the foot and dragged.

[1] Allis's views will be found in "An Inquiry Into the Difficulties Encountered in the Reduction of Dislocations of the Hip," by Oscar H. Allis, M. D. This highly original and valuable treatise received the Samuel D. Gross Prize of the Philadelphia Academy of Surgery in 1895.

Dislocation Forward of the Knee-joint.—In the *complete* form of forward dislocation the deformity is obvious. The limb is usually extended, but it may be flexed. Much shortening exists; the condyles are felt posterior and below; the head of the tibia is felt anterior and above; the patella is movable and the quadriceps is lax; pressure of the condyles upon the contents of the popliteal space arrests the tibial pulse and causes edema and intense pain. In *incomplete* dislocation the symptoms are identical in kind, but are less pronounced.

Treatment.—Compound dislocation of the knee-joint often demands excision or amputation. In simple dislocation give ether, have one assistant extend the leg while another makes counterextension on the thigh, and the surgeon pushes the bone into place. Reduction is easy because of ligamentous laceration. Place the limb on a double inclined plane, and combat inflammation by the usual methods (see Synovitis, page 702). Begin passive motion in the third week. The patient must wear a knee-support for months. Very extensive laceration of ligaments calls for incision and suturing. If the popliteal vessels are much damaged, gangrene will supervene and amputation will be demanded.

Fig. 478.—Old dislocation of the patella outward.

Dislocation Backward of the Knee-joint.—In the *complete* form of backward dislocation of the knee-joint displacement is not so great as in dislocation forward. The head of the tibia projects posteriorly and above, the femoral condyles anteriorly and below; the leg is, as a rule, partly flexed, but it may be extended, and there is moderate shortening. In *incomplete* dislocation the symptoms are less marked.

The *treatment* of backward dislocation of the knee-joint is the same as for forward dislocation.

Dislocation outward of the knee-joint is usually incomplete. The inner tuberosity of the tibia in outward dislocation lies upon the outer condyle of the femur (Pick); the inner condyle of the femur projects internally; the outer tibial tuberosity and fibular head project externally, the former having a depression below it, and the latter above it; the leg is semiflexed, but shortening is absent.

Dislocation inward of the knee-joint is usually incomplete. The outer tuberosity of the tibia in inward dislocation lies upon the inner condyle of the femur; the outer condyle of the femur forms an external prominence, and the inner tuberosity of the tibia forms an internal prominence. Pick cautions us not to mistake a separation of the lower femoral epiphysis for lateral dislocation (the former is reduced easily, the deformity tends to recur, and there is soft crepitus).

Treatment.—In treating lateral dislocation of the knee-joint, effect extension and counterextension as in anteroposterior dislocations. The leg is moved from side to side and attempts are made at rotation. The after-treatment is the same as that for anteroposterior luxations.

Dislocation of the patella is seldom congenital. There are 35 congenital cases on record (Bajardi). There are three forms of dislocation of the patella:

outward, inward, and edgewise. The so-called dislocation upward is, in reality, rupture of the ligamentum patellæ (see page 809).

Dislocation of the patella outward (Fig. 478) may be due to muscular action or to direct force, and occurs during extension of the leg. It occasionally happens on a person with knock-knee. If dislocation is complete the bone lies upon the external surface of the external condyle; if incomplete, the patella rests upon the anterior surface of the external condyle. The leg is extended, flexion is impossible, and attempts at flexion produce great agony. In the patient shown in Fig. 478 flexion became possible in an unreduced dislocation, but not until months after the accident. The knee is wider than normal. There is a hollow in front of the joint. The bone is felt in its new position.

Dislocation of the patella inward is very rare. The signs are like those of dislocation outward, except that the patella rests upon the inner condyle.

Treatment of Lateral Dislocations of the Patella.—Give ether. Raise the body upon a bed-rest and flex the thigh. Grasp the patella and depress the margin which is farthest from the center of the joint (Pick). The muscles may pull the bone into place. Extend the extremity and immobilize for three weeks, and then begin passive motion. Incision may be necessary in order to effect reduction.

Dislocation of the Patella Edgewise.—The patella rotates vertically, one edge resting between the condyles. As a rule, the outer border is in the intercondyloid notch. This condition is produced by direct force when the extremity is partly flexed. Twisting and muscular action have been assigned as causes. The condition is obvious at a glance.

Fig. 479.—Dr. Morris Booth Miller's case of outward dislocation of the patella from direct force. Six months after the fall. Failed of reduction under ether anesthesia.

Treatment.—Give ether. Pick recommends "sudden and forcible bending of the knee." In some cases the bone can be pushed into place, the limb being extended and flexed as in the reduction of a lateral dislocation. In some cases incision will be necessary.

Dislocation of the Semilunar Cartilages of the Knee-joint (*the Internal Derangement of Hey; Subluxation of the Knee-joint*).—The condition was described by Hey, of Leeds, in 1803. The interarticular cartilages of the knee-joint are attached in front of and behind the tibial spine, and the convexity of each cartilage is attached to the edge of the corresponding tibial tuberosity by means of the coronary ligament. The internal cartilage is fastened to the internal lateral ligament and has a moderate freedom of movement. The

outer cartilage is not connected with the external lateral ligament and is not freely movable. It has been stated that the outer cartilage is more frequently dislocated than the inner, but modern experience indicates that this is not true, and that the internal cartilage is the one to suffer in at least nine cases out of ten. In 17 cases operated upon by Barker the internal cartilage was involved in every case ("Lancet," Jan. 4, 1902). Those persons whose occupations force them to pass considerable time upon their knees are predisposed to this accident (Annandale). The derangement of the cartilage is usually caused by a sudden external rotation or abduction of the tibia while the knee-joint is in partial flexion; for instance, when the patient stumbles over an obstacle, the knee-joint being partially flexed, the tibia is twisted outward When the joint is flexed a normal cartilage moves backward, and when it is extended moves forward again. When the cartilage is thrown out by the sudden eversion and flexion of the tibia it is caught and does not move into place readily when the leg is extended. The tear takes place in the direction of the fibers of the cartilage. In a very few cases the cartilage has been displaced by abduction during extension. In nearly all cases the cartilage is displaced inward.

Symptoms.—The first indication of interarticular cartilage displacement is a sudden, violent, sickening pain in the knee, which may be so severe as to cause the patient to fall to the ground. The knee is in a position of fixed semiflexion. Further flexion is possible, but extension is impossible. In some cases the patient can voluntarily make further flexion; in others, the pain is so severe that he either cannot or will not do it; but increase of flexion can be obtained by passive motion. The joint is, however, blocked both to passive and to voluntary extension. Attempts at passive motion are productive of fierce pain. If either cartilage is displaced away from the tibial spine, a prominence may be found on one or the other side of the knee-joint. If the displacement takes place toward the tibial spine a prominence may be found on one side of the ligament of the patella. Subluxation is rapidly followed by inflammation of the synovial membrane of the joint and inflammation of the cartilage itself; and swelling quickly masks the projection of the cartilage. This accident is frequently mistaken for the blocking of the joint by a floating cartilage; but a dislocated cartilage always remains in the same position, and a loose cartilage changes its position from time to time (Turner). Loose bodies in a joint produce pain of a shifting character and interference with both flexion and extension, or with either flexion or extension in an irregular way (Cotterill). In regard to the diagnosis, Cotterill points out that in a sprain of the joint extension is not painful, but flexion is interfered with; whereas, in the dislocation of a cartilage of the joint, flexion is still possible, but extension cannot be carried out ("Lancet," Feb. 22, 1902).

Treatment.—To reduce a displaced semilunar cartilage I have used with satisfaction a method described by Henry W. Jacob ("Brit. Med. Jour.," March 7, 1908). It is not followed by severe synovitis unless the patient has walked or has made repeated efforts to reduce the displacement, and as it is a painless method ether is not required. Jacob describes it as follows:

"The patient lies on a bed or couch, the surgeon standing on the outer side of the limb affected, with his face toward the patient's foot; the patient then raises his leg off the couch in the semiflexed position, the surgeon grasps the patient's leg in both hands, and using his own thigh as a fulcrum, by means of a steady pulling movement draws the patient's leg outward while the surgeon's thigh keeps the patient's femur in a fixed position; directly this movement is effected the patient must steadily extend the limb, and the displaced cartilage will probably go back with a slight click; if the first movement of extension is not successful the maneuver must be repeated without any hurry or unnecessary force, and after a few attempts the cartilage can usually be felt to slip in without pain or inconvenience."

In treating dislocation of a semilunar cartilage of the knee it is customary to give ether and reduce by forced flexion, and internal rotation of the tibia. Extension becomes possible if the cartilage is freed. During these maneuvers an assistant endeavors to push any projection of cartilage into place. Robert Jones reduces the cartilage by acutely flexing the leg, rotating the tibia inward, telling the patient to make forcible extension and aiding him in the accomplishment of it. After reduction apply a splint for two weeks and combat inflammation by proper remedies (see Synovitis); then begin passive motion. At the end of two weeks apply a firm knee-cap made of leather and let the patient get about on crutches. After a couple of weeks the crutches can be laid aside. As recurrence of the displacement is usual, the patient should wear a knee-cap during the day for many months. A partial tear may entirely heal when thus treated by rest and support; an extensive tear will not, although even in such cases a useful but somewhat stiff joint may be obtained. If it is found impossible to unlock the blocked joint, or if the tear is extensive and redislocation is prone to occur, an operation is advisable. The joint is opened and the loose cartilage is pushed into place and held by stitches to the periosteum, or the loosened portion is excised. Annandale, in 1885, sutured through a transverse incision. Freeman and others used sutures to fix the cartilage. Excision is just as satisfactory as suturing, and after excision recurrence of the trouble is impossible. After excision the extremity is placed upon a posterior splint. Passive motion is begun in two weeks.

Dislocation of the Fibula at the Superior Tibiofibular Articulation.—This injury is rare. The head of the fibula may go forward or backward. The *causes* are direct force and violent adduction of the foot with abduction of the knee (Bryant).

Symptoms.—After dislocation of the fibula the position is one of semiflexion of the knee, voluntary extension and flexion being impaired or lost. A distinct movable projection is readily noticed in front or behind, which is found to be continuous with the fibula. There is a depression over the normal position of the head of the fibula.

Treatment.—In treating dislocation of the fibula bend the knee to relax the biceps, and proceed to push the bone into place. Put a compress over the head of the fibula, apply a bandage, and put the limb on a double inclined plane. The peroneal nerve winds around the neck of the fibula and care must be taken to avoid making injurious pressure upon the nerve. At the end of three weeks put a lacing knee-support upon the knee and let the patient up. As displacement is liable to recur, a knee-cap must be worn for a year.

Dislocation of the Ankle-joint.—This injury is not unusual. Fracture is a frequent complication. There are five forms of ankle-joint dislocation—outward, inward, forward, backward, and upward.

Lateral dislocation of the ankle-joint is either outward or inward, and may be complete or incomplete. In these dislocations the astragalus rotates. In incomplete dislocation "there is no great separation of the trochlear surface of the astragalus from the under surface of the tibia, but the outer or inner margin of this surface is brought into contact with the articular surface of the tibia, and the whole foot presents a lateral twist" (Pick). The *causes* of these dislocations are twists of the joint.

Symptoms.—Incomplete outward dislocation of the ankle-joint occurs in *Pott's fracture* (see page 697). *Dupuytren's fracture* comprises complete outward dislocation of the astragalus, the articular surface of the astragalus being displaced completely outward from the articular surface of the tibia, and a fracture of the fibula with separation of the inferior tibiofibular articulation. In incomplete dislocation the foot goes outward and upward, the fibula is fractured, and the tibiofibular ligaments are torn off. In Dupuytren's fracture

the ankle is broad, the inner malleolus projects and looks lower than natural, the outer malleolus ascends with the foot, the foot rotates outward, and crepitus can be detected. In inward dislocation which is associated with fracture of the inner malleolus there is inversion, the outer malleolus projects, and crepitus can be detected. In incomplete separation the symptoms are similar, but are not so marked.

Treatment.—In treating a case of dislocation of the ankle-joint the deformity is reduced by flexing the leg on the thigh and the thigh on the pelvis; an assistant makes counterextension from the knee; the surgeon makes extension from the foot, and at the same time rocks the astragalus into place. Dupuytren's fracture is treated in the same manner as Pott's fracture (see page 698). Dislocation inward is treated in a fracture-box for the same period as Pott's fracture.

Anteroposterior dislocation of the ankle-joint is rare. The *cause* is the catching of the foot in jumping or falling—direct violence. In dislocation forward the foot is lengthened, the heel is not conspicuous, the tibia and fibula project against the tendo Achillis, and the relation of the malleoli to the tarsus is altered. In incomplete dislocation the symptoms are similar, but less pronounced. In dislocation backward the foot is shortened, the tibia and fibula project in front, the heel is prominent, and the relation between the malleoli and the tarsus is altered. In incomplete dislocation the symptoms are similar, but less marked.

Treatment.—In anteroposterior dislocation of the ankle-joint reduce as in lateral dislocations. Sometimes the tendo Achillis must be cut. Apply a plaster-of-Paris dressing and let it be worn for two weeks; then begin passive motion, and let the patient wear side-splints for a week longer.

Dislocation upward of the ankle-joint, or *Nélaton's dislocation,* is a very rare injury. The astragalus is wedged between the widely separated tibia and fibula. This dislocation is usually associated with fracture. The *cause* is a fall upon the feet from a great height.

Symptoms.—Upward dislocation of the ankle-joint is indicated by the widening of the ankle and by the flattening of the foot. The malleoli are nearly on a level with the plantar surface of the foot, and there is absolute rigidity.

Treatment.—In treating upward dislocation of the ankle-joint give ether, and try to reduce by powerful extension and counterextension. Treat the injury afterward in the same manner as an anteroposterior luxation.

Dislocation of the Astragalus.—The astragalus may be displaced from the bones of the leg and at the same time be separated from the rest of the tarsus. The displacement may be forward, backward, outward, inward, or rotary.

Dislocation of the astragalus forward or **backward** is caused by falls or twists.

Symptoms.—In forward dislocation the astragalus projects strongly; there is shortening of the foot, and the malleoli approach the plantar aspect of the foot; the foot is deviated to one side or to the other, and there is absolute rigidity of the ankle-joint. In incomplete luxations the symptoms are similar, but less marked. This dislocation may be obliquely forward. In backward dislocation of the astragalus the foot is not deviated to either side; the astragalus projects between the malleoli and above the os calcis, and the tendo Achillis is stretched over the projection. Rigidity is absolute. This dislocation may be obliquely backward.

Lateral and Rotary Dislocations of the Astragalus.—Lateral dislocations of the astragalus are rare, are always compound, and are always associated with fracture. In rotary dislocation the astragalus remains in its normal habitat after rotating on its own axis, either horizontally or vertically. The *causes* of rotary dislocation are twists of the foot when it is at a right angle to the leg (Barwell). The *symptoms* of rotary dislocations are obscure. There is rigidity, but sometimes the position of the astragalus may be made out.

Treatment of Dislocation of the Astragalus.—In treating astragalus dislocation reduce under ether by flexing the knee to relax the gastrocnemius, extending the foot, and pushing the bone into place. It may be necessary to cut the tendo Achillis. After reduction put up the foot and leg in a plaster-of-Paris dressing for two weeks, and then begin passive motion and apply side-splints, which are to be worn for one week more. If reduction fails, support the limb on splints, combat inflammation, and endeavor to bring about union between the dislocated bone and the tissues. Often, in unreduced dislocation, the skin sloughs over the projecting bone. Excision is demanded the moment sloughing is seen to be inevitable. Cases of compound dislocation of the astragalus require immediate excision.

Subastragaloid Dislocation.—This condition is a separation of the astragalus from the os calcis and scaphoid, without separation from the bones of the leg. Pick states that the usual classification for these dislocations is forward, backward, inward, and outward, but that the displacement is, as a rule, oblique, the foot passing backward and outward or backward and inward. The *cause* is twisting.

Symptoms.—In subastragaloid dislocation the astragalus projects on the dorsum; the foot is everted in outward dislocation and inverted in inward dislocation; the relation of the malleoli to the astragalus is unaltered; the ankle-joint is not absolutely rigid; the foot "is shortened in front and is elongated behind" (Pick).

Treatment.—To treat subastragaloid dislocation make extension in the direction opposite to that of the displacement. In dislocation of the tarsus backward fix a bandage around the foot, on a level with the heads of the metatarsal bones, which bandage the surgeon ties around his shoulders. The surgeon puts one knee in front of the ankle and thus fixes the leg, raises himself up to make extension upon the tarsus, and molds the bone into position. Tenotomy may be necessary. After reduction apply a plaster-of-Paris dressing and have it worn for three weeks. The ankle-joint, fortunately, is not involved, and stiffness of this articulation need not be apprehended. If reduction is impossible, take the same course as in luxations of the astragalus.

Dislocations of the other tarsal bones are very rare. Single bones may be dislocated, or the luxation may occur at the mediotarsal articulation.

Symptoms and Treatment.—Projection is an obvious *symptom* in dislocation of the other tarsal bones. The *treatment* is to reduce by extension and molding, the part being put up in plaster-of-Paris dressing for two weeks.

Dislocations of the metatarsal bones are rare.

Symptoms and Treatment.—Shortening of the toes and projection of the dislocated bone are *symptoms* of dislocation of the metatarsal bones. To *treat* these dislocations reduce by extension under ether and put up in a plaster-of-Paris dressing for two weeks. If reduction fails, the functions of the foot will not be much impaired.

Dislocations of the phalanges are very rare. The first phalanx of the big toe is the one most liable to dislocation.

Symptoms and Treatment.—Dislocations of the phalanges are obvious. The *treatment* is by reduction and fixation, as in dislocation of the thumb. Immobilize for two weeks.

Operations Upon Bones and Joints

Osteotomy.—By the term *osteotomy* the modern surgeon means literally the sectioning of a bone for the purpose of straightening a limb ankylosed in a bad position, correcting a bony deformity, or amending a vicious union of a fracture. In a *linear osteotomy* the bone is transversely or obliquely divided at one spot; in a *cuneiform osteotomy* a wedge-shaped portion of bone is removed.

The operation of osteotomy may be performed with a saw (Fig. 480) or with an osteotome. The saw creates dust, draws much air into the wound, and lacerates the tissues to a considerable degree. Most surgeons prefer the chisel or the osteotome. The osteotome slopes down to a point from each side (Fig. 481); the chisel is straight on one side and on the other is bevelled to a point.

Osteotomy for Genu Valgum, or Knock-knee (*Macewen's Operation*, Fig. 482).—Operation is never done until the subacute stage of rickets has passed and the greatest care is taken not to traumatize the epiphysis. The patient lies upon his back, being rolled a little toward the diseased side. The leg of the diseased side is partly flexed upon the thigh and the thigh upon the pelvis, and the extremity is laid upon its outer surface, a sand-bag being pushed between the extremity and the bed, opposite to the site of section. The flexion of the knee relaxes the popliteal vessels and saves them from injury. The surgeon, if operating on the right leg, stands outside of that extremity; if operating on the left leg, he stands opposite the left hip (Barker). The knife is inserted into the tissues and carried to the bone at the inner side of the knee,

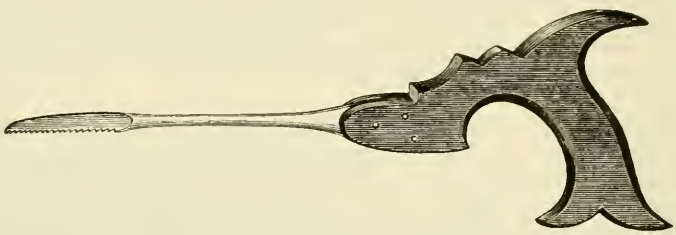

Fig. 480.—Adams's large saw. (In this day of surgery the saw has a metal handle.)

just in front of the adductor tubercle of the inner condyle and on a level with the upper border of "the patellar articular surface of the femur" (Barker). An incision is made upward 1 inch in length, in the direction of the axis of the femur.

Fig. 481.—Osteotome.

The knife is left in as a guide until the osteotome is inserted at the lower angle of this wound. After the insertion of the osteotome the knife is withdrawn and the blade of the osteotome is turned to a right angle with the shaft of the femur, ½ inch above the epiphysis (Fig. 482). The osteotome is struck several times with a mallet; the handle is moved several times toward and from the body, so as to widen the cut in the bone (Fig. 483); the osteotome is again struck with the mallet several times; it is again moved to and fro, and this process is continued until the bone is cut two-thirds through. If the osteotome becomes tightly fixed, it should be withdrawn and a smaller one introduced. In the soft bone of a young girl this to-and-fro movement of the chisel, if carefully executed, is not liable to break the instrument. In dense bone it may break the instrument; hence, when doing an osteotomy in dense bone, the osteotome is moved to and fro across the limb and slight downward pressure upon the handle will to a great extent prevent binding. When the bone is cut two-thirds through the osteotome is withdrawn, a piece of wet antiseptic gauze is held over the wound, and the surgeon fractures the femur by strong adduction. The wound is neither sutured nor drained, but is dressed aseptically, the entire extremity is wrapped in cotton, and a plaster-of-Paris dressing is applied and carried up to the groin. The dressing may be removed in two weeks, and the patient may subsequently be treated with sand-bags, as for an ordinary fracture of the thigh, but without extension. This operation is scarcely ever fatal.

Ogston's Operation for Knock-knee (Fig. 482).—In this operation the internal condyle is sawed off obliquely with an Adams saw—a proceeding which permits the straightening of the knee. The objection to the procedure is that it opens the knee-joint, and that this cavity fills up more or less with a mixture of blood and bone-dust. Macewen's operation is decidedly the safer.

Osteotomy for a Bent Tibia.—The tibia is divided transversely or obliquely (linear osteotomy), or a wedge-shaped piece is removed (cuneiform osteotomy). The oblique incision is the best. If the convexity of the tibial curve is inward, cut the bone from above downward and from in front backward; if the curve is forward, section the bone from above downward and from within outward. The fibula need rarely be interfered with. After the osteotomy the limb is treated just as it would be for a fracture.

Osteotomy for Faulty Ankylosis of the Hip-joint.—This operation is performed in order to allow straightening of a limb that has undergone bony ankylosis in a faulty or an inconvenient position. In some cases an attempt is made to obtain a movable joint, but in most cases the surgeon must be satisfied with ankylosis in extension. Osteotomy may be performed through the neck of the femur or through the shaft of the femur below the trochanters.

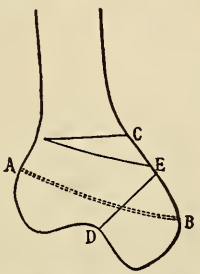

Fig. 482.—Osteotomy of the right femur in a case of knock-knee: A B, Epiphyseal line; C, section of Macewen; D E, section of Ogston.

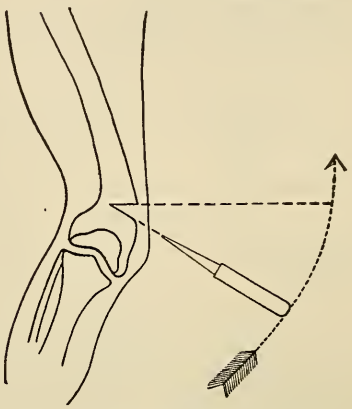

Fig. 483.—Macewen's operation for genu valgum. The chisel is held in the line for striking with a mallet; the arrow shows the direction in which the chisel is levered up and down so as to make a wide gap in the bone (after Barker).

Osteotomy through the neck of the femur is performed (1) with a saw (Adams's operation) or (2) with an osteotome.

Adams's Operation (Fig. 484, A).—The patient lies upon his sound hip; the surgeon stands upon the side to be operated upon, and back of the patient. The knife is entered a finger's breadth above the great trochanter, is pushed in until it strikes the neck of the bone, is then carried across the front of and at a right angle with the neck, and is withdrawn, enlarging the wound, in the soft parts as it emerges, to the extent of 1 inch. The saw is then introduced and the neck of the femur is entirely divided. After the osteotomy dress the wound antiseptically and place the extremity straight. To straighten the limb it may be found necessary to cut contracted tendons and fascial bands. After securing extension and applying dressings use the weight-extension apparatus and the sand-bags. Begin passive movements from the start if a movable joint is desired; few patients can tolerate the pain necessary to bring this about. If it is determined to aim for a stiff joint, treat the case as an intracapsular fracture would be treated.

With an Osteotome.—The position of the patient is the same as that for Adams's operation. An incision 1 inch long is made, starting just above the great trochanter, ascending in the axis of the femoral neck, and reaching to

the bone. An osteotome is introduced, is turned to a right angle with the neck of the bone, and is struck with a mallet until the bone is *completely* divided. (It is not to be divided partially and then broken.) The after-treatment is the same as that for Adams's operation. The operation by the osteotome is to be preferred to that by the saw.

Osteotomy of the Shaft of the Femur Below the Trochanters (*Gant's Operation*).—In this operation (Fig. 484, B) the saw may be used, but the osteotome is to be preferred. The position in Gant's is like that in Adams's operation. A longitudinal incision 1 inch long is made upon the outer aspect of the femur and on a level with the lesser trochanter. The osteotome is inserted and the bone is completely divided below the lesser trochanter. The after-treatment is the same as that for Adams's operation. Gant's operation is the best method for correcting faulty position in bony ankylosis, and Adams's operation can only be employed in those cases in which the femur still has a neck which is practically unchanged.

Osteotomy for Faulty Ankylosis of the Knee-joint.—This operation is performed for bony ankylosis of a knee in a position of flexion. In these cases it is nearly always necessary to cut contracted tendons and fascia. These contractures tend to draw the tibia backward as in a posterior dislocation. The patient lies upon his back with his thighs flat upon the bed, the legs hanging over the end of the bed. The surgeon stands on the patient's right side. Just above the patellar articular surface upon the femur a transverse incision is made, 1 inch in length and reaching to the bone. The osteotome is introduced and the bone is cut *nearly* through. The leg is then forcibly extended. It must not be extended too violently or the popliteal vessels may be injured. In cases in which the structures of the popliteal space are tense and have not been divided the leg must not be brought at once into extension, but this position should be attained gradually by means of weights. The wound is dressed aseptically, and the extremity is placed upon a double inclined plane and is treated as for fracture near the knee-joint.

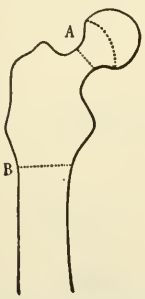

FIG. 484.—Osteotomy through the neck of the femur: A, Adams's operation; B, Gant's operation.

Osteotomy for vicious union of a fracture is performed in case of angular deformity, and is carried out in the same manner as are the above procedures. It is best, when possible, to enter the osteotome upon the concavity of the bent bone, so that the periosteum will not rupture when extension is made, and the patient will in consequence gain a longer limb.

Osteotomy for Hallux Valgus.—In this operation a linear osteotomy is made through the neck of the metatarsal bone of the great toe, the toe is forcibly adducted, and a splint is applied to the inside of the foot and the toe. A cuneiform osteotomy may be done instead of a linear osteotomy. The osteotomy is made through the neck of the metatarsal bone. A wedge-shaped piece of bone (the base of which is to the inner side of the foot) is removed. Charles H. Mayo makes a flap of the bursal sac and capsular ligament, divides the metatarsal bone with a Gigli wire saw, sutures the flap over the bone end, closes the skin incision, and fixes the toe in the adducted position.

Osteotomy for Talipes Equinovarus (*After Barker*).—The patient lies upon his back, the thigh is semiflexed, the knee is bent, and the sole of the foot rests upon the table. The surgeon stands to the right side if it is the right limb which is to be operated upon, and to the left side if it is the left limb. He feels for the outer surface of the cuboid bone, and cuts away from over the latter a piece of skin corresponding in size with the bone-wedge intended to be removed (this piece of skin must include the bursa which forms in these cases). The

foot is then turned outward, the astragaloscaphoid articulation is located, and over this an incision is made "from the lower to the upper dorsal border of the scaphoid bone" (Barker), reaching through the skin only; the foot is placed again in the first position, all the soft parts are raised from off the superior surface of the tarsus, and a triangular surface corresponding with the base of the wedge to be removed is cleared; a "kite-shaped" director (Fig. 485) is passed into the external wound and projected from the internal wound; the saw is pushed through the groove of the director nearest the toes, and is made to cut through the tarsus, from the dorsum to the sole, at right angles to the metatarsal bones; the saw is pushed through the groove of the director nearest the ankle, and is made to cut from the dorsum to the sole, at right angles to the long axis of the calcaneum; the wedge-shaped piece of bone is grasped by sequestrum forceps and cut out by scissors, by bone-forceps, or by a blunt bistoury. The wound is well irrigated, the foot is straightened, the internal wound is sewed up, the external wound is sutured except at its lowest portion, where a drainage-tube is to be retained for twenty-four hours, and dressings are applied to the wound. The foot is put up in plaster or upon a Davy splint. Some surgeons insert the wedge of bone into the opening made by a linear osteotomy on the inner side of the foot.

Osteotomy for Talipes Equinus.—This operation is described by Mr. Davy, who devised it, as follows:[1] "Taking the line of the transverse tarsal joint as a guide, on the outer and inner sides of the foot, and immediately over the joint, two wedge-shaped pieces of skin are removed, equal in extent to the amount of bone demanded. The soft structures are freed on the dorsum of the foot in the way previously described; but, as the base of the osseous wedge for equinus cases is at the dorsum and its apex at the sole, the parallel wire director, instead of the kite-shaped varus one, is used. The saw is successively inserted in its grooves, and by keeping in mind the idea of a keystone a clean wedge of bone is cut out from the dorsum to the sole of the foot." The wedge is extracted, and the foot is straightened and is put up in plaster of Paris or is placed on a Davy splint.

Fig. 485.—Davy's director (Pye).

The Question of Operation for Recent Fractures.—(See page 608.)

Operation for Recent Simple Fracture.—Very early after the injury is a fairly safe period for operation. Lane favors very early operation. During the first week, excluding the early hours after the injury, is a dangerous period to operate because the area of injury has a low resistance to infection. About the tenth day is a safer period for operation. Very careful sterilization is imperatively necessary. Make a free incision and expose the fracture. Remove all tissue from between the bone ends. König disagrees with Lane that all blood-clot should be removed. Arrest bleeding. Bring the fragments into apposition by extension and by using powerful forceps (Fig. 325) as a lever. Apply nails, screws, or what apparatus we desire.

The Lane plate is an excellent device (see Fig. 319). Select a suitable place, remove the lever, fix the plate and bones by Lowman's clamp (see Fig. 326), bore the bone by a drill (see Figs. 320, 486, 487) at each screw hole, insert and fix the screws, remove the clamp, and close the wound without drainage or with a cigarette drain. The part is placed upon a splint.

Figure 374 shows Lane's plate applied. If it does not loosen and does not give trouble a plate is not removed surgically.

Recent Transverse Fracture of the Patella.—(See page 689.)

Recent Fracture of the Olecranon Process of the Ulna.—(See page 650.)

Bone-grafting, or Transplantation.—(See pages 574 and 610.)

[1] Barker's "Manual of Surgical Operations."

Operative Treatment of Ununited Fracture.—A method of operation long in vogue and still used is as follows: Incise longitudinally down to the seat of fracture, retract the periosteum from the bone, drill the bones before cutting them, chisel away the material imperfectly uniting the fragments, saw through each bone end far enough from the seat of fracture to reach sound tissue, cut away the hard plug in each medullary cavity, pass large silver wire through the holes (this wire should be $\frac{1}{10}$ inch in diameter for the femur, $\frac{1}{16}$ inch for the patella, etc.) (Fig. 488), twist the wires a fixed number of times (two complete turns) in the direction that the hands of a watch move (this is Keen's direction; in case removal of the wires should be demanded later we know how to untwist them; of course the surgeon must remember where he stood in relation to the limb and regard the hypothetical watch as being face up upon the part), sever the ends of the wires, and hammer their stems against the bones. The wires may never require removal. The soft parts are sutured, no drain or a cigarette drain is used, and the limb is encased in plaster of Paris. The objection to wire in fracture of a long bone is that the wire acts as a hinge and, as a consequence, alignment is apt to be disturbed. Various plans besides wiring have been employed in ununited fracture. Gussenbauer's clamp is used by some. Clayton Parkhill's bone-clamp is a useful appliance, and holds the fragments firmly in

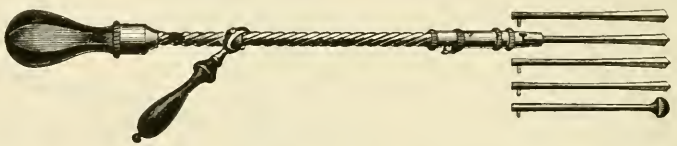

Fig. 486.—Hamilton's improved bone-drills.

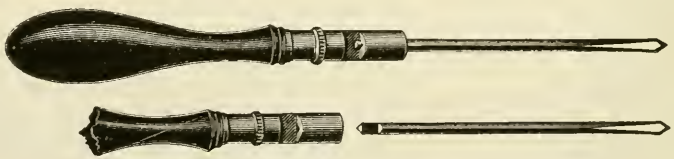

Fig. 487.—Brainard's drills with Wyeth's adjustable handles.

contact. Some surgeons unite the fragments with kangaroo-tendon instead of wire (suturing of bone); others use nails of bone or ivory; others use screws. Senn asserted that the above methods will not hold fragments in contact if these fragments have a tendency to become displaced. Senn fastened the bones together by hollow cylinders of decalcified bone or ivory, the cylinders being perforated in many places (bone-ferrules). I regard the silver plate of Halsted and steel plate of Lane as the most satisfactory appliances in use for fixation.

Albee's Operation.—Albee has emphasized the true principle. Fixation alone is seldom successful. The osteogenetic power is impaired in these injuries. Plates will fix the fragments but will not stimulate bone production. This can be done by a bone-graft. The graft is cut from sound bone ends or from another bone on the same individual. When fixed in place a graft holds the fragments like a plate, stimulates osteogenetic power, acts as a scaffolding for new bone-cells, and, at least so Albee believes, actively participates in repair. It is far and away the best method. The method for ununited fracture is as follows: Expose the fracture, cut away fibrous union and freshen the bone ends, remove the sclerosed plug from the medullary cavity of each fragment; if there is overriding make traction, divide the periosteum, take the twin saw and cut the groove for the insert. This groove goes through the cortex. The loose bone is removed. Drill holes through the cortex on each side of the groove. Expose the tibia and cut a groove with the twin saw. Remove the graft from the sound tibia and insert it into the

groove of the fractured bone. Kangaroo tendon having been run through the drill holes is now tied over the graft. (See Albee, in "Am. Jour. of Surgery," 1914, xxviii and "Bone-graft Surgery," by Albee.)

Ununited Fractures of the Femoral Neck.—Loreta did the first successful operation for this condition a number of years ago. The operation is not adapted to the aged, but should certainly be employed in youths and middle-aged individuals if the general condition of the patient or some particular diseased state does not forbid, and if pain is severe and disability is pronounced.

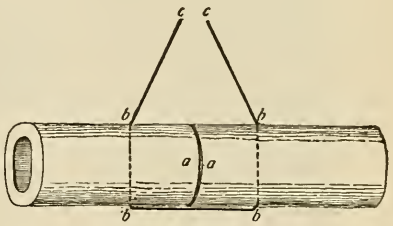

Fig. 488.—Wiring of bones for ununited fracture: *a*, *a*, Sawn surfaces approximated after removal of old material which was interposed between the fragments; *b*–*b*, *b*–*b*, perforations drilled completely across the bone; *c*, *c*, wires ready for twisting.

Leonard Freeman advises an anterior incision beginning below and external to the anterior superior iliac spine and extending downward, external to the sartorious, for 3 or 4 inches ("Annals of Surg.," Oct., 1904). When the fragments are exposed, the connective tissue between them is cut away by means of scissors, the surfaces of the fragments are freshened by a chisel or a curet, oozing is arrested by pressure and hot water, and loose osseous splinters are removed (Freeman). Some surgeons have fixed the fragments together by nails, screws, or pegs of bone or ivory, access to the trochanter being best obtained for this purpose by making a second incision over the outer portion of that bony process. As Freeman points out, however, the head is often so very soft that none of these appliances will secure fixation.

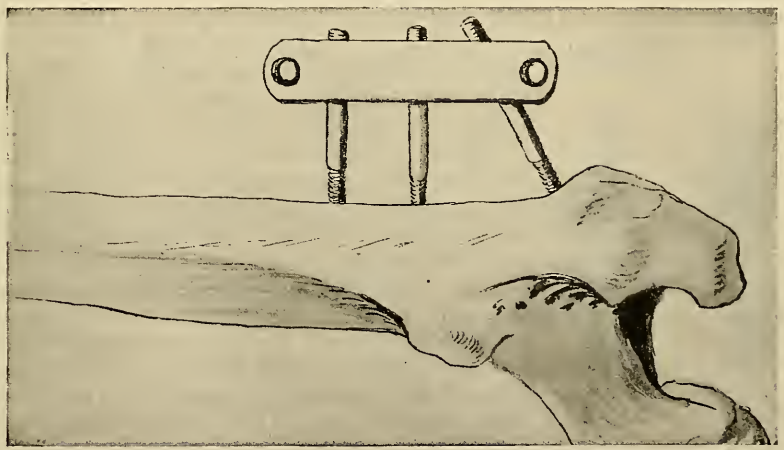

Fig. 489.—Method of securing screw of Freeman's apparatus in fracture of neck of femur; the wooden plates embracing screws (Freeman, in "Annals of Surgery," Oct., 1904).

Freeman has devised a clamp for this purpose (Figs. 489, 490). An additional incision is made over the trochanter and holes are bored for the clamp screws, one hole being drilled "through the base of the trochanter, the external fragment of the neck, and into the head of the bone" ("Annals of Surgery," Oct., 1904). The wound is closed, dressings are applied, and extension is made on a long side splint, a pad being placed beneath the trochanter to prevent the disposition to pass backward, as this movement, if it occurs, will cause external rotation of the limb and separation of the fragments. In about

eight weeks the extension is removed and the patient is allowed about on crutches. Dr. H. Augustus Wilson has succeeded by simply nailing the fragments together without attempting to freshen their faces. He got his patient up on crutches in two weeks ("Amer. Jour. Orthopedic Surgery," Jan., 1908).

In Freeman's case the screws were removed in two weeks because of infection

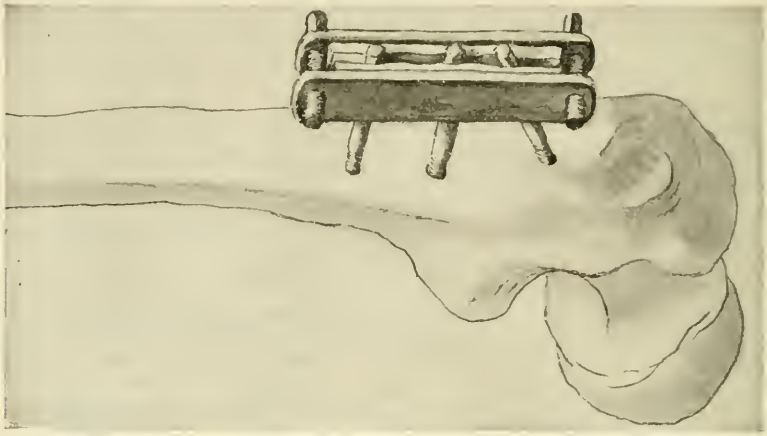

Fig. 490.—Completed screw and clamp of Freeman's apparatus for fixation of fracture of neck of femur (Freeman, in "Annals of Surgery," Oct., 1904).

of the cancellous tissue. A similar condition arose in Davis's case, in which two steel drills were used. Dr. H. Augustus Wilson has collected 36 cases of direct fixation of old intracapsular fractures (Ibid.).

Ununited Fracture of Patella.—Ten days before operating inject the knee-joint with 15 c.c. of a 2 per cent. solution of formalin in glycerin. This will produce a chemical inflammatory reaction, which coffer-dams the lymph spaces and strengthens immunity to infection (John B. Murphy, in his "Surgical Clinics," Vol. iv). A semilunar incision is made about the fragments, the convexity pointing up or down (this avoids the prepatellar bursa), or an incision is made in the long axis of the limb, over the middle of the space between the fragments, from well above the upper fragments to well below the lower piece. The soft parts are retracted, but the periosteum is undisturbed; each fragment is bored (Fig. 491, 1) in one or two places; the surfaces of the fragments are sawed straight across, through sound bone; all old reparative material is cut away; the wires are passed through the perforations, twisted, cut off, and hammered down (Fig. 491, 2). If the bone-fragments cannot be approximated, it may become necessary to incise the muscle around and above the patella or partially to separate the tuberosity of the tibia and bend this process upward. A small drain is inserted above the bone, the wound is sutured, aseptic dressings are applied, and the limb is put upon a Macewen splint.

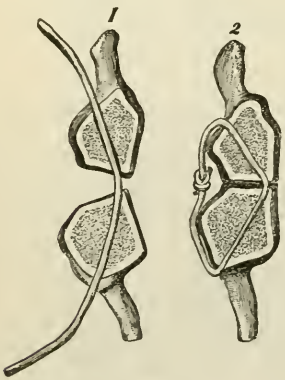

Fig. 491.—Wiring of the patella: 1, Fragments cut and cleaned and the wires passed; 2, wires twisted and hammered down upon the bone (after Barker).

Treves's Operation for Caries of the Lumbar and Last Dorsal Vertebræ, with Abscess in the Psoas Magnus or Quadratus Lumborum Muscle.—The patient lies upon his left side, with the knees drawn up and a

sand-bag under the left loin. The surgeon stands behind the patient (Barker). An incision is made at the outer border of the erector spinæ mass, reaching from the last rib to the iliac crest and going down at once to the lumbar fascia. The lumbar aponeurosis is opened, the erector spinæ muscle is retracted inward, and the anterior portion of the erector spinæ sheath is incised. The quadratus lumborum muscle is next cut, and then the anterior leaflet of the lumbar aponeurosis is slit. The abscess is thus reached and opened and tuberculous pus flows out. The abscess-cavity is irrigated with quantities of warm corrosive sublimate solution (1 : 5000). The cavity is filled, the fluid is allowed to flow out, its exit being aided by pressure in front and changes of posture; the cavity is filled again, and so on, and, after all loose débris is removed, the bodies of the vertebræ are carefully examined with the finger and diverticula are opened. Loose pieces of bone are removed by spoons or forceps, and cavities are thoroughly but lightly curetted, as in some places the wall is very thin. By means of properly shaped spoons carious bone can be removed even from the anterior surface of the column (Treves). Thus the wall of the abscess is completely removed. Finally, all débris is washed out by irrigation with mercurial solu-

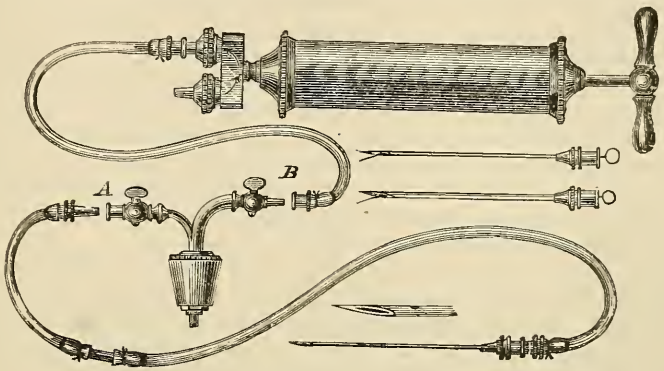

Fig. 492.—Aspirator and injector.

tion; any mercurial solution which might remain is washed out by warm water or salt solution, and the interior of the cavity is wiped dry. At this stage most operators introduce iodoform emulsion. Whether or not this is done, "the wound is closed by a series of silkworm-gut sutures, passed sufficiently deep to include the greater part of the muscular and tendinous structures with the skin" (Treves's "Operative Surgery"). Treves's operation gives a high mortality.

Aspiration of Joints.—In certain cases of joint-effusion from inflammation, tuberculous or otherwise, and sometimes in hemorrhage into a joint, it is desirable to remove the fluid by aspiration. The pneumatic aspirator (Fig. 492) is used. The trocar and cannula are thoroughly asepticized and the joint is prepared as for a set operation. The needle is entered at a point free from large vessels. The directions for using an aspirator are as follows: insert the stopper firmly into a strong bottle (preferably a clear glass one), then attach the short elastic hose to the stopcock *B* of the tube projecting from the stopper, and attach the other end of the same elastic hose to the exhausting or inward-flowing chamber of the pump. Next, attach one end of the lower elastic hose to the stopcock *A* projecting from the stopper and the other end to the needle. Care should be taken that all the fittings or attachments are placed firmly into their respective places. Now close the stopcock *A* and open the stopcock *B*. By giving from thirty-five to fifty strokes of the pump a sufficient vacuum can be produced to fill with the fluid from the joint a bottle holding from a pint to a quart. After having formed the vacuum, close the stopcock *B*, and insert

the needle in the joint. When the stopcock *A* is opened, suction through the needle draws the fluid from the joint. The trocar may be used to inject antiseptic agents. After the completion of aspiration the part is dressed antiseptically and the extremity is put at rest upon a splint.

Excisions of Bones and Joints.—The ancients practised excision and resection for compound dislocations and fractures. For centuries surgeons removed pieces of diseased bone from joints. The operation was set forth as a definite procedure, and was first formally advised as a substitute for amputation in joint disease by Mr. Park, of Liverpool, in 1781. In 1782 the elder Moreau, of Bar-sur-Ornain, independently devised a like operation. The terms "excision" and "resection" are usually employed as synonymous, but such a use is not strictly accurate. According to Professor Ashhurst, the term *excision* means "the removal of an offending part without that total ablation of the affected portion of the body which is implied by the term 'amputation.' Hence we speak of excisions of tumors, of joints, of the eyeball, etc." *Resection* has a more restricted meaning; it signifies "an operation which takes away a middle portion and brings the ends together again, and is thus in strict surgical language limited to partial excisions of the long bones" ("International Encyclop. of Surgery," edited by John Ashhurst, Jr.). Excision of a joint is the removal of the articular portions of the bones of the joint, and also the cartilage and synovial membrane. In the hip-joint and shoulder-joint only the head of the long bone may be removed, and not the articular surfaces of both bones. In partial excision of a long bone, excision (resection) for bone disease, enough bone is known to have been removed only when the remaining bone bleeds. *Complete excision* of a bone is the removal of an entire bone. *Partial excision* or *resection* is the removal of a portion only of a bone. Excision is a conservative operation which often averts amputation.

Excision may be performed by the *open* method, in which the periosteum is not preserved, or it may be performed by the *subperiosteal* method, in which the periosteum is carefully separated by a rugine and the capsular ligament is preserved. This method was devised by Ollier, of Lyons. *Arthrectomy*, or *erasion*, is the excision of the diseased synovial membrane and ligament, and also small foci of disease of bone and cartilage.

Excision may be employed for compound dislocation, and in compound dislocations of the elbow and the shoulder it is usually performed. Excisions for compound dislocations in other large joints are very dangerous; they are rarely attempted in battlefield practice, and are to be avoided even in civil practice unless the patient is young and vigorous and every advantage can be given him during the operation and convalescence. Excision for deformity is rarely performed except upon the hip, the knee, and the shoulder, and these excisions must not be employed if the patient's condition leads one to fear the result of a protracted convalescence. Excision of the elbow, however, is usually a safe operation. In excising for deformity always consider the patient's trade and the demands of habitual position which it makes upon him.[1]

Excision is largely employed for joint-disease, especially for tuberculous joints. Bell states that attempts to preserve the limb without excision are more justifiable in the lower than in the upper limbs, because operation in the lower extremity is more dangerous than in the upper, and because a cure without operation in the lower limbs, if this cure can be brought about, gives as good a result as a cure by excision. In the upper extremity the danger from operation is less than is the danger from waiting. In a young subject an excision may remove the epiphysis, and thus lead to permanent shortening, which is productive of less inconvenience and deformity in the arm than in the leg. A danger of excision operations is that the section may be made through cancellous bony tissue; hence, if infection takes place, disastrous

[1] Joseph Bell, in his "Manual of Surgical Operations."

suppuration, phlebitis, myelitis, septicemia, or pyemia will follow; further, in excision the cut is often made through diseased tissue, and a protracted convalescence is then inevitable. Amputation is effected through healthy tissue, and the convalescence is short. Excision, however, when successful, gives the patient a very useful limb.

Erasion, or Arthrectomy.—This operation was suggested by Cross, of Bristol, and was perfected and established by Wright, of Manchester, between 1881 and 1888. *Erasion* is the complete removal of diseased synovial membrane, ligaments, and small foci of disease in bone and cartilage. This operation seeks to remove a depot of infection in an early stage of tuberculous synovitis, and it possesses the conspicuous merit of not interfering with the epiphysis. The term "erasion" is also used by some to designate the operation of removing healthy synovial membrane, ligaments, etc., for the purpose of producing fixation of a flail-joint due to infantile paralysis, but in such cases *arthrodesis* is the proper term for the operation. Erasion is oftenest practised upon the knee-joint.

Erasion of the Knee-joint.—The patient lies upon his back; the leg is flexed, with the sole of the foot planted upon the table, and an Esmarch bandage is applied at a point well up on the thigh. The surgeon stands to the right of the patient. The incision is begun in the midline of the thigh (on the side opposite to that occupied by the surgeon), about 3 inches above the patella; it is carried down across the ligament of the patella and up to a corresponding point on the opposite side of the thigh. This incision goes down to the bone; the flap is turned up and the joint exposed; the knee-joint is strongly flexed, and the synovial membrane and diseased ligaments are dissected away with scissors and forceps, great care being taken that the posterior ligaments (which, fortunately, are rarely implicated early in the case) are not divided and that the contents of the popliteal space remain intact. After removing the diseased ligaments and synovial membrane the cartilage is examined and any diseased portion is removed. The bone is then examined and any tuberculous foci are gouged away. Exposed vessels are ligated. The wound is irrigated by salt solution, the extremity is straightened, and the ends of the ligamentum patellæ are sutured, a drainage-tube is inserted at each angle of the wound, the skin is sutured, and antiseptic or sterile dressings are applied. The limb is placed upon a posterior splint for a few days, then the drainage-tubes are removed, the dressings are changed, and a plaster-of-Paris cast is applied, trap-doors being cut on each side, and the joint is kept immobile for two or three weeks. This operation is only suited to early cases in which the lesion involves chiefly or purely the synovial membrane and ligaments, and in these cases it frequently gives a good result, some capacity for motion being not unusually preserved.

Excision of the Shoulder-joint.—Bent, of New Castle, performed the operation in 1771 ("Manual of Operative Surgery," by Sir Frederick Treves). Syme really established the operation in surgical confidence. In the shoulder-joint *partial* excision is often performed, the head of the humerus being removed and the glenoid being undisturbed; but some patients require complete excision, the entire glenoid depression, as well as the head of the humerus, being removed by the surgeon. Excision of the shoulder-joint is made, if possible, an intracapsular operation, the capsule being opened, but the capsular attachment to the anatomical neck of the humerus not being interfered with. In advanced cases, however, the capsular attachment must be destroyed. Excision of the shoulder-joint for trauma is a far less common operation in civil, than in military, practice. It is performed for gunshot-wounds, compound dislocations, tuberculous disease, and tumors of the head and upper portion of the humerus.

Operation by Anterior Incision.—The patient lies supine; a pillow is placed

beneath the shoulders, and a sand-pillow is put beneath the shoulder to be operated upon. The arm is held to the side with the outer condyle forward and the bicipital groove inward (Barker's directions). The surgeon stands by the affected side. An incision 3 or 4 inches in length is made from just external to the coracoid process of the scapula, running straight down the humerus (Fig. 493, A). This incision divides the border of the deltoid muscle and brings into sight the long head of the biceps. The tendon of the biceps is retracted inward, unless it is diseased, in which case it is resected. The knife is carried up the groove and opens the capsule of the joint. The periosteum is lifted from the neck of the bone while an assistant rotates the elbow to make the muscles tense. In some places, if the periosteum tears, muscular insertions must be cut with a knife. The head of the bone is sawn off while the bone is in place, or the elbow is strongly pulled back, and the head of the bone is forced out of the wound, and is then sawn off at the point required. In ordinary cases only the articular head is removed; in other cases the section is made just above the surgical neck; in still others a portion of the shaft must also be cut away. If the glenoid cavity is found slightly diseased, the dead bone must be removed by the chisel and mallet or by the cutting forceps. If the cavity is seriously diseased, the entire glenoid should be removed. Scrape away all damaged tissue; ligate bleeding points; irrigate the wound with corrosive sublimate solution; swab it out with a solution of chlorid of zinc (20 gr. to 1 oz.); dust with iodoform; close the upper portion of the wound and insert a drainage-tube in the lower angle; dress the wound antiseptically; place a small pad in the axilla; apply the second roller of Desault; and put the patient in bed with a pillow under the affected shoulder. In seven days the hand-sling is substituted for the bandage, and with the elbow hanging free the patient is permitted to get up and is advised to move his arm frequently. Drainage is maintained until the wound is well healed from the bottom. Great limitation of movement inevitably follows a shoulder-joint resection.

Excision by the deltoid flap is performed when the head of the bone is much enlarged (as by a tumor) or when the tissues are thick and indurated. The deltoid flap is in the shape of a U or is semilunar (Fig. 494, A). Raising this flap exposes the head of the bone most satisfactorily. Bell states that when the glenoid cavity is chiefly involved the incision should be posterior (Fig. 494, B).

Senn's Method.—Senn[1] described an incision which does not damage important vessels, muscles, tendons, or nerves, and which is followed by good functional results. A semilunar skin-flap is formed, the incision running from the coracoid process to the posterior border of the axillary space. The flap is turned up, exposing the upper half of the deltoid muscle. The acromion is sawn off and turned down with the attached deltoid. The capsule is now freely exposed; it is opened, and either arthrectomy or excision is performed, according to conditions. In closing the wound it is not necessary to bore the acromion and pass silver wires to join the fragments; it is enough to suture the periosteum with catgut.

Excision of the Elbow-joint.—This operation was suggested by Park in 1782, but the first employment of it was by Moreau in 1794. It is performed for wounds, faulty ankylosis, and chronic articular disease. Excision must be complete. Endeavor to make a subperiosteal resection; this maintains the shape of the articulation and gives the best chance for a movable joint. The patient is "supine, but inclining to the sound side, the affected arm being held almost vertical, with the forearm flexed and nearly horizontal" (Barker). The incision is made on the posterior surface of the joint. A single posterior incision is usually employed (Fig. 494, D). An incision is made a little internal to the long axis of the olecranon, beginning 2 inches above and terminating 2 inches below the tip of the olecranon. This incision goes down

[1] "Phila. Med. Jour.," Jan. 1, 1898.

to the bone, and throughout the entire operation the surgeon must guard and shield the ulnar nerve. The periosteum and soft parts are well separated; the olecranon is sawn off; forced flexion exposes the joint-cavity freely, and enables the surgeon to lift the periosteum and soft parts from the humerus; the humerus is sawn through at the beginning of its condyloid processes; the radius and ulna are cleared and are sawn at a level below that of the base of the coronoid process of the ulna. Diseased tissues are cut and scraped away; the wound is irrigated, sutured, drained, and dressed. In some cases an H-shaped incision is employed (Fig. 494, C), but the cicatrix of a transverse cut will limit flexion of the limb.

After excision of the elbow the patient is put to bed and the arm is laid upon a pillow, the elbow being placed midway between a right angle and

Fig. 493.

A–G, Excisions: A, excision of shoulder-joint (deltoid flap); B, of shoulder-joint (posterior incision); C, of elbow-joint (H-shaped incision); D, of elbow-joint (linear incision); E, of hip-joint (Gross's); F, of os calcis; G, of scapula.

complete extension, the forearm being placed midway between pronation and supination. No splint is used, as a rule. Esmarch used the splint shown in Fig. 495. The aim in treatment is to obtain a freely movable joint. Passive motion is begun in one week, at which time the patient gets up. The hand is carried in a sling for a time after healing of the wound is complete.

Excision of the Head of the Radius.—This operation is practised for irreducible dislocation of the radius. An incision is made through the supinator longus muscle down to the head of the radius, and the neck of the bone is divided by means of a Gigli saw or bone-cutting forceps. The musculospiral nerve lies to the inner side. Some bone is always taken from the external condyle in order to make a sufficient gap to prevent subsequent ankylosis ("The Operations of Surgery," by Jacobson and Rowlands).

Excision of the Wrist-joint.—This operation was first performed by Moreau in 1794. Bell states that, whatever method of excision is chosen, three cardinal rules must be borne in mind: (1) remove all the diseased bone, including the portions of the radius, ulna, carpus, and metacarpus which are covered with cartilage; (2) interfere with the tendons to the least possible degree, and (3) begin passive motion of the fingers very early. Many surgeons prefer the simple gouging away of diseased foci and the scraping of sinuses instead of a formal resection of the wrist, amputation being employed in severe cases or when scraping fails after several trials. Formal excision is not frequently performed, and the results cannot be regarded as very favorable.

Lister's Open Method of Excision.—Break up adhesions as completely as possible by forcible movements. Apply a tourniquet or an Esmarch apparatus. The patient lies upon his back, the arm and the forearm being brought, from stage to stage, into the most desirable positions. Begin an incision over the middle of the dorsum of the radius, on a level with the styloid process; carry it downward in the direction of the inner edge of the articulation of the first phalanx of the thumb with the first metacarpal bone, and when the knife reaches the radial side of the second metacarpal bone alter the direction of the incision and carry it downward in the long axis of the metacarpal bone to about its middle (Fig. 496, A). This is known as the *radial incision*, and the only tendon divided is that of the extensor carpi radialis brevior muscle. The

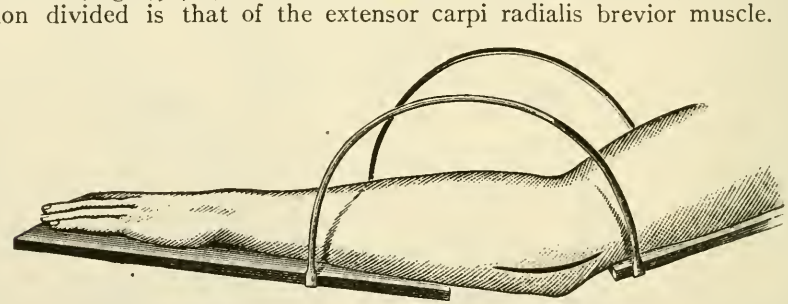

Fig. 495.—Esmarch's splint for the treatment of a limb after excision of the elbow-joint.

tissues upon the radial aspect of the incision are dissected up, the tendon of the extensor carpi radialis longior muscle is divided at its point of insertion (Bell), and all the soft structures are retracted outward, exposing the trapezium, which is cut off from the rest of the carpus, but which is left in place, as its removal at this stage endangers the radial artery (Barker). By extending the hand the tendons are loosened and the carpus is cleared in the direction of the ulnar border of the hand.

Another incision is made, starting upon the inner surface of the wrist, 2 inches above the articular surface of the ulna, and midway between the ulna and the flexor carpi ulnaris tendon. This incision, which is known as the *ulnar incision*, is carried down until it is opposite the middle of the fifth metacarpal bone in the palm (Fig. 496, B). "The dorsal lip of this incision is raised" (Bell), and the extensor carpi ulnaris tendon is divided and dissected from its depression, but is not separated from the integument. The extensor tendons are lifted; the ligaments upon the dorsum and sides of the wrist-joint are cut; the flexor tendons are raised from the carpal bones; the pisiform bone is cut from the carpus, but is not yet removed; and the unciform process of the unciform bone is cut with forceps. The anterior radiocarpal ligament is divided, the carpometacarpal articulations are cut through, and the carpus is pulled out with bone-forceps. The ends of the radius and ulna are forced out of the ulnar incision. All that portion of the ulna which is crusted with cartilage is to be removed, the saw-cut is to be oblique, and the base of the styloid process

is to be left behind. A thin section is to be sawn from the radius, and the tendon-grooves are not to be impinged upon. The articular surface of the ulna is cut away by pliers (Bell). If foci of disease are discovered beyond these points, they are to be gouged out. The ends of the metacarpal bones are sawn off, and their articular facets are cut away by means of pliers. The trapezium is dissected out, the end of the first metacarpal bone is sawn off and its facet is cut away with pliers, and a portion of the pisiform bone is removed (the entire bone being removed if it be diseased). The wound is irrigated, vessels are tied, the radial incision is closed, the ulnar incision is partly closed, a drainage-tube is inserted by way of the ulnar incision, the wounds are dressed antiseptically, and the Esmarch apparatus is taken off. The forearm and hand are placed upon a splint which immobilizes the wrist and leaves the fingers semiflexed. Passive motion of the fingers is begun after thirty-six hours. The splint is worn for many months until the wrist-joint is immobile and solid. Esmarch uses the splint shown in Fig. 498.

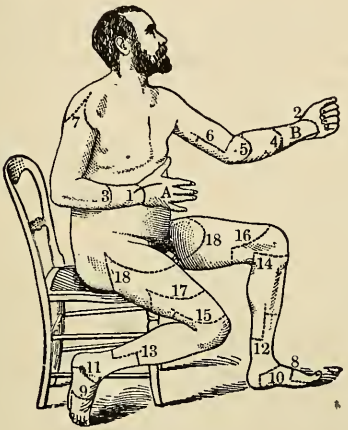

Fig. 496.

Fig. 497.—1–10, Amputations (Joseph Bell): 1, of lower third of forearm (Teale's); 2, at shoulder-joint by large postero-external flap (second method); 3, at shoulder-joint by triangular flap from deltoid (third method); 4, 5, through tarsus (Chopart's); 6, 7, at knee-joint; 8, by single flap (Carden's); 9, 10, of thigh (Teale's). A, excision of hip, B, B, of ankle-joint (Hancock's incision).

Excision of Metacarpal Bones and of Phalanges.—Excision of a metacarpal bone, except in cases of necrosis with the formation of large quantities of new bone, usually leaves a useless finger; hence amputation of the bone with the finger is usually preferred to excision. This rule does not apply to the metacarpal bone of the thumb, which is occasionally excised. The incision for this operation is made upon the dorsum, and is straight. Excision of the proximal phalanx of the thumb is sometimes performed. Excision for disease is rarely performed upon the finger-joints, amputation being preferred, though the operation is sometimes undertaken for compound dislocation. In the metacarpo-phalangeal joint of the thumb excision, if it can be performed, is preferred to amputation. The incision for resection of this joint is placed upon the radial aspect.

Excision of the Hip-joint.—Treves and Jonathan Hutchinson, Jr. ("Manual of Operative Surgery"), tell us that the operation was first performed by Anthony White, of the Westminster Hospital, in 1818. Sir William Fergusson established the operation in surgical confidence. Some surgeons advocate this operation; others, notably Marsh, are emphatically opposed to it. Excision should be performed in the early stage of tuberculous disease *if less radical*

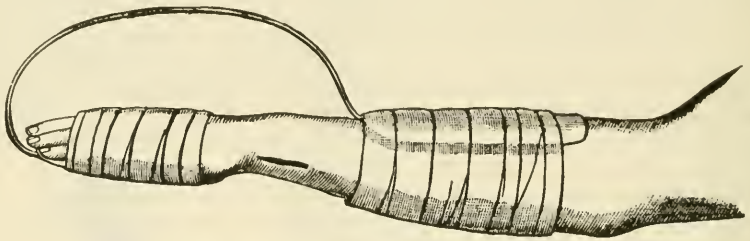

Fig. 498.—Esmarch's interrupted splint applied.

treatment has failed. In this stage the usual position of the limb is one of flexion, abduction, and eversion. In cases of long duration, especially where dislocation exists, excision is an easy and a comparatively safe operation; in recent cases it is difficult and carries with it decided dangers, but the peril of delay may be greater than the peril of an early excision. In cases of hip disease with involvement of the acetabulum the mortality is 50 per cent., whether operation is or is not attempted. Excision is performed especially for tuberculous disease and for gunshot-injuries.

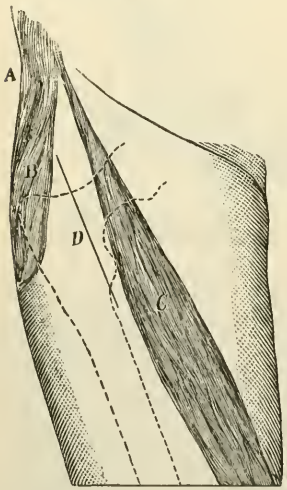

Fig. 499.—Excision of the hip-joint: A, Gluteus muscle; B, tensor vaginæ femoris muscle; C, sartorius muscle; D, anterior incision.

Operation by Anterior Incision (Fig. 499) (*Barker's Operation*).—In this operation the patient is supine, with the thighs extended as thoroughly as circumstances permit. The surgeon stands to the right of the patient. An incision is begun ½ inch below and ½ inch external to the anterior superior iliac spine, and it is carried downward and a little inward for about 3 inches (Fig. 499, D). If dislocation exists, the incision need not be so long. This incision is carried at once deeply between the muscles, and the capsule of the joint is opened. The neck of the bone is divided from its upper surface downward by a saw or an osteotome, and without dislocating the bone through the wound by forcible extension and eversion. The head of the bone is removed. All tuberculous foci must be scraped away, and the flushing gouge is used upon tuberculous areas of the acetabulum. All sinuses should be thoroughly scraped. Bleeding is arrested, the wound is irrigated with normal salt solution, mopped with chlorid of zinc solution, and dusted with iodoform. A drainage-tube is inserted at the lower angle of the incision, and the upper portion of the cut is closed. The wound is dressed antiseptically. Extension is made by the extension apparatus until healing has obtained good headway, when a double Thomas splint is applied, so that the patient may be taken out daily in the air and sunlight. As a rule, rigid ankylosis results from resection of the hip, but occasionally a joint results with a small range of movement.

Operation by Lateral Incision (*Langenbeck's Operation*).—In this operation a straight incision 2 inches in length is made in the direction of the axis of the

femur, and passing downward from the apex of the great trochanter. From the beginning of this incision a curved incision is carried toward the head of the bone, the convexity of the curve being backward (see Fig. 497, A). Bell advises the use of the saw after bringing the head of the bone into the wound by abduction and eversion of the thigh. Barker applies the saw with the bone *in situ*, and strongly opposes wrenching the bone out of the incision because of the danger of peeling off the periosteum, which, if it takes place, favors necrosis.

Incision of Gross.—In Gross's operation a semilunar flap is made with the convexity backward (see Fig. 494, E).

Excision of the Knee-joint.—The complete operation was first performed by Park, of Liverpool, in 1781. In this operation a complete excision should be performed, and the patella ought to be removed. The operation is performed for tuberculous disease, some compound fractures and compound dislocations, and some cases of angular ankylosis. It is rarely employed for gunshot-injuries.

Operation by Anterior Semilunar Flap.—The patient lies upon his back, and the joint, if not ankylosed in extension, should be semiflexed. The surgeon stands to the right side. An incision is made which at once opens the joint. The incision begins at one condyle and reaches the other condyle by a curve which passes through the ligamentum patellæ midway between the tuberosity of the tibia and the inferior margin of the patella (see Fig. 493, B). The flap is dissected up, the knee is thrown into forced flexion, the lateral ligaments and crucial ligaments are cut, and the end of the femur is well cleared. The blade of Butcher's saw is passed beneath the bone, which is sawn from below upward (Ashhurst). The end of the tibia is cleared and a portion is sawn off. If, after sawing, diseased foci are discovered, another section can be sawn off or the foci can be gouged away. Ashhurst, who had a vast experience with this operation, insisted that in sawing through the femur the natural obliquity of the bone must be borne in mind and the section must be made in "a line parallel to that of the free surface of the condyles." If the section is made transverse to the axis of the femur, "the limb, after adjustment, will be found to be markedly bowed outward." The same surgeon said that the epiphyseal line is somewhat higher on the front than it is on the back of the femur, and in consequence the following rule is formulated for section of the condyles: the section of the condyles should be "in a plane which, as regards the axis of the femur, is oblique from behind forward, from below upward, and from within outward." Ashhurst advocated section of the tibia "in a plane transverse to the long axis of the bone, with a slight anteroposterior obliquity, so as to correspond with that of the section of the condyles," and he further says that the patella must be removed whether it is diseased or not, and quotes Péniére's observations to the effect that excision of the patella diminishes the risk of death one-third, and its retention doubles the probability of an amputation becoming necessary in the future.

After removing the patella the diseased synovial membrane is clipped away with scissors and all sinuses and diseased territories are well curetted. The posterior ligament of the joint is not removed unless it is diseased; its retention prevents displacement and guards the popliteal space. In some cases tenotomy is required to permit extension. In children the fragments should be wired together; in adults this need not be done. After hemostasis, irrigate by salt solution, insert a drainage-tube, suture, dress antiseptically, and adjust the limb upon Price's splint or Ashhurst's bracketed wire splint. Instead of the bracketed splint, a long fracture-box may be used. If the femur tends to project anteriorly, use an anterior splint. If there be a tendency to outward bowing, adopt Ashhurst's expedient of carrying a strip of adhesive plaster around the outside of the limb and fastening it to the inner side of the splint.

The splint is kept on until bony union is complete, as in this operation a movable joint is never sought. Many surgeons use a fenestrated or interrupted plaster-of-Paris splint, which is employed until the parts have become apparently firm and solid (Fig. 500). Even for many months after the parts have apparently become solidly united, bending may occur. How long fixation should be used has been much debated. In order to avoid the danger of flexion or other deformity, fixation by some form of apparatus should be maintained for "at least a year and probably nearly two years after excision" (J. Torrance Rugh, "Am. Jour. Orthopedic Surgery," Feb., 1909).

Excision of the Ankle-joint.—Excision of the ankle was first performed by Moreau in 1792. This operation is performed chiefly for gunshot-wounds, compound dislocations, and in some cases of tuberculous joint disease. Excision of the ankle is an operation which is seldom performed.

Operation by Hancock's Method.—In this operation the patient lies upon his back, the foot rests upon its inner side, and the surgeon stands to the outer side of the damaged limb. Begin an incision just behind and 2 inches above the external malleolus, and carry it across the front of the joint to a corresponding point above and behind the internal malleolus (see Fig. 497, B); this incision goes through the skin only, and the flap thus marked out is reflected. "Cut down upon the external malleolus, carrying the knife close to the edge

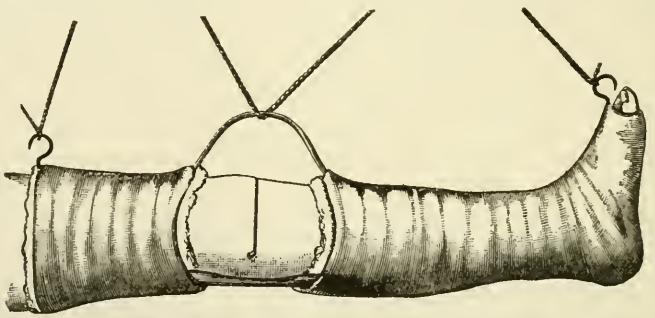

FIG. 500.—Watson's plaster-of-Paris swing-splint.

of the bone both behind and below the process, dislodge the peronei tendons, and divide the external lateral ligaments" (Joseph Bell). Cut the fibula 1 inch above the malleolus by means of pliers; divide the tibiofibular ligament; turn the foot upon its outer side; dissect from their habitat back of the inner malleolus the tendon of the posterior tibial muscle and the tendons of the flexors of the toes; carry the knife around the inner malleolus close to the bony edge; separate the internal lateral ligament, and dislocate the lower end of the tibia through the wound by turning the sole of the foot downward; saw off the lower end of the tibia and the articular process of the astragalus, sawing away from the tendo Achillis, and removing the fragments by bone-forceps. Cut away diseased synovial membrane, and curet all sinuses and tuberculous areas. Arrest bleeding, irrigate, and drain. Sew up the wound, insert a tube at the outer angle, and cause it to emerge at the inner angle. Apply antiseptic dressings, and put up the foot in fixed dressing or in splints at a right angle to the leg (Fig. 501). In Langenbeck's operation the excision is subperiosteal. If, in an excision of the ankle-joint, the astragalus is found extensively diseased, remove the entire bone.

Excision of the Os Calcis.—In caries limited to the os calcis most surgeons prefer to gouge away the dead bone, leaving the periosteum and, if possible, a shell of healthy bone, and draining thoroughly. Others advocate excision in some cases. Extensive disease limited purely to the os calcis is rare, and

most surgeons advise gouging for limited caries, and Syme's amputation in the event of the disease extending beyond the periosteum or reaching adjacent bones.

Operation by Subperiosteal Method.—In this operation the position assumed by the patient is supine, with the leg extended and the foot resting on its inner side. The incision, which cuts the tendo Achillis and reaches the bone at once, is begun at the upper border of the os calcis and the inner margin of the tendo Achillis, and is taken outward and horizontally forward to a point in front of the calcaneocuboid articulation (see Fig. 494, F). A vertical incision is begun near the forward termination of the initial incision, is carried across the outer edge and plantar surface of the foot, and terminates at the external margin of the inner surface of the os calcis. Some surgeons carry the vertical incision a little upward, toward the dorsum. The periosteum is entirely stripped by an elevator, the os calcis is removed, the cavity is packed with iodoform gauze, the wound is stitched, a drain is inserted posteriorly, the foot is dressed antiseptically, is placed at a right angle to the leg, and plaster of Paris is applied, trap-doors being cut for drainage. Later the drain is removed and the packing of gauze changed daily.

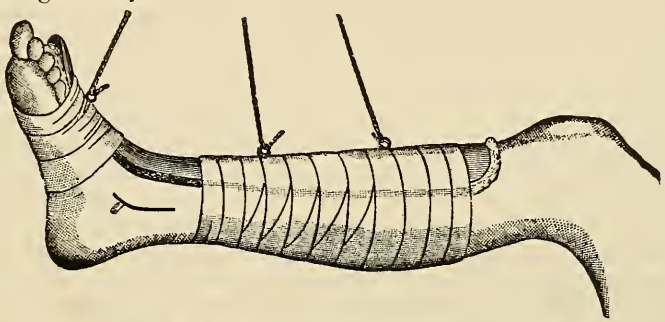

FIG. 501.—Volkmann's dorsal splint for excision of the ankle.

Astragalectomy, or **excision of the astragalus,** is seldom performed. Astragalectomy is employed occasionally for relapsed and inveterate cases of club-foot. The indications are pointed out by Willard ("International Clinics," vol. iii, 12th series): "(1) Adults with great bony deformity; (2) neglected children of five to fifteen years, who have markedly distorted their tarsi by locomotion; (3) relapsed cases which have resisted the milder forms of operation, or which have been neglected by parents after previous operation; (4) only occasionally, young children in whom from infancy the bones of the foot have been exceedingly rigid and unyielding, and where there is practically but little motion either at the ankle-joint or in the tarsus."

Operation by the Subperiosteal Plan.—Barker advises an incision going at once to the bone, from the "tip of the external malleolus forward and a little inward, curving toward the dorsum of the foot." The foot is extended and turned inward, the periosteum is lifted, the astragalus is removed, and the wound is treated and the foot is dressed as is done after excision of the os calcis

In cases of *paralytic calcaneus* Whitman ("Orthopedic Surgery") recommends removal of the astragalus through a curved external incision; freeing the malleoli and making new sockets for them beside the cuboid and scaphoid bones. He puts the foot in marked plantar flexion and holds it by plaster.

Excision of the Metatarsophalangeal Articulation of the Great Toe.—In this operation make a lateral incision and cut off or saw off the proximal end of the first phalanx and the distal third of the first metatarsal bone. (See Mayo's Operation for Bunion, page 780.)

Excision of the Metatarsal Bone of the Great Toe (*Butcher's Method*).—In this operation a lateral straight incision is made, the periosteum is elevated, and the shaft is sawn from each extremity and removed.

Excision of the clavicle may be required for dislocation, caries, necrosis, gunshot-wound, tumor of this bone, as a preliminary to ligation of the artery and vein in certain cases of amputation at the shoulder-joint, or in cases of removal of the entire upper extremity. In excision of the clavicle the position of the patient is the same as that for ligation of the third part of the subclavian artery (see page 545). An incision is made down to the bone, from the sterno-clavicular joint to the acromioclavicular articulation. If the case is suitable, the periosteum is stripped and the bone is sawn and removed; if not, the bone is sawn and each half is separately disarticulated. The wound is sutured and dressed, and the limb is put up in a Velpeau bandage. McCreary, of Kentucky, in 1811 performed the first complete excision of the clavicle.

Excision of the Scapula.—Complete excision of the scapula is usually performed for tumors. Partial excision requires no detailed description. In excision of the scapula the patient lies upon his sound side. Treves suggests the following incisions: one outside the vertebral border of the scapula, from its superior to its inferior angle; another from over the acromioclavicular joint, along the acromion process and spine of the scapula, to meet the first incision. Syme used an incision carried transversely inward from the acromion process to the vertebral border of the scapula, and another cut directly downward from the center of the first incision (see Fig. 494, G). In the method of Treves[1] the upper flap is reflected and the trapezius muscle is divided; the lower flap is reflected and the deltoid muscle is divided. The patient's hand is placed on the sound shoulder; the muscles of the vertebral border are divided, the posterior scapular artery is tied, and while the vertebral border of the scapula is pulled toward the surgeon, the serratus magnus muscle is cut, the upper border of the shoulder-blade is cleared, and the suprascapular artery is tied. The hand is now brought down to the side; the acromioclavicular joint is disarticulated; the conoid and trapezoid ligaments are divided; the muscles of the coracoid process are cut; the capsule is incised, with the supraspinatus and infraspinatus, the subscapularis, and the scapular origins of the biceps and triceps muscles; and finally the teres major and minor muscles are divided, the subscapular artery is tied, and the bone is removed. The wound is stitched, a drain is introduced, and antiseptic dressings are applied. The patient lies upon his back until healing is well under way, when the arm is placed in a sling. The drainage-tube may be removed in twenty-four hours. Langenbeck, of Berlin, in 1855 performed the first complete excision of the scapula.

Excision or Resection of a Rib (Fig. 658).—In *caries* the gouge and rongeur may remove the disease. In other cases excision is performed. In this operation the patient lies upon his sound side unless the operation is performed for empyema, in which case he lies on his back or only partly on the sound side. (See Empyema, Operation for.) The surgeon faces the patient. Make an incision down to the bone, in the long axis of the rib. The periosteum, if not diseased, is lifted from the bone, and the intercostal artery is lifted out of the way with the periosteum and is thus saved from being cut. After dividing the bone beyond the limits of disease, remove it. During the sawing a metal retractor is held beneath the rib, between the rib and the periosteum. It is better to saw it than to cut it with ordinary biting forceps, because the latter splinters the bone. The author usually uses a forceps known as a *costotome*, which cuts the rib without splintering. If the periosteum is diseased, remove it after tying the intercostal artery. It should be removed in a case of empyema, otherwise bone-formation may interfere with drainage. In *empyema*, after removing the periosteum, open into the pleural cavity, allow pus to flow out slowly, remove

[1] "Manual of Operative Surgery."

fibrinous masses, employ a finger to feel if there are adhesions and if the lung will probably expand, and insert a drainage-tube. In resection for rib disease curet sinuses and pack with iodoform gauze for some days. Sew up the wound except at one end. Dress antiseptically and apply a binder. (See Operations Upon the Chest and Estlander's Operation.)

In *removing a cervical rib* make an incision along the posterior edge of the sternocleidomastoid, avoid the pleura, subclavian vessels, and brachial plexus, and remove the periosteum with the rib in order that the bone will not be reproduced.

Complete Excision of One-half of the Upper Jaw.—The whole upper jaw has been removed, but in what follows only resection of one-half the jaw will be described. This operation is performed for malignant tumors of the superior maxillary bone or its antrum. Up to 1826, at which time Lizars, of Edinburgh, suggested the operation, tumors of the antrum were treated by scraping them away with a sharp spoon. Gensoul, of Lyons, in 1827 performed the first operation for resection of the upper jaw. Heyfelder, in 1844, removed both superior maxillary bones. Excision of a superior maxillary bone is not justifiable except as a palliative measure, if the orbit is invaded, if the skin and subcutaneous tissues are infiltrated, or if the disease extends widely beyond the superior maxillary and palate bones. The mortality is about 15 per cent. Half the sarcoma cases which recover from operation will show no return in a year. One-third of the recoveries show no return in 3 years. Carcinoma almost invariably returns and quickly.

Some surgeons ligate the external carotid artery or compress it temporarily. In a number of excisions of the upper jaw I have always found the hemorrhage readily controllable as soon as the bone is removed, and have never felt it necessary to resort to preliminary ligation or compression.

Operation by Median Incision.—The patient, whose face has been shaved, is placed in the Trendelenburg position, thus avoiding the possible need of instant tracheotomy; or, what is even better, he lies horizontal or with the head a little raised and takes ether by intratracheal insufflation (see page 1340). The surgeon stands to the right side of, and faces, the patient. The incisor tooth on the diseased side is pulled out. The incision, which is really Weber's incision (called by some Nélaton's, by some Fergusson's, by some Liston's), is begun ½ inch below the inner canthus of the eye, and is carried along the side of the nose, around the ala of the nose, by the margin of the nostril, and through the middle of the lip. While the lip is being incised the assistant arrests hemorrhage by grasping the corners of the mouth, and after the lip has been divided the coronary arteries are at once ligated. Some operators approach the mucous membrane cautiously and ligate the vessels before opening the cavity of the mouth. The upper portion of the wound having been compressed by another assistant during these manipulations, pressure is now removed and bleeding points are ligated. Another incision is now carried outward from the beginning of the first incision, along the orbital margin to well over the malar bone (Fig. 502). The flap is lifted from the periosteum, and the bleeding from the infra-orbital artery and the small vessels is restrained by pressure. The nasal cartilage is separated from the bone, and the nasal process of the superior maxillary is sawn (line A–B, Fig. 503). The orbital periosteum is lifted up, and the orbital plate is cut by forceps from the saw-cut in the superior maxillary bone to the sphenomaxillary fissure (line B–C, Fig. 503). The malar bone is sawn or is bitten through about its center, the cut running into the sphenomaxillary fissure and taking a downward and outward direction (line C–D, Fig. 503). The soft parts covering the hard palate are incised in the median line, a corresponding incision is made along the floor of the nose near the septum, and the soft palate is separated from

the hard palate by a transverse cut. The saw is introduced through the nose, and the palate is sawn (line E, Fig. 503). The upper jaw-bone is grasped by Fergusson's lion-jaw forceps and removed, the removal being aided by the use of the scissors and bone-cutters; the latter are used to separate the upper jaw from the pterygoid process (Treves). Every vessel that can be seen is tied, and severe bleeding from bone is arrested by antiseptic wax. Oozing is controlled by hot water and pressure or by Paquelin's cautery. Examine carefully to see if all the diseased area is removed; if it is not, use the gouge, scissors, chisel, and saw until healthy tissue is reached. The wound is packed with iodoform gauze, and the end of the strip is so placed as to be accessible through the mouth. The wound is sutured (the mucous membrane of the lip must be stitched, as well as the skin) and is dressed antiseptically (the eye being protected by aseptic gauze), and a crossed bandage of the angle of the jaw is applied. After this operation it is common to have the eye sink to a lower level (causing double vision), to have persistent swelling of the lower lid, and to have tears flow over the lid instead of down the duct. This may be prevented in some cases by making a hammock for the orbital contents from a flap of the temporal muscle.

Excision of One-half of the Lower Jaw.—In some rare instances the entire inferior maxillary bone is removed. The lesions necessitating removal of the

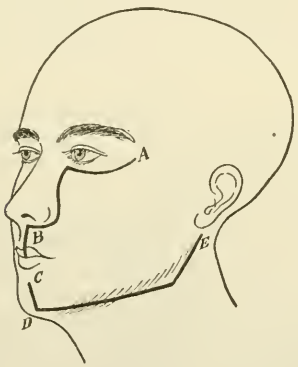

FIG. 502.—*A–B*, Incision of the soft parts preliminary to excision of the upper jaw; *C–D–E*, incision of soft parts preliminary to excision of the lower jaw.

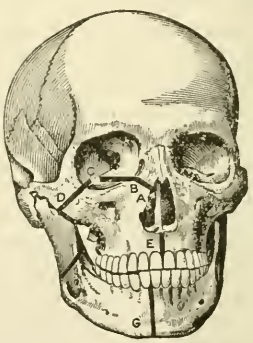

FIG. 503.—1, Excision of the upper jaw: A–B, Section of the nasal process; B–C, section of the orbital plate; D, section of the malar bone and orbital plate; E, section of the alveolus and hard palate. 2, Excision of the lower jaw: G, Section of the inferior maxillary; H, section of the ramus in partial resection.

lower jaw are of the same nature as cause us to remove the upper jaw. The names of many surgeons are connected with this operation, viz., Deadrick, White, Dupuytren, Sir Astley Cooper, and Valentine Mott.

In this operation the patient is placed in the same position as for excision of the upper jaw, the chin having been previously shaved. A vertical cut is made through the chin-tissue, starting below the margin of the lip and reaching to below the border of the jaw (C–D, Fig. 502). From the point D an incision is carried outward below the border of the jaw and then back of the ramus, as shown in the line D–E (Fig. 502). Treves's advice is to carry this incision down to the bone, except at the line of the facial artery, at which point it must go through the skin only. The facial artery is now to be sought for, tied in two places, and divided. Except in malignant cases the periosteum is lifted from the external surface of the bone, from the symphysis outward. Hemorrhage is arrested. The buccal mucous membrane is cut from the alveolus. A lateral incisor tooth is pulled, and the bone is sawn in the line G (Fig. 503). The bone is grasped in a lion-jaw forceps and is drawn outward. The mylohyoid insertion is cut; the internal pterygoid muscle is cut and the periosteum at this spot is

lifted; the inferior dental artery is cut and tied; the jaw is pulled down; the insertion of the temporal muscle upon the coronoid process is cut away, and the external pterygoid muscle is divided. The capsule of the joint is opened, and the bone is separated from the ligaments which still hold it in place. Bleeding is arrested, the wound is sutured, a tube is introduced in the posterior portion of the wound and retained for twenty-four hours, and antiseptic dressings and a Gibson or a Barton bandage are applied. Partial excisions of the alveolus may be performed through the mouth by means of chisels and rongeur forceps, and Wyeth has thus removed half of the jaw; but if any considerable part of the body of the jaw is to be removed, it is usually best to make an incision below the inferior maxillary.

Partial Excision.—This operation is frequently made necessary by epithelioma involving the periosteum or bone. After this operation, unless means are taken to prevent deformity, there will be asymmetry of the two portions of jaw bone remaining and malrelation of the teeth. Various attempts have been made to fill up this gap at the time of operation by some material, or to hold the two portions of the mandible in symmetrical relation by the insertion of trusses of silver wire, or by fastening each piece of bone to a metal plate.

John B. Murphy suggested the use of a bridge of silver wire. All of my trials with such a bridge failed. It always ulcerated out and usually through the skin, but did some good by keeping the bone ends further apart than they otherwise would have been.

Stanley Stillman ("Annals of Surgery," July, 1912) advocates bone-grafting as the only proper method, in order to prevent contraction during healing after the removal of the jaw bone. "When the teeth on the sound side are numerous and firm enough to stand the strain, they may be prepared beforehand with the aid of a dentist, so that a few days after the operation they may be clamped firmly to those of the upper jaw" (Ibid.). When the wound heals, Stillman separates the flap, freshens the bone-ends, and wedges a section of rib between them. The clamps are left in place until the bones unite, which requires six to eight weeks. In cases in which the teeth cannot be used to clamp, a silver bridge is inserted, which is left in place until the parts are ready for the insertion of the bone.

Barker's Operation for Dislocation of the Semilunar Cartilages of the Knee-joint.[1]—Begin the incision over the ligament of the patella, ½ inch above the articular surface of the tibia, and carry it in a curve downward and outward to the anterior edge of the internal ligament. The periosteum should be divided by the cut. This incision forms a flap the lower edge of which is ½ inch below the border of the articular surface of the tibia. The flap is lifted until the cartilage is seen "under the attachment of the meniscus, which if partially attached will rise with the flap until its under surface is seen." If partially torn anteriorly it is stitched to periosteum by a few silk sutures. The periosteum is then stitched in place, no drain is used, the joint is immobilized, and for one week ice is kept upon the part. If the meniscus is found completely separated and curled up, it may, if the injury was recent, be reduced. If the injury was old and if the cartilage is shrunken, it should be completely cut away (Barker). Personally I would omit the application of ice.

Operation for Congenital Dislocation of Hip.—*Lorenz's Bloodless Method of Reduction.*—The method of reducing by manipulation a congenital dislocation of the hip was advised by Paci and modified and improved by Lorenz. It has long been known that reduction is easy at birth because an acetabulum, though probably a shallow one, exists, and the head of the bone is not firmly held in its new situation. In an older child the problem is far more difficult, because, even if reduction is effected, the acetabulum may be extremely shallow or absent, and redislocation may readily occur. Lorenz aims to effect thorough

[1] "Lancet," Jan. 4, 1902.

reduction and then fixes the limb in abduction for months, so that the acetabulum will deepen and the bone will become firm in its proper socket. This operation is rarely successful in children over six years of age. The child is anesthetized and an attempt is made to draw the femoral head on to a line with the acetabulum. If the child has never walked, this is readily accomplished. If it has walked, the procedure may be very difficult, and it may be necessary to make extension by a fillet fastened above the knee, and counterextension by a screw and a perineal band. The drawing down of the head is made easier by stretching and massaging the adductor muscles. The next step is to flex the thigh, strongly rotate it a trifle internally, and then abduct it while flexion is maintained. This causes the head of the femur to pass around the posterior margin of the acetabulum and frequently produces reduction. "Full abduction being kept up, the thigh is rotated out, thus forcing the head of the femur more firmly into the socket." (See the description of the Lorenz method in J. Jackson Clark's "Orthopedic Surgery.") The strongly abducted limb is put up in plaster of Paris. In about three months the plaster is removed, the abduction is diminished, the plaster is reapplied, and is retained for another three months. During the continuance of immobilization of the hip the child walks about, with the knees bent. When the plaster is finally removed, manipulation, massage, and exercise strengthen the muscles and give freedom to the joint. In a double dislocation one joint may be cured before the other is operated upon, or both may be operated upon at the same séance. In double dislocation plaster must be worn more than six months. The Lorenz operation is safe when applied to very young children, but has elements of danger which increase with the years of the subject. A patient may suffer grave lacerations of muscles and ligaments, and even vessels and nerves. Death may result from shock, and extensive deep-seated hemorrhage may occur. In fact, it is a mistake to call it a bloodless method. The blood flows, though we do not see it. An untrained man may do fearful mischief by this operation, and it should only be attempted by an experienced, skilful manipulator and upon properly selected cases, when it is a very successful procedure. I am satisfied that, except in the case of a very young child, in whom reduction is easy, one who performs the Lorenz operation should be something more than skilful and experienced. He should be physically strong, so that traction and abduction will be powerful and steady. A weak man will jerk, will throw his weight upon the part, and will be apt to tear structures instead of stretching them. Sudden forcible movements are apt to break the bone.

Fig. 504.—Lorenz method. Unilateral congenital dislocation of hip (reduced). Cast applied with leg in "frog position."

Hoffa's Cutting Operation.—Make the external incision of Langenbeck to open the joint (see page 792). The capsule is incised at its insertion into the neck, and the periosteum and muscles are lifted from the great trochanter. Hoffa claims that in children less than five years of age the head of the bone can be readily replaced into the acetabulum by flexing the thigh and making direct pressure upon the head of the bone. After replacing the femoral head it is held in place while an assistant extends the leg in order to stretch the muscles. In children over five years of age cut with a tenotome the muscles

which spring from the ischial tuberosity and also the adductors; cut the fascia lata and muscles which arise from the anterior superior iliac spine by incision; open the joint and liberate the head of the bone; remove the ligamentum teres; scrape out the acetabulum, removing "cartilage, fat, and considerable spongy tissue" (Tubby); and replace the head of the bone in the acetabulum. The limb is maintained in inversion, abduction, and extension for several weeks, when it is straightened. Massage and passive motion are begun in the fifth week. The patient now gets about, wearing for many weeks an apparatus which permits the head of the bone to move in the socket, but prevents redislocation.

Lorenz's Cutting Operation.—This is a modification of Hoffa's. The muscles inserted into the greater and the lesser trochanter are not cut; the sartorius, the hamstrings, and the external portion of the fascia lata are cut (Tubby).

The incision of Lorenz is longitudinally from the anterior superior spine. Another incision is carried inward from this at the level of the lesser trochanter. The capsule is opened by a crucial cut; the acetabulum is enlarged; the head of the bone, if it remains, is inserted into the acetabulum; if there is no true head, a new one is formed and inserted into the cavity. The limb is immobilized in a position of moderate abduction. Massage and passive motion are begun in the fifth week, and are continued for months.[1]

Reduction by Means of Mechanical Appliances.—As the chief factor in the reduction of a congenital dislocation is thorough stretching of the muscles and ligaments before attempting replacement, numerous forms of levers have been devised to accomplish this. The best-known one is that of Bartlett, of Boston. It consists of a pelvic rest with perineal support, rods to fix the pelvis and traction rods to make extension. Great care is necessary in the use of all such appliances because of the danger of injury to vessels and nerves or of fracturing bony parts. After the parts have been thoroughly stretched replacement is accomplished by manipulation, as in the usual methods of manual reposition.

XXI. DISEASES AND INJURIES OF MUSCLES, TENDONS, AND BURSÆ

Myalgia, or **muscular rheumatism,** is a painful disorder of the voluntary muscles and of the fibrous and periosteal areas where they are attached. The term "muscular rheumatism" is not strictly correct. It is possible that in some cases the muscular structure is inflamed, but it is certain that in many cases the pain is distinctly neuralgic. Muscular rheumatism may be due to cold and wet, to overexertion and strain, to acute infectious disorders, to syphilis, to chronic intoxications (lead, mercury, and alcohol), and to disturbances of the circulation. Gouty and rheumatic persons are especially predisposed, men being more liable to the disease than women. The disease is usually acute, but it may be chronic.

Symptoms.—Muscular rheumatism is apt to come on suddenly. The pain, which may be very acute and lancinating or dull and aching, is in some cases constantly present; in other cases it is awakened by muscular contraction only, and it is frequently relieved by pressure, though there is often some soreness. The skin above the muscle is sometimes tender to light pressure. The disease usually lasts for a few days, but it tends to recur. There is little, if any, fever.

Lumbago is myalgia of the muscles of the loins. *Rheumatic torticollis* is myalgia of the muscles of the neck. Usually one side of the neck is attacked.

[1] I have drawn upon the very lucid description of these operations in A. H. Tubby's treatise upon "Deformities."

The chin is turned from the affected side and the neck is stiff. *Pleurodynia* is myalgia of the intercostal muscles. The pain is very severe, is aggravated by deep respiration, by coughing, and by yawning, there may be tenderness, and the patient tries to limit chest-movement. In *intercostal neuralgia* the pain is limited, is not constant, but occurs in distinct paroxysms, and is linked with the presence of the tender spots of Valleix. Pleurodynia lacks the physical signs of pleurisy. *Cephalodynia* is myalgia of the muscles of the scalp. The muscles of the shoulder, upper dorsal region, abdomen, and extremities may also be attacked by myalgia. Myalgia must not be confused with the pains of locomotor ataxia.

Treatment.—Remove any obvious cause. Treat any existing diathesis, such as gout or rheumatism. Rest is of the first importance. For lumbago, put the person to bed. For pleurodynia, strap the side of the chest. A hypodermatic injection of morphin and atropin into the affected muscles at once allays the pain, and a deep injection of distilled water is sometimes curative. Relief may be afforded by painting the surface with 30 drops of a mixture of equal parts of guaiacol and glycerin and covering the painted area with cotton. The introduction of four or five aseptic needles into the muscles, and their retention for a few minutes, sometimes acts most favorably. Ironing the skin above the painful muscles with a very warm iron, a piece of flannel being interposed, is a useful domestic remedy. Vigorous rubbing of the area with a piece of ice allays the pain. Hot poultices do good. If the pain is widely diffused, alters its seat, or is very obstinate, order hot baths or Turkish baths and administer diuretics. In chronic cases employ blisters or counterirritation by the cautery, give iodid of potassium and nux vomica, and have the patient take a Turkish bath every week. The constant electric current finds advocates. In an ordinary severe case order a hot bath, put the patient to bed with a hot-water bag over the part, and administer 10 gr. of Dover's powder; the next morning order to be taken four times daily a capsule containing 5 gr. of salol and 3 gr. of phenacetin, until the pain disappears. Citrate of potassium, citrate of lithium, chlorid of ammonium, or the salicylate of colchicin may be ordered instead of salol and phenacetin.

Infective myositis is a widespread inflammation of the voluntary muscles, due to an unknown infective cause. It is a disorder accompanied by pain and stiffness, by cutaneous edema, and by various paresthesiæ. Myositis resembles trichinosis, and can be distinguished from it only by spearing out a bit of muscle and examining it microscopically. Occasionally diffuse suppuration occurs.

Ordinary myositis arises from injuries, from syphilis, or from rheumatism, and it presents the usual inflammatory symptoms. Contraction and adhesions may follow. I operated upon a case of myositis of the rectus abdominis in a boy of eight. There was a large mass like a full bladder. There had not been an attack of typhoid and there was not hereditary syphilis. Caseation existed. The condition was possibly tuberculous, although no bacilli were found.

Treatment of Myositis.—Infective myositis is treated by anodynes, stimulants, nutritious food, hot applications, and rest. If pus forms, it should be evacuated. Rheumatic myositis calls for the administration of the salicylates, the alkalis, or salol. Syphilitic myositis is treated with mercury and iodid of potassium. The remedies employed for myalgia are used in traumatic myositis.

Hypertrophy of the muscles may arise from their increased use. In *pseudohypertrophic paralysis* the muscle is greatly augmented in bulk, but it contains less muscle-structure and more fat or connective tissue.

Atrophy of the muscles arises from want of use, from injury, from continuous pressure, from interference with the blood-supply, from disease of the nerves or their centers, or from lead-poisoning.

Degeneration of Muscles.—The muscles may undergo granular degeneration, waxy degeneration, fatty degeneration and calcareous degeneration, and may become pigmented.

Local Ossification and Myositis Ossificans.—It is not unusual for a small portion of bone to form in the periosteal insertion of a muscle which is subjected to frequent strain. In persons who ride many hours a day there not infrequently develops the *riders' bone*, which is an area of ossification in the adductor muscles of the thigh.

Myositis ossificans traumatica is a circumscribed ossification of muscle due to a single severe closed injury. It does not follow open injuries (O. M. Shere, in "Jour. Am. Med. Assoc.," 1915, lxv). The usual cause is a contusion and laceration of muscle by a dislocated bone or a rupture of muscle may be followed by the ossifying process. The bone formed is cancellous. The nature of

Fig. 505.—Myositis ossificans progressiva.

Fig. 506.—Myositis ossificans progressiva.

the process is uncertain. Some observers believe the process is inflammatory, a real myositis. Many believe that the osteoblasts come from the periosteum or that a bit of periosteum was pulled off by the muscle. Oliver ("Jour. Am Med. Assoc.," 1914, lxiii) says the process is not a myositis but is a metaplasia of connective tissue or a periosteal growth. The treatment is early excision. This treatment is particularly important when we remember that the condition may be mistaken for, and perhaps may sometimes be, sarcoma.

I operated upon a traumatic case by removing an ossified area in the thigh muscles. The laboratory report was myositis ossificans. Growth quickly recurred after operation, but the new growth showed very little ossification. The laboratory report was spindle-celled sarcoma. This case and also another one reacted to Coley's fluid. It seems possible that local myositis ossificans may, in some cases at least, be a sarcoma in which rapid ossification occurs.

Myositis ossificans progressiva is a widespread ossification of the muscles arising during the first ten years of life and much more common in males than in females. The cause of this rare condition is unknown. It is probably due to congenitally defective organization. The thumbs and great toes are commonly short (microdactylia). This is due to imperfect development of the proximal phalanges or of the metacarpal and metatarsal bones. There may be osteomata

of the skull, scapula and other bones. The disease usually begins about the back, shoulders and neck. There are stiffness, local cyanosis and a feeling of doughiness. The areas later become hard. Most of the muscles may suffer (the tongue, heart, diaphragm, muscles of deglutition, and the sphincters are never attacked). Involvement of the masseters locks the jaws. The *x*-rays show the bone. Death takes place usually before the twentieth year, in most cases from bronchopneumonia. No treatment is of even the slightest avail.

Tumors of the Muscles.—Primary tumors of the muscles are rare. Among those which may occur are sarcoma, fibroma, lipoma, osteoma, angioma, myxoma, and enchondroma. Most cases of supposed primary sarcoma of muscle are, in reality, cases of syphiloma (Esmarch).

Syphilis may cause inflammation. Gummata may form, or gummatous infiltration may take place.

Fig. 507.—Trichinosis of right leg.

Trichinosis or **trichiniasis** is a disease due to the embryos of the Trichina or Trichinella spiralis. Sir James Paget recognized the nature of the previously known encysted or larval form. It was long believed that the Trichina spiralis was a harmless parasite, but in 1860 Zenker, of Dresden, proved that it might be responsible for dangerous epidemics. The trichina is normally a parasite of the rat. Man is infected by eating flesh which contains trichinæ and has been insufficiently cooked. The flesh of the pig is the medium of infecting man. The pig becomes infected by eating rats suffering from the disease or offal and slaughter-house refuse containing trichinallized flesh. Dr. Joseph Leidy discovered the trichina in pork. People are most commonly affected by eating raw sausage, smoked sausage, or underdone pork. Imperfectly boiled ham may be responsible. Albert reported 14 cases from eating boiled ham. W. Gilman Thompson found records of 52 sporadic cases occurring in New York City during six years ("Amer. Jour. Med. Sciences," August, 1910). These nematodes are carried into the intestine, there to develop and multiply. In from seven to nine days a horde of embryos develop in the bowel, and leave the alimentary canal by passing through the peritoneum or by means of the blood, and finally reach the connective tissue of the muscles. From the connective tissue the embryos migrate into the primitive muscle-fibers, where they dwell and enlarge. Myositis develops, and in the course of five or six weeks the parasites become encapsulated and develop no further. The cyst-walls may calcify and the worms may become calcified, or may live for years. The eating of infected meat is not inevitably followed by the disease, and a few embryos lodged in muscle may cause no symptoms.

The **symptoms** of trichinosis often appear in a day or two after eating infected meat. The symptoms of acute gastro-intestinal catarrh or of cholera morbus are common, but in some cases no gastro-intestinal manifestations usher in the disease. In from seven to fourteen days after the infected meat is eaten the migration of the parasites develops obvious symptoms. A chill may be

noted; there is usually fever; muscular pain, tenderness, swelling, and stiffness are complained of. This condition may be widespread. Involvement of the muscles of mastication interferes with chewing; of the larynx, with talking and respiration; of the intercostals and diaphragm, with respiration. Skin-edema and itching are marked. In some cases delirium exists. The writer saw in the Philadelphia Hospital one fatal case which was mistaken for erysipelas because of the high fever, the delirium, and the edematous redness of the face and neck. Dyspnea is frequent. Mild cases get well in a week or two; severe cases may last many weeks. The mortality varies in different epidemics from 1 to 30 per cent. (Osler). The diagnosis is made by spearing out a piece of muscle, which is then examined for trichinæ under a microscope; or the worms may perhaps be detected in the feces by means of a pocket-lens. In a case under the care of the author, in St. Joseph's Hospital, there was no record of any attack of gastro-intestinal disturbance and the first manifestation was enlargement of the calf of the left leg. In most cases of trichinosis there is eosinophilia, but in the author's case, previously referred to, eosinophilia was not present.

Treatment.—To treat trichinosis employ purgatives (senna and calomel) early in the case, and give glycerin, and also santonin or filix mas. When muscular invasion has taken place, sedatives, hypnotics, nourishing diet, and stimulants are indicated.

Ischemic Myositis, or Volkmann's Contracture (*Volkmann's Paralysis; Ischemic Paralysis; Ischemic Muscular Atrophy, with Contractures and Paralysis*, Fergusson calls it).—It is occasionally noticed, particularly in children, after prolonged fixation of the forearm, especially after prolonged fixation of the elbow-joint by some appliance that impedes the freedom of circulation in the part. Contractures of the fingers occur and perhaps rigidity and flexion of the wrist. In 1875 Volkmann described severe contractures of the hand observed in some cases as a result of the use of tight bandages to hold splints in place in treating fractures of the arm. He believed that the condition was due to deprivation of arterial blood, that the muscles perished for want of oxygen, and that rigor mortis occurred. He pointed out that paralysis and contracture occur simultaneously, whereas in primary nerve lesion paralysis precedes contracture. The condition may come on after the application of an Esmarch band, after a severe injury in the neighborhood of the elbow-joint, may follow ligation of the main artery of a limb, venous embolism, venous thrombosis from injury or infectious disease, Raynaud's disease, or exposure to cold. One of Sir Robert Jones's cases followed a rapidly developing traumatic myositis ossificans; two followed crushes; in one an elastic tourniquet had been kept on a child's arm to prevent bleeding after an operation for webbed fingers; in one pad pressure had been maintained for twenty-four hours to check bleeding ("Amer. Jour. Orthop. Surg.," April, 1908). A case of mine resulted from embolism of the brachial artery. There are two forms, one due to almost complete arterial ischemia, lasting for several hours at least; another due to interference with venous return. Volkmann's contracture is due to muscular degeneration, infiltration, induration, and contraction, the result of marked and prolonged arterial ischemia, or interrupted venous return, and it is frequently spoken of as ischemic myositis (Dudgeon, "Lancet," Jan. 11, 1902). In some cases distinct neuritis with paralysis also exists. One characteristic of ischemic contracture is the rapidity with which it comes on. Dudgeon points out that in half a day, or even in less time in some cases, the symptoms appear, these symptoms being paralysis of the part with contracture. Pain is unusual, unless the nerves are seriously involved and then it is violent. In some cases the fingers and hand swell and become discolored. The absence of pain frequently prevents the recognition of the condition; therefore, the causative splint or bandage pressure may be maintained for days after the trouble has become serious. When the

splints and bandages are removed and the forearm is examined, there is almost always tenderness over the muscles and the nerve-trunks; and in the majority of cases in which a splint has been the cause a portion of the skin will have sloughed. Dudgeon points out the characteristic position of the deformity as follows: When the wrist is extended, the metacarpophalangeal joints are also extended; but the interphalangeal joints of the fingers and the terminal joint of the thumb are so strongly bent that the tips of the fingers touch the palm, and this position cannot be corrected by any justifiable amount of force. As soon as the wrist-joint is bent to a right angle, the interphalangeal joints can readily be extended. In a very severe case the wrist itself will become markedly flexed, and it will be impossible to extend it. The forearm is usually semiflexed and the hand pronated. The ulceration or sloughing so frequently present causes a *splint-sore*. There is always marked induration about a splint-sore. The flexor muscles themselves are indurated and usually wasted. The condition of sensation depends upon the state of the nerves of the part. When neuritis is absent, sensation will be normal; but in accordance with the amount of neuritis and degeneration there will be hyperesthesia, partial anesthesia, or complete anesthesia. A curious feature of these cases that is dwelt upon by Dudgeon and commented upon by Turner is the fact that in young children there is a cessation of growth of the bone. Sir Robert Jones (loc. cit.) reports that 19 cases out of 40 were associated with fracture. In 13 of the 19 cases there was pronounced malunion.

Fig. 508.—Rugh's splint for Volkmann's contracture. Splint applied. Looking at the palmar surface.

Treatment.—The old view of this condition was that it was practically hopeless. Anderson and Dudgeon, however, maintain that restoration may usually be obtained, the treatment consisting in regular, active motion, passive movement, massage, and electricity. Forcible extension under ether is of no benefit whatever.

Jones's plan of treatment is very beneficial ("Amer. Jour. Orthop. Surg.," April, 1908).

Operative procedures on arms that necessarily have deficient circulation are hazardous, and Jones has discontinued all operative correction and relies upon purely mechanical and manipulative routine, as follows:

Five splints are cut out of zinc, tin, or sheet wire, to fit each finger and the thumb. The wrist is forcibly flexed and held while each finger is separately splinted. It will be observed that in the fully flexed position of the wrist the fingers are all relaxed.

When the finger splints have been applied the wrist is released, and the patient is directed to systematically extend the metacarpophalangeal joints. In a few days the second splinting may usually be employed by embedding the entire hand to the wrist and the already splinted fingers in plaster of Paris, while the

wrist is again flexed. Several days are devoted to systematic voluntary efforts at extension of the hand in a similar manner employed for the metacarpophalangeal joints.

The third splinting embraces that already employed and in addition embraces the wrist in the fullest extension possible, which in a few days may be increased until full extension is obtained. The latter position of full extension of wrist, hand, and fingers is maintained for some weeks until all contractible elasticity has disappeared.

It is usually observed that when the hand can be held in hyperextension without tendency to relapse, the circulation will almost invariably improve and the fingers resume their normal function and appearance except in cases of nerve destruction. Jones has found that in many cases in which the nerves had lost their function during contracture, the extension of the hand was the starting-point of recovery.

In making any splint pressure to straighten the fingers the greatest care must be exercised. The skin of the dorsum of the fingers will not endure prolonged pressure. I have used Rugh's splint with much satisfaction (Figs.

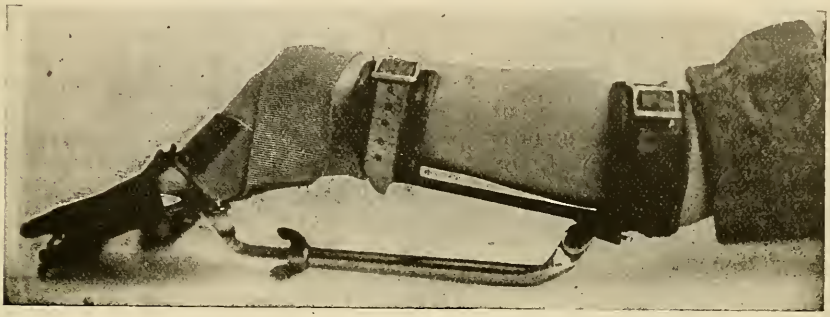

Fig. 509.—Lateral view of splint shown in Fig. 508.

508, 509). It is best in the beginning to apply the splint for five or ten minutes twice a day. The time of each séance is gradually increased as the tissues develop resistance. Frequent bathing with alcohol aids the skin to bear pressure.

R. H. Sayre ("Volkmann's Ischemic Paralysis and Contracture," "Amer. Jour. Orthop. Surg.," Nov., 1908, p. 221) advocates the Jones method in all cases, inasmuch as cutting operations may be employed later if the results of Jones's treatment are not entirely satisfactory. The improvement in the circulation and function obtained by Jones method will make the operative field more capable of rapid recovery.

In a persistent and long-continued case an operation may be necessary. The operation may consist in dividing in the forearm the flexor muscles of the fingers, as advised by Davies Colley, and then, at a later period, dividing the flexor tendons. The objection to his procedure is that it destroys permanently the capacity to flex the fingers. Another suggestion has been to excise a piece from both the radius and the ulna, and wire the fragments together. The best surgical treatment is probably exposing the nerves, separating them from adhesions, stretching them, and then doing tendon-lengthening, but this should not be done until all the improvement it is possible to secure by conservative treatment has been obtained. Conservative treatment should be tried for at least three months.

Wounds and Contusions of the Muscles.—*Wounds* of muscles may be either *open* or *subcutaneous*. In a longitudinal wound the edges lie close together, and hence drainage must be provided for by the surgeon. In a transverse

wound the edges separate widely, and catgut stitches must be inserted. *Contusions* of muscles, like contusions of other tissues, vary in extent and in severity. There are pain (which is increased by attempts to use the muscle), loss of function, swelling beneath the deep fascia, and discoloration, which may appear at once because of superficial damage from the initial injury, or which may appear in dependent parts after many days because of gravitation of blood and blood-stained serum. As a result of contusion, suppuration, inflammation, or atrophy may arise.

Treatment.—In a longitudinal wound, drain; in a transverse wound, suture the muscle. The further indications in wounds and contusions of muscles are to obtain rest by means of splints and to secure relaxation. Limitation of swelling is secured by bandaging. Inflammation is combated first by cold and lead-water and laudanum; later by iodin, blue ointment, ichthyol, and intermittent heat. To prevent loss of function employ, as soon as the acute symptoms subside, massage, passive motion, and stimulating liniments, and, later in the case, electricity (galvanism if the reactions of degeneration exist; faradism, if they are absent).

Strains.—A muscular strain is a stretching of a muscle with rupture of a few fibers. It is caused by traction in the long axis of the muscle. The muscle becomes swollen, tender, stiff, weak, and sore, and attempts at motion produce sharp pain. A strain of a tendon is a trivial or partial rupture. It leads to the development of acute thecitis, with fluid swelling and pseudocrepitation. Strains are common in the deltoid, the ham-string muscles, the back, the calf, the biceps, and the great pectoral. *Strain of the psoas muscle* causes pain on voluntary flexion of the thigh, and is associated with tenderness in the iliac fossa. Strain of the right psoas may be mistaken for appendicitis, but it lacks the intense local tenderness, the abdominal rigidity, and the constitutional symptoms. *Lawn-tennis arm* is a strain of the pronator radii teres muscle. *Riders' leg* is a strain of the adductor muscles of the thigh. A strain of the long head of the biceps flexor cubiti produces the condition called by ball players a *glass arm*. A strain may be the only injury, or may be associated with some other condition (fracture of bone, dislocation, sprain, contusion, etc.). A strain may be followed by periostitis at the point of insertion of the muscle. Atrophy of the muscle occasionally follows a strain.

A strained muscle is usually rigid, is tender, and pains greatly when an attempt is made to use it. The skin over it, especially over its point of insertion, is usually tender.

A *strain of the back* is a very common accident, which is often associated with sprains of the vertebral articulations. There is great pain when the patient voluntarily straightens up. If the vertebral ligaments are not damaged, the patient can be straightened by passive motion without pain. The skin is tender in certain areas. The muscles are often rigid. There may be unilateral rigidity. In a back injury make a careful examination to be sure no damage has been inflicted upon the vertebræ or cord.

Treatment.—Relaxation by suitable position; rest by the use of splints or by putting the patient to bed; bandages for compression; hot fomentations or a hot-water bag, and ichthyol. As soon as acute symptoms subside, employ friction and massage. Strapping with adhesive plaster is of service in strain of the back and of the calf. If there is severe pain after a strain, administer Dover's powder, or even morphin.

Rupture of Muscles and Tendons.—**Rupture of a muscle** is announced by a sudden and violent pain and by loss of function, arising during powerful muscular contraction or strong traction in the long axis of a muscle. The rupture may be announced by a clearly audible snap (A. Pearce Gould). A distinct gap is felt between the retracted ends of the torn muscle; great pain develops on movement; there are tenderness, loss of power, and swelling.

Rupture may be followed by atrophy, so may a contusion. Among the muscles which occasionally rupture we may mention the quadriceps, biceps, triceps, deltoid, plantaris, etc.

Rupture of the biceps flexor cubiti or its tendon is not very common; 72 cases have been collected by W. W. Keen, ("Annals of Surgery," May, 1905). Alexander collected 74 cases and added 8 ("Annals of Surgery," 1915, lxi). It is much more common in men than in women. Loos's table of 66 cases contains records of only 2 women (Doane, in "Jour. Amer. Med. Assoc.," May

Fig. 510.—Author's case of rupture of the long head of the biceps.

16, 1908). The rupture may be where the muscular belly passes into the lower tendon, through the muscular belly, in the muscular part passing either to the long or short head, or at the part where the muscular belly joins the long or short head. The tendon of the long head may be torn through or the long head may be torn from the glenoid cavity. The muscular portion is far more often injured than the tendinous. In rupture of the muscle belly a part of the muscle, in rupture of the long head the entire muscle, becomes soft and relaxed.

Fig. 511.—Author's case of rupture of the long head of the biceps.

In rupture of the belly there is a gap between the two portions and each portion causes a lump. In rupture of the tendon there are not two lumps with a gap between, but there will be a single muscular lump. In rupture of the long head the muscular belly is much nearer the elbow than in health (Figs. 510 and 511). If rupture takes place at the lower part of the belly, the muscle passes toward the shoulder. *Rupture of the long head of the biceps* allows the humerus to pass somewhat forward and upward.

Flexion with the forearm supinated is much less powerful than flexion with the forearm pronated (*Hüter's sign*).

In a case of my own in the Blockley Hospital the accident had occurred while carrying a heavy bucket. Forearm flexion was possible, but slow, feeble, partial, and incomplete. On flexion the short head contracted, but the muscular "bunch" of the belly was nearer the elbow than normally. *Rupture of the plantaris muscle (coup de fouet; lawn-tennis leg)* is an injury which is frequently not diagnosticated. It occurs during exercise (walking, bicycling, jumping, playing tennis) or is first complained of after exercise. It produces sudden pain in the middle of the calf, swelling, and often ecchymosis and inability to walk except with a rigid ankle and everted toes. *Rupture of the quadriceps extensor femoris tendon* results occasionally from force which in other cases fractures the patella. The rupture is just above the patella. The patient cannot extend the thigh and cannot walk or stand and there is severe pain. A gap can be felt just above the patella, unless it is hidden by synovial effusion, and the muscle is bunched above. *Rupture of the extensor longus pollicis tendon (drummer's paralysis)* may take place when the tendon has become necrotic from injury or weakened by repeated traumatism. Sometimes it occurs, apparently spontaneously, a number of weeks after the occurrence of Colles's fracture.

Treatment.—In limited rupture treat as a severe strain. In treating extensive rupture of an important muscle, when the ends are widely separated, expose by incision, unite the divided ends by sutures of chromicized catgut (Fig. 112), and sew up the skin with silkworm-gut. Treat the part in any case by rest and relaxation and combat inflammation by appropriate means. Passive motion and massage are employed as soon as union is firm. In rupture of the quadriceps extensor femoris, operation should be undertaken, because mechanical treatment frequently gives a bad result and confines the patient to bed for weeks. *Rupture of the biceps* requires incision and suture. In a case in the Blockley Hospital (Figs. 510, 511) I operated and found that the long head with a portion of periosteum had been torn from the glenoid cavity. A portion of the upper end of the tendon was cut away and the tendon was fastened to the short head by splitting and suture. Nine months later the result was perfect (Keen, in "Annals of Surgery," May, 1905). In Alexander's table of 82 cases only 10 were operated upon (Ibid.). *Rupture of the plantaris* is treated at first by rest on a posterior splint and compression and later by massage and the use of an elastic bandage. The patient is allowed to walk with the aid of a cane in one week, but he should not raise the heel for several weeks. Rupture of the quadriceps is treated by suturing. In rupture of the extensor longus pollicis tendon the torn ends may be freshened and sutured, or, as Heineke recommends, the peripheral end can be fastened to the extensor tendon of the index finger or to the tendon of the long extensor of the carpus.

Hernia of Muscles.—When a tear takes place in a muscular sheath, a portion of the muscle protrudes.

The **treatment** is incision, restoration or extirpation of the protruding mass of muscle, and suturing of any muscle wound and of the sheath.

Contractions of muscles may result from injury, from joint disease, from malposition of parts (as in old dislocation or torticollis), or from diseases of the nervous system.

The **treatment** in some cases is sudden extension, in other cases gradual extension, tenotomy, or myotomy. Macewen recommends the making of a number of V-shaped incisions in the muscle. In some cases of spasmodic contraction nerve-stretching is of value.

Dislocations of Muscles and Tendons.—The long head of the biceps is oftenest displaced. The flexor carpi ulnaris, the peroneus brevis, the peroneus longus, the tibialis posticus, the sartorius, the plantaris, the quadriceps extensor femoris, and the extensors back of the wrist may be dislocated. What is known as dislocation of the latissimus dorsi, a condition in which that muscle

no longer lies upon the angle of the scapula, is, in reality, paralysis of the serratus magnus (see page 843). Most of these accidents are associated with chronic disease or with fracture, but displacement may exist as a solitary injury. *Dislocation of the long head of the biceps* may occur tolerably early in the progress of rheumatoid arthritis of the shoulder-joint, and the displaced tendon may be absorbed.

Symptoms.—After dislocation of a tendon the muscle of the tendon can still contract, but it acts at a disadvantage; thus the corresponding joint exhibits partial loss of function. The displaced tendon can be felt, and a hollow exists where it normally resides.

When the muscle contracts, the tendon is felt to slip from its groove. When the tendon of the biceps is dislocated, the head of the bone passes forward (so-called *subluxation of the humerus*).

Treatment.—In tendon dislocation reduction is easy, but the displacement is apt to recur because of laceration of the sheath. The treatment usually advised is to effect reduction by relaxation of the limb and manipulation of the tendon, to place the part upon a splint so that the muscle belonging to the tendon will be relaxed, and to apply pressure over the point of injury. This treatment generally fails, and if the tendon does not become firmly anchored in its proper situation in four weeks we should operate. In some tendons it is enough to incise, freshen the edges of the torn sheath, and sew up with kangaroo-tendon or chromicized catgut. In a tendon lying in a long groove make a halter for the tendon by incising the periosteum and suturing it over the tendon.[1] Passive movements are begun at the end of the first week. Even if the tendon will not remain reduced, a useful joint will probably be obtained.

Wounds of Tendons.—Subcutaneous wounds of tendons are usually inflicted by the surgeon, and they heal well. Open wounds require rigid antisepsis and suturing of the tendon. In wounds of the wrist especially always suture the divided tendons (see Fig. 113), and be sure to bring the proper ends into apposition.

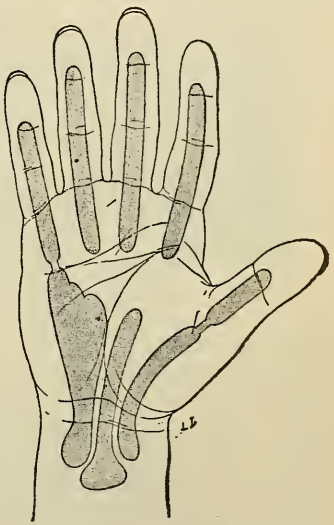

Fig. 512.—Palmar synovial sheaths (vaginæ tendinum), normal adult type (Poirier and Charpy).

Rupture of Tendons.—A violent muscular effort may rupture a tendon and as the accident occurs a snap may often be heard.

The **symptoms** are sudden pain and loss of power, fulness of the associated muscle from retraction, and absolute inability to bring the tendon into action. A gap may often be felt in the tendon (see page 809).

Treatment.—The best procedure in treating rupture of a tendon is exposure by incision and the introduction of sutures. Some surgeons relax the parts and apply splints (see page 808).

Thecitis, or **tenosynovitis,** is inflammation of the sheath of a tendon.

Acute thecitis may arise from a contusion, from a wound, from repeated overaction in working or while engaged in some sport, from rheumatism, from gonorrhea, from pyogenic infection, from influenza, from a continued fever, or from syphilis. In early syphilis certain tendon-sheaths may rapidly develop effusion because of hyperemia of the sheaths (Taylor).

Symptoms.—In *non-suppurative* cases of thecitis the symptoms are pain, swelling, tenderness, and moist crepitus along the tendon-sheath, due to

[1] Walsham's case of dislocation of the peroneus longus, "Brit. Med. Jour.," Nov. 2, 1895.

inflammatory roughening. The crepitus disappears as the swelling increases, but it reappears as the swelling diminishes. In *suppurative* cases (*phlegmon of the tendon-sheaths*) the symptoms are great swelling, pulsatile pain, dusky discoloration, inflammation spreading up the tendon-sheaths, and often the constitutional symptoms of sepsis.

Treatment.—In treating non-suppurative thecitis employ splints, use the hot-air oven, and apply locally iodin, blue ointment, or ichthyol, and administer suitable remedies to combat any causative constitutional disease. In the suppurative form inject 1 c.c. of formalin-glycerin (2 per cent.) after withdrawal of part or all of the exudate. If this fails, make free incisions, irrigate, drain, dress with hot antiseptic fomentations, and employ Bier's method (see page 122). (See Felon, page 814.)

Palmar Abscess.—We mean by this term an abscess beneath the palmar fascia and not a superficial collection of pus. Palmar abscess may arise after wounds, abrasions, burns, or inflammations of the skin of the palm. A thecal abscess in a flexor tendon of a finger travels rapidly upward and may produce a palmar abscess. A thecal abscess of either the index, ring, or middle finger is usually arrested at the lower end of the palm, but suppurative thecitis of the thumb or the little finger conducts pus along the tendon-sheath and up the arm (Fig. 512). If the theca ruptures, pus is diffused over the palm. Abscess

Fig. 513.—Tuberculous thecitis (compound ganglion).

produces great swelling of the hand and fingers, the dorsum being swollen as well as the palm. The fingers become flexed and rigid. Violent pulsatile pain and decided constitutional disturbance exist. Discoloration is late in appearing. Related lymph-glands enlarge. Palmar abscess is a most serious affection. The pus may dissect up all the structures of the palm, may pass between the bones and reach the dorsum, or may pass beneath the anterior annular ligament into the connective-tissue planes of the forearm. In some cases it leaves a clawed, stiff, and useless hand.

Treatment.—A palmar abscess demands radical treatment at the earliest possible moment; delay will be responsible for stiff and contracted fingers and hyperesthetic skin, a damaged and perhaps a useless hand. The patient should be placed under the influence of ether. The incision is made in the line of the metacarpal bone and, if possible, below the palmar arches. A line in the transverse axis of the palm and in line with the palmar surface of the fully extended thumb is distal to both the palmar arches. In an incision above this line try not to cut either arch; but if one should be cut, at once take means to arrest the hemorrhage (see page 512). In a severe case it may be necessary to make several palmar incisions, to open the tendon-sheaths on the flexor surface of the forearm above the wrist, and to make counter-openings in the back of the hand, and it is sometimes necessary to introduce tubes, and drain through and through the hand. After operation, if the patient will consent to enter the hospital use Dakin's fluid. If the patient refuses to enter the hospital apply hot antiseptic fomentations and put the part upon a splint. Bier's passive hyperemia is very useful. When granulations

begin to form, dry dressings are substituted for hot moist dressing. It may be necessary to give morphin for pain, and stimulants may be needed. There is great danger of stiffness of the fingers occurring, the tendons becoming adherent to their sheaths. Hence passive movements are inaugurated as soon as granulations begin to form.

Chronic thecitis may follow acute thecitis, but may be due to injury, to rheumatism, to gummatous infiltration, to rheumatoid arthritis, or to tuberculous inflammation of a tendon-sheath. Chronic thecitis is commonest in the tendons at the wrists, the ankles, and the knees; it may spread to a joint or it may arise from a tuberculous joint. This condition causes very little pain. In ordinary non-tuberculous thecitis the part is weak, tender, painful and stiff, crepitates on motion, and is swollen. In *tuberculous thecitis* there is at first distention of the tendon-sheath with serum. The serum contains *rice*, *riziform*, or *melon-seed* bodies, and the wall of the tendon-sheath is here and there thickened and caseating. Later in the case the interior of the tendon-sheath becomes lined with tuberculous granulations and a tuberculous abscess may form. Rice bodies are sometimes fibrinous masses, are sometimes pieces of separated and dead recently formed fibrous tissue, and are sometimes masses of proliferating cells. In tuberculous cases the swelling is firm or doughy when due to granulation tissue, but is fluctuating when due to fluid. Grating is marked. Tubercle bacilli are present in the fluid or in the granulation tissue. Tuberculous thecitis is most common about the wrist, constituting the so-called *compound ganglion* (Fig. 513).

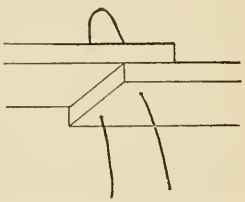

Fig. 514.—Method of suturing the annular ligament of the wrist.

Treatment.—*Tuberculous cases* are treated as follows: If there is a fluid effusion and no rice bodies, make a small incision, wash out with salt solu-

Fig. 515.—Ganglion of extensor tendon-sheaths of the wrist.

tion, introduce iodoform emulsion or formalin-glycerin, and close the wound. In cases in which there are rice bodies, open the sheath, evacuate the contents, scrape the walls thoroughly, inject iodoform emulsion or formalin-glycerin, and close the wound. (If the annular ligament requires division, stitch it before closing the wound—Fig. 514.) In cases with extensive thickening apply an Esmarch bandage, make a large incision, and remove all infected tissue from the sheath, around the sheath, and from the tendon. In tuberculous thecitis Bier's method (see page 122) may be of service and so may the *x*-rays. In *ordinary traumatic thecitis* use for the first few days rest associated with applications of ichthyol. Later employ hot and cold douches, mas-

sage and passive movements, strapping of the part, inunctions of ichthyol, and the hot-air bath. If effusion is persistent or rice bodies exist, make an incision and scrape the interior of the tendon-sheaths. In rheumatic cases give antirheumatic remedies and employ the hot-air bath. In syphilitic cases administer mercury and iodid of potassium.

Simple Ganglia.—In connection with tendon-sheaths and joints simple ganglia may develop. They are small, tense, round swellings, which are firm, grow progressively though slowly, are painless when uninflamed, and contain a fluid of the appearance and consistence of glycerin-jelly (Bowlby). Ganglia are commonest upon the dorsum of the wrist and they occur especially in those who constantly use the wrist muscles. Ganglia are occasionally seen on the dorsum of the foot. Paget states that a *simple* ganglion is due to cystic degeneration of a synovial fringe inside a tendon-sheath, and that the fluid of the ganglion does not communicate with the fluid of the tendon-sheath. Other pathologists have maintained that a simple ganglion is a hernia of synovial membrane through a rent in a tendon-sheath, all communication between the herniated part and the tendon-sheath being soon obliterated. The belief is now general that a ganglion is due to cystic degeneration of an area of connective tissue adjacent to a joint or a tendon, this area of tissue having been rendered extremely cellular by traumatism. A number of minute cysts form and they coalesce into one cyst. The cyst may form a secondary communication with the interior of a tendon-sheath or joint. Ganglia occasionally diminish in size or even disappear spontaneously.

Fig. 516.—Deep felon, with sloughing of soft parts and necrosis of bone.

Treatment.—A ganglion is treated by aseptic puncture by a tenotome, evacuation, scarification of the walls, antiseptic dressing, and pressure. An old-time method of treatment was subcutaneous rupture brought about by striking with a heavy book. Duplay treats a ganglion by injecting a few drops of iodin through a hypodermatic needle. The cyst is not evacuated before injection. The parts are dressed antiseptically, and cure is obtained in one week. Recurrent ganglia, very large ganglia, and ganglia with very thick contents should be dissected out.

Felon, or **whitlow,** is a violent, rapidly spreading pyogenic inflammation of a finger or a toe which resembles cellulitis, and which is sometimes followed by gangrene of the soft parts or by necrosis of bone (Fig. 516). An injury precedes the whitlow—an abrasion of the surface which admits pus-organisms or a contusion which creates a point of least resistance. The commonest seat of a felon is the last digit of a finger or the thumb. An abrasion of the surface at this point absorbs pus-organisms and the superficial lymphatics carry the bacteria directly inward, the micro-organisms lodging, it may be, in the skin, in the subcutaneous tissues, in the tendon-sheath, or beneath the periosteum. The perpendicular direction of the fibers of the subcutaneous tissue favors this passage inward.

Felons are very rare in infants, but may occur in children. Women are more

liable to them than men. The fingers are much more prone to infection than the toes, because they are more exposed to injury. Several fingers may be attacked at once or successively in persons of dilapidated constitution. Whitlow is most apt to occur and is most severe in persons broken down by disease, alcoholism, overwork, or worry. In certain cases of neuritis painless suppuration may arise. In syringomyelia *painless felons* are common, and they are apt to be associated with necrosis of bone. Painless and destructive whitlows constitute a characteristic part of *Morvan's disease*.

There are two forms of felons, the *superficial* and the *deep*.

Superficial Felons.—One form of superficial felon is between the cuticle and the true skin and is rarely followed by involvement of deeper parts. The infection is in the skin. The point of infection becomes dark red, swollen, painful, and tender. The epidermis is lifted up into a pustule by the seropus which forms, and a considerable area may be attacked before the spread of the process is arrested. The commonest form of superficial felon is subcutaneous suppuration, the pus collecting in the fibrofatty pad at the palmar surface of the last digit (G. B. Mower White, in "Brit. Med. Jour.," Feb. 24, 1906). This form often spreads deeply. If the subcutaneous tissues only are involved the symptoms are those of an ordinary cellulitis. There is severe pain, increased by motion, pressure, and a dependent position. Swelling and discoloration are early and marked. Pus forms within forty-eight hours. *Paronychia*, or *ring around*, is cellulitis starting at the end or side of the digit, and involving the parts around and below the nail. The pus-organisms obtain entrance by means of an abrasion, a puncture, or an ulcerated "step-mother." In paronychia pain is throbbing and violent; is increased by motion, pressure, or a dependent position; the skin is dusky red, but the swelling is slight. In about forty-eight hours pus forms in the superficial parts, the epidermis being lifted into pustules or blebs, and pus may also form under the nail. A portion of the nail or the entire nail may be lost.

If the tendon-sheath becomes involved as well as the subcutaneous tissue, the symptoms are those of suppurative thecitis, with more marked discoloration of the skin.

Deep Felons (Fig. 516).—There are two forms of deep felon. One is a thecal suppuration involving the flexor tendon-sheath, arising secondarily to subcutaneous suppuration and spreading widely. In suppurative thecitis of the three middle fingers the process seldom reaches the palm; in suppurative thecitis of the theca of the thumb or little finger the pus may pass above the wrist and a true palmar abscess may form (see Fig. 512). Another form is suppuration beneath the periosteum. This form is the so-called *bone felon*. It is occasionally primary, but more often arises secondarily to suppurative thecitis or to subcutaneous suppuration. In some cases a deep felon involves most of the structures of the finger (periosteum, bone, tendon, tendon-sheath, and cellular tissue), and may destroy the digit or the finger. The bacteria causative of a deep felon are lodged in the deeper parts. The pain is agonizing, entirely preventing sleep, pulsatile in character, associated with excruciating tenderness, greatly aggravated by motion or a dependent position, and often extending up the hand and forearm. The skin is dusky red and edematous, and the part is enormously swollen. Pus forms quickly; diffuse cellulitis may arise; sloughing of the tendon and subcutaneous tissue may take place; necrosis of one or more bones may ensue, and in some cases gangrene of the finger follows.

In deep whitlow lymphangitis of the forearm and arm is not unusual, adenitis of the axillary glands is common, and almost always there is fever. In superficial felon constitutional symptoms are slight or absent, and lymphangitis and adenitis arise in a minority of cases.

Treatment.—In a subcuticular felon, after cleansing, soften the parts well in an antiseptic fluid and then pare off the cuticle with a very sharp knife. This plan

of White's is an excellent one; it gives vent to pus and prevents the inoculation of the deeper tissues which may follow incision. In subcutaneous suppuration incise the abscess, but be careful not to open the tendon-sheath or periosteum, as this would diffuse infection (White, in "Brit. Med. Jour.," Feb. 24, 1906). In neither of the above instances is it necessary to give an anesthetic. After operating, the parts must be irrigated, dressed with hot antiseptic fomentations, the hand must be placed upon a splint, and Bier's passive hyperemia is to be induced daily. In a deep felon I am convinced that we should operate immediately. Allay tension and prevent pus formation by early incision. Do not waste time with poultices; to wait means agonizing pain, sleepless nights, constitutional involvement, and, perhaps, sloughing of tendons or death of bone. Incision and drainage constitute *the* treatment, but incision conducted in a particular manner. I have only lately learned how to treat a deep felon. I formerly treated all cases by incisions down to the bone alongside of the tendon (Fig. 517), and was frequently disappointed by a spread of the suppuration in spite of incisions, by necrosis of bone, or by extensive sloughing of tendons. I obtained new light upon this subject from an article on "Whitlow," by G. B. Mower White ("Brit. Med. Jour.," Feb. 24, 1906). I immediately put in practice the common-sense suggestions in this valuable article and have seen a surprising improvement in results. The chief points in White's plan of treatment are as follows: To plunge a knife through an area of infection into a tendon-sheath, if that sheath is not infected, will lead to infection, and the way to be sure whether it is or is not infected is to look through a carefully made incision and see. After careful sterilization, anesthetize, drain the extremity of blood by elevation, and apply an Esmarch band to the arm. This enables us to see what we are doing. Slowly and carefully make an incision by the side of the tendon-sheath (Fig. 517), and on reaching it see if it is distended. If in doubt, insert a hypodermatic needle and withdraw fluid. If we get turbid serum, the theca is infected. If the theca is not infected, do not open it, but incise the subperiosteal area of suppuration if it exists. If the theca is infected, remember that this infection has surely ascended more or less, and we must not only open at the lower point, but must also incise at the upper point. Do not incise the theca over the length of the tendon, as sloughing will follow. If one of the three middle fingers is involved, incise the distal end of the theca and also the proximal end over the head of a metacarpal bone in the midline, wash from opening to opening, and drain. If the theca of the thumb or little finger is involved, open distally and then proximally above the wrist. To reach the proximal end of the theca of the thumb cut at the radial side of the tendon of the flexor carpi radialis. Also open the palmar sac of the flexor longus pollicis, making the cut along the inner border of the outer head of the flexor brevis pollicis.

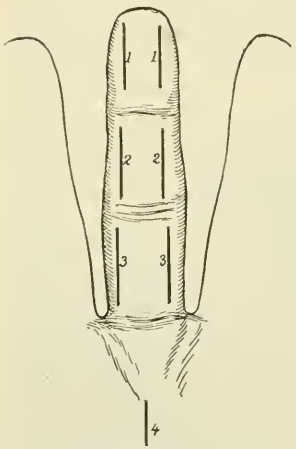

FIG. 517.—1, 2, and 3, Incisions for felon of finger and for ordinary suppuration; 4, palmar incision.

To reach the proximal end of the theca of the little finger begin an incision at the upper margin of the annular ligament and carry it up along the inner border of the flexor sublimis. Retract the tendons and pus will usually be found between the tendons of the superficial and deep flexor. Look beneath the profundus tendons for the bursa and open it. Then open the palm by an incision in the line of the axis of the ring-finger. Thus three openings are made in either case, and the theca can be thoroughly washed and drained. If either the thumb or little finger bursa is found infected, the other must be exposed

and examined, as they usually communicate at their proximal ends or a communication may form as a result of suppuration. Rupture of either bursa may diffuse pus widely. White, in order to prevent secondary hemorrhage, ligates the radial artery in two places and removes 1½ inches of it (if operating on the thumb bursa); and ligates the superficial arch and removes 1 inch of it (if operating on the palmar expansion of the little finger theca). These arterial ligations seem a serious and perhaps unnecessary addition to the operation and I have not *practised* them. After thorough irrigation apply antiseptic fomentations, splint the extremity, and induce Bier's passive hyperemia daily. If the patient cannot sleep, give morphin. See that the bowels are moved once a day. Give quinin, iron, and milk-punch. As soon as granulations begin to form, use dry dressings and make passive motion daily. If bone undergoes necrosis, let it loosen and then remove it. Amputation is sometimes necessary.

Bursitis is inflammation of a bursa. *Acute bursitis* arises from strain, from traumatism, or from infection. The symptoms of acute bursitis are pain, limited swelling, moist crepitus, fluctuation, and discoloration in the anatomical position of a bursa. In *chronic bursitis* there is intermittent pain, tenderness, and progressive, fluctuating swelling. *Bursitis of the retrocalcaneal bursa* (*Albert's disease*) is a painful affection which is often overlooked. It is rather common in storekeepers who rise often on the toes to reach shelves, in motormen who use a foot gong, in street-car conductors, and in clerks who stand at desks. It may follow gonorrhea and may be tuberculous. Walking causes great pain in the heel. Raising up on the toes is exceedingly painful. It is usually associated with flat-foot. In these cases osteophytes often form within the bursa. There are numerous bursæ about the hip. Some anatomists count twenty-one.[1] The two most important bursæ and the ones usually affected are the iliac and the deep bursa over the great trochanter.[2] Inflammation of the *iliac* or *iliopsoas bursa* produces below Poupart's ligament a swelling which is tense, but exhibits fluctuation on careful examination. Often the swelling attains large size. In some cases the sac can be emptied by pressure, the fluid passing into an adjacent bursa or into the joint. The swelling is beneath the femoral artery and consequently lifts that vessel (F. B. Lund, in "Boston Med. and Surg. Jour.," Sept. 25, 1902). The enlargement often presses on the anterior crural nerve and causes spasmodic pain throughout the nerve's trajectory. The limb, according to Zuelzer, is usually slightly flexed, abducted and rotated outward, and movement in an opposite direction causes pain. Inflammation of the bursæ about the hip may produce symptoms resembling those of incipient coxalgia, but in bursitis the symptoms do not remit, as in hip-disease. Iliopsoas bursitis occasionally results from gonorrhea. The bursa is sometimes involved in joint-disease. In inflammation of the iliac bursa flexion is not so marked as in coxalgia, and the trochanter is never above Nélaton's line. In inflammation of the deep trochanteric bursa the position is the same as in iliac bursitis, and resembles that of coxalgia. In coxalgia, however, there is pain on pressure upon the front of the joint or directly on the trochanter or on tapping the sole of the foot. These manipulations do not cause pain in bursitis (Zuelzer). In inflammation of the *gluteal bursæ* there is moderate pain back

Fig. 518.—Olecranon bursitis.

[1] Synnestvedt, of Sweden.

[2] Zuelzer, in "Zeit. f. Chir.," vol. l.

of the thigh and knee, which disappears when the patient is at rest; there are a marked limp, limitation of motion, and an area of deep fluctuation in the buttock (Brackett).

Fig. 519.—Housemaids' knee.

It is difficult to differentiate between inflammation of a deep bursa and synovitis; indeed, in bursitis the joint is apt to be secondarily affected. This difficulty is especially vexatious in distinguishing between joint-injury and injury of the bursa beneath the deltoid. In subdeltoid bursitis there is a tender spot over the bursa when the arm is by the side. When the surgeon abducts the patient's arm the bursa slips up under the acromion and no tender spot can be found. Suppuration may take place in a bursa. Direct force may rupture a bursa. The bursa beneath the deltoid is frequently ruptured. When this accident happens, there are pain, marked swelling, a large area of moist crepitus, and later extensive discoloration from blood. Chronic bursitis may follow acute bursitis, or the disease may be chronic from the start. It may be due to tuberculosis. Bursæ particularly apt to become tuberculous are those about the hip, the subdeltoid, the olecranon, the prepatellar, and the retrocalcaneal. In tuberculous bursitis during the first stage the bursa is distended by fluid, due to oversecretion, the walls are thickened here and there, and perhaps contain caseous foci and rice bodies are found in the bursal fluid. In a more advanced stage the bursal wall is lined with caseating granulation tissue and the bursa may become a tuberculous abscess, the walls may give way with diffusion of the process, or mixed infection with pyogenic organisms may occur. In some cases of tuberculous bursitis tending to cure the bursal walls become enormously thickened by fibrous tissue.

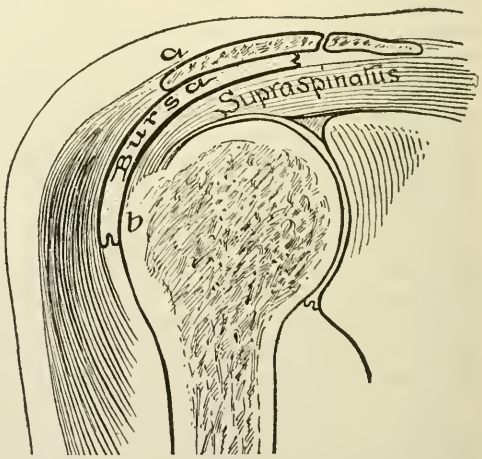

Fig. 520.—Diagram from a frozen section. Notice the deltoid and its origin, from the edge of the acromion. Notice the subdeltoid or subacromial bursa with its roof made by the under surface of the acromion and by the fascia beneath the upper portion of the deltoid. Its base is on the greater tuberosity and the tendon of the supraspinatus, which separates it like an interarticular fibrocartilage from the true joint (Codman).

The symptom of chronic bursitis is swelling but little or no pain unless acute inflammation arises. Chronic bursitis of the prepatellar bursa is known as *housemaids' knee* (Fig. 519). Chronic bursitis of the subhyoid bursa is known as *Boyer's cyst*. There are six bursæ about the ham, the largest of which is the bursa of the semimembranosus muscle.

Treatment.—Acute bursitis is treated by rest, pressure, and the application of iodin, blue ointment, or ichthyol. If the swelling persists, aspirate and apply pressure, or incise the sac and remove it partly or completely. If pus forms, incise, paint the interior of the sac with pure carbolic acid, and pack with iodoform gauze. Chronic bursitis may be cured by the use of pressure and the application of blue ointment, and with treatment of any causative diathesis, but most cases require incision and packing. A ruptured bursa is treated as an acute bursitis. In bursal tuberculosis the best treatment is excision. If we are dealing with a very deep bursa the proper treatment is incision, scraping with a sharp spoon, mopping with carbolic acid, and packing with iodoform gauze.

Bursitis of the subacromial bursa has been considered by A. E. Codman ("Boston Med. and Surg. Jour.," Oct. 22 and 29, Nov. 5, 12, 19, and 26, and Dec. 3, 1908), who points out that the deltoid and the subacromial bursa are one and the same thing. When the arm is abducted, the entire bursa is subacromial; when it is adducted, a large portion of the bursa is subdeltoid. Codman describes three types of conditions associated with inflammation of this bursa, first: The acute, or spasmodic type, in which there is local tenderness on the point of the shoulder, just below the acromion process and outside the bicipital groove. In some cases Dawbarn has shown that the tender point, which is the base of the bursa, disappears under the acromion when the arm is abducted. Codman goes on to show that in attempting abduction about ten degrees of motion can be obtained without moving the scapula. Then the scapula is locked by spasm and moves with the humerus. This spasm may be temporary in mild cases. Sometimes pain prevents the patient from voluntarily raising the arm, though it may be raised by passive motion. The pain may run down the outer side of the arm, even into the hand; the patient frequently locates the pain about the insertion of the deltoid, and may be able to note swelling of the bursa.

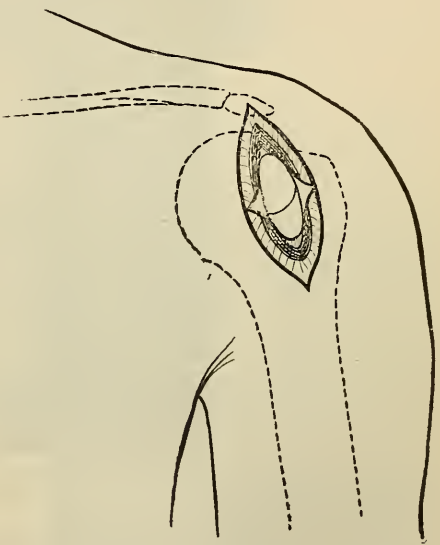

Fig. 521.—Showing incision used for demonstration of the bursa (Codman).

Codman describes type two, the subacute or adherent type, in which there are adhesions between the roof and floor of the bursa and a definite mechanical hindrance to abduction and external rotation. There may or may not be local tenderness, but Dawbarn's sign is absent, owing to the presence of the adhesions. Abduction is limited to such a great degree that, as a rule, the tuberosity will not pass beneath the acromion. Any movement in abduction beyond ten degrees causes the scapula to move. The pain is located as in type one, and frequently also passes into the neck. In some cases it is very severe.

Codman's third form is the chronic and non-adherent. In this the full arc of motion is retained, but motion is painful. The bursa is thickened and irregular. There may or may not be local tenderness; and if this is present, one will find Dawbarn's sign. Abduction and external rotation are limited little, if at all, but at some point during abduction there is severe tenderness,

which disappears as soon as the tuberosity passes beneath the acromion. The scapula does not accompany the motions of the humerus. There is often considerable pain after motion.

Codman points out that the prognosis in type one is very favorable if treatment is correct. In type two the disability, even without treatment, seldom lasts more than two years. He says that even severe or adherent

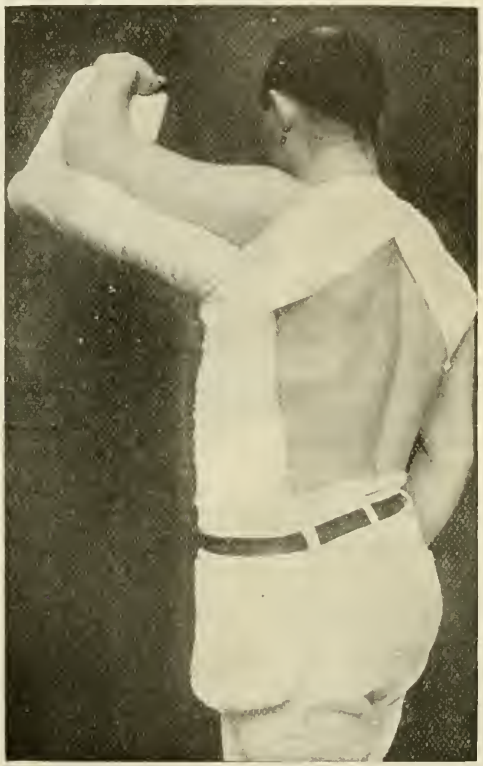

Fig. 522.—Showing the abduction splint in position, the patient standing. It is held by a figure-of-8 bandage, which crosses behind the shoulders and by a belt about the hips. The arm is at rest (Codman).

Description of Splint.—The frame of the splint which I use is made of iron wire (diameter, ¼ inch), stiff enough to maintain its form and to carry the weight of the arm securely. Sufficient wadding to pad it thoroughly is bandaged over it and the whole covered with cotton or linen cloth. The general shape is shown in the photograph. It should be just long enough to extend from the axilla to the seat of the chair on which the patient sits. It is best held in position by a belt around the pelvis and a figure-of-8 flannel bandage about the shoulders crossing back of the neck. A pad should be placed in the opposite axilla to prevent excoriation of the skin by the bandage.

During the first twenty-four hours and afterward, if worn at night, the arm should also be lightly bandaged to the projecting part of the splint. Additional security is given by the application of a swathe, which may be pinned to the bandage of the axilla.

When properly adjusted it is perfectly comfortable. Unless it is comfortable it is useless. The use of the splint is not essential and is even harmful if not skilfully cared for.

cases, if there are no secondary contractures in the forearm muscles, will recover in from one to two years. In infective cases the prognosis is far worse than in traumatic cases. In chronic cases, in which the arc of mobility is not affected, the prognosis is fairly good.

Treatment.—Acute cases of subacromial bursitis should be treated by keeping the arm abducted in a splint (Fig. 522). Monks suggests that the

patient may sit by a table, the arm being abducted and placed upon a pillow that is on the table. This relaxes the short rotators and the deltoid, and keeps

Fig. 523.—Bursitis of left olecranon bursa of three years' duration.

the base of the bursa from being in contact with the acromion. At night Codman places the arm on a pillow, with its long axis at right angles to the patient's body as he lies recumbent. If the patient has to get about, he may use a sling most cautiously. He should take the arm out from time to time and rest it on a table. Massage should be used about the bursa, but not directly over it. In the more severe cases with adhesions one may employ massage, passive and active movements, baking, forcible movement and manipulation under an anesthetic, followed by fixation in the position of abduction (Fig. 522), or perhaps incision of the bursa with division of the adhesions or excision of the subdeltoid portion of the bursa (Codman). In the cases in which there is irregularity of the surface of the bursa, one should excise and remove the thickened folds or other irregularities.

Fig. 524.—Enlargement of the deep infrapatellar bursa; chronic and the result of traumatism.

Housemaids' knee (see Fig. 519) is thickening and enlargement of the prepatellar bursa, the result of intermittent pressure. In effusion into the knee-joint the fluid is behind the patella and the bone floats up; in housemaids' knee the fluid is above the bone and the osseous surface can be felt beneath it.

In **bursitis of the deep infrapatellar bursa** the swelling is under the ligament of the patella.

Miners' elbow (Figs. 518 and 523), which is a condition similar to housemaids' knee, affects the olecranon bursa.

Weavers' bottom is enlargement of the bursa over the tuberosity of the ischium. A bursa which is simply thickened and enlarged rarely gives rise to annoyance; but when it inflames, as it is apt to do, it causes the ordinary symptoms of bursitis.

The **bursa of the semimembranosus muscle** is the largest one about the ham. It lies between the inner femoral condyle and inner head of the gastrocnemius and the semimembranosus muscle. It communicates with the knee-joint. When the joint is flexed, it partly empties into the joint and becomes small and lax. When the joint is extended, it becomes large and tense.

Treatment of Special Forms.—Some few cases of housemaids' knee may be cured by rest and blistering, but in most cases it is necessary to incise and pack with iodoform gauze. In enlargement of the bursa beneath the ligamentum patellæ, if rest and blistering fail to cure, aspirate or incise. In enlargement of the bursa beneath the tendon of the semimembranosus and also in "weavers' bottom" and in "miners' elbow," incise and pack. In operating for iliopsoas bursitis I follow Lund's advice and make a vertical incision below Poupart's ligament, and between the anterior crural nerve and the femoral artery. The fibers of the iliopsoas muscle are separated and the bursa is opened and drained. Some few cases of retrocalcaneal bursitis recover after rest, but most of them require incision and drainage. If osteophytic formations exist, the bony stalactites must be removed by means of the rongeur. Flat-foot, if it exists, is treated by a support (see page 833). The treatment of subacromial bursitis is considered on page 820.

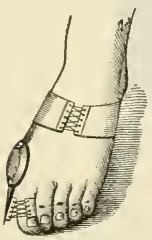

Fig. 525.—Bigg's apparatus for bunions.

A **bunion** is a bursa due to pressure, and it is most commonly situated above the metatarsophalangeal articulation of the great toe, but is occasionally seen over the joint of another toe. When the big toe is pushed toward the other toes by ill-fitting boots a bunion forms. When a bunion is not inflamed it may cause but little trouble, but when it inflames the bursa enlarges and the parts become hot, tender, and exceedingly painful. Suppuration may occur and pus may invade the joint, and the bone not unusually becomes diseased and very greatly enlarged.

Treatment.—In treating a bunion the patient must wear shoes that are not pointed, that have the inner border straight, and that have rounded toes (Jacobson). For a mild case a bunion-plaster gives comfort. Sayre advises the use of a linen glove over the toe, the toe being drawn toward the inner side by a piece of elastic webbing, one end of which is fastened to the glove and the other end to a piece of strapping from the heel. A special apparatus may be worn (Fig. 525). In many cases osteotomy of the first phalanx or of the first metatarsal bone is required; in some cases excision of the joint is necessary; in others amputation must be performed. Charles H. Mayo has operated on 65 cases successfully. He removes the head of the metatarsal bone and with it two-thirds of the hypertrophy on the inner side, and turns the bursa into the joint area in front of the bone. He sutures this bursa in place and now has a synovial membrane for a joint which becomes satisfactorily movable ("Annals of Surgery," August, 1908). When the bursa is not inflamed, but only thickened, blisters should be employed over it, or there should be applied tincture of iodin, ichthyol, or mercurial ointment. When the bursa inflames, ichthyol ointment is applied, and intermittent heat by foot-baths gives relief. Suppuration demands immediate incision and antiseptic dressing. If an ulcerated bunion does not heal by antiseptic dressing, stimulate it with nitrate of silver and dress it with unguent. hydrarg. nitrat. (1 part to 7 of cosmolin). Jacobson recommends skin-grafting for some cases.

Tenotomy is the cutting of a tendon. It may be *open* or *subcutaneous*, the open operation being preferred in dangerous regions.

Open Division of the Sternocleidomastoid Muscle for Wry-neck.—Subcutaneous tenotomy for wry-neck has been largely abandoned. It is not only more unsafe than the open operation, but it never completely divides all the contracted band.

The patient is placed recumbent, the chin being drawn more than is habitual toward the opposite side. A transverse incision is made over the muscle about ¼ inch above the clavicle. The superficial parts are divided, the muscle is exposed and sectioned, bleeding is arrested, and the skin is sutured. Avoid the anterior jugular vein, which is underneath the muscle, and also the external jugular, which is close to the outer edge of the muscle. Mikulicz advocates the removal of almost the entire muscle, leaving, however, the upper and posterior portion where the spinal accessory nerve passes. After operation for wry-neck plaster of Paris is used to secure fixation for from four to eight weeks. Then inaugurate motions, active and passive.

Subcutaneous Tenotomy of the Tendo Achillis.—This operation is performed for club-foot, in which the heel is raised. The tendon is cut about 1 inch above its point of insertion. The instrument used for the first puncture is a sharp tenotome. The patient lies upon his back, "with his body rolled a little toward the affected side" (Treves), the foot being placed so that its outer side rests on a sand-pillow. The surgeon stands to the outer side. The tendon is rendered moderately rigid, and a sharp tenotome, with its blade turned upward, is inserted along the anterior border of the tendon until the surgeon's finger feels the knife approaching the outer side. The sharp-pointed instrument is withdrawn and a blunt-pointed tenotome is inserted in its place. The tendon is drawn into rigidity, and the surgeon turns the blade of his knife toward the tendon, places his finger over the skin, and saws toward his finger. The tendon gives way with a snap. Treves states that a beginner is apt not to push the knife far enough toward the outside, or he may in the first puncture push the knife through the tendon; in either case the tendon is not completely cut. Another method is to insert the tenotome between the skin and the tendon and cut the tendon by a sawing motion. In this method the danger of cutting through the skin is obviated. The little wound, which is covered by a bit of gauze, will be entirely closed in forty-eight hours. In club-foot cases after tenotomy some surgeons at once correct the deformity and immobilize the limb in plaster; some partially correct the deformity and apply plaster for one week, at which time they remove the plaster, correct the deformity further, reapply the plaster, and so on; other surgeons do not attempt correction of the deformity until the cut tendon has begun to unite, when they gradually stretch the new material.

Subcutaneous Tenotomy of the Tendon of the Tibialis Anticus Muscle.—The tendon is divided about 1½ inches above its point of insertion. It can be made tense by extending and abducting the foot. The sharp-pointed tenotome is entered upon the outside of the tendon, and is passed well around it. The blunt-pointed tenotome is used to cut the tense tendon.

Subcutaneous Tenotomy of the Tendons of the Peroneus Longus and Brevis Muscles.—These two tendons are cut together back of the external malleolus, and 1½ inches above the tip of the malleolus, so as to avoid the synovial sheath (Treves). The patient lies upon the sound side, the outer aspect of the deformed foot being upward and the inner aspect of the ankle resting upon a sand-pillow. A sharp tenotome is introduced close to the fibula, and is carried around the loose tendons. A blunt-pointed tenotome is now

introduced, its edge is turned toward the tendons, and these structures are cut as they are made tense.

Subcutaneous Tenotomy of the Tendon of the Tibialis Posticus Muscle.—This tendon is sectioned above the point where its synovial sheath begins; that is, above the internal annular ligament (Treves). The tendon is made tense and the pointed knife is entered above the base of the inner malleolus. The knife is entered just back of the inner edge of the tibia, and is carried around the muscle and is kept close to the bone. The tendon is sectioned with a blunt knife.

Subcutaneous Fasciotomy of the Plantar Fascia.—The contracted bands are discovered by motions which render them tense, and they are divided just in front of the attachments to the os calcis. The sharp knife

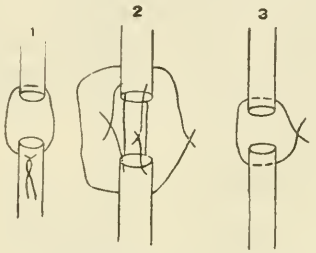

FIG. 526.—Tendon-sutures: 1, Of Le Fort; 2, of Le Dentu; 3, of Lejars.

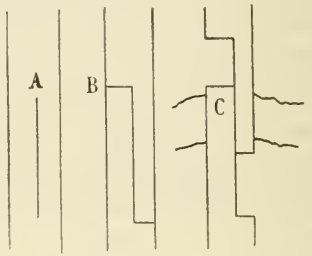

FIG. 527.—Anderson's method of tendon-lengthening.

passes between the skin and fascia at the inner side of the sole of the foot. The fascia is cut from without inward by the blunt-pointed tenotome. It is usually necessary to section the fascia at more than one point.

Tendon-suture and Tendon-lengthening.—Chromicized gut, kangaroo-tendon, or silk is used for an ordinary case, silver wire for a suppurating wound. In performing tendon-suture make the part aseptic and bloodless. It is wise to apply a rubber bandage on the proximal side, the bandage being applied centrifugally, forcing the proximal end of the tendon into view (Haegler). If searching for the proximal end of a flexor of the finger, flex the injured finger and hyperextend the adjoining fingers (Filiget). If this expedient fails, enlarge the incision or, what is better, make a large flap in the skin. After finding the ends, approximate them, being sure the proper ends are brought into contact; stitch them together by a continuous suture or by one of the sutures shown in Fig. 526, 1, 2, and 3. In a suppurating wound suture by silver wire should be tried, though it usually fails. After suturing, remove the Esmarch apparatus, arrest bleeding, close the wound and dress it antiseptically, relax the parts, and place the limb on a splint. If, after suturing, there is much tension, stitch the cut tendon above the sutures to an adjacent tendon, and apply a splint, the finger which was injured being flexed, the others being extended. If only the distal end of the tendon can be found, graft it upon the nearest tendon with a like anatomical course and function. After a tendon has been sutured, begin gentle massage in two weeks. Positive passive motion is begun in three or four weeks. In old injuries, when the ends cannot be brought into apposition, lengthen one end or both ends. Dr. J. Neely Rhoads ("Med. News," Nov. 28, 1891) suggested that slight lengthening could be accomplished by "cutting half through the tendon at different levels and from opposite sides, leaving some longitudinal fibers to slip on each other, thus gaining slight elongation" (H.

FIG. 528.—Czerny's method of tendon-lengthening.

Augustus Wilson, in "International Clinics," vol. i, 4th series). Poncet makes several zigzag incisions on each side of the tendon, and when the tendon is pulled upon it elongates decidedly. Bayer's method is shown in Fig. 529. Anderson's open method is the most satisfactory (Fig. 529*a*). One of these methods of lengthening may be used if there is deformity from tendon contraction. If the tendon cannot be lengthened sufficiently, make a bridge of catgut from one cut end of it to the other, or graft in another tendon from one of the lower animals, or graft the distal end to a tendon of like function (*tendon-grafting*).

The annular ligament is sutured as shown in Fig. 514.

Tendon-transplantation and Silk Inserts.—Tendon-transplantation is the transplantation of the tendon of a healthy muscle to take the place of the tendon of a paralyzed muscle. Silk inserts have been used to take the place of paralyzed muscles, "to lengthen normal tendons for the purpose of using them in transplanting, and to reinforce joints as artificial ligaments, in place of arthrodesis" (James W. Sever, "Jour. Am. Med. Assoc.," May 11, 1912). Tendon-transplantation is usually said to have been devised by Nicoladoni in 1882; as a matter of fact, Duplay did the operation in 1876, endeavoring to secure function in an arm rendered nearly powerless by an injury (Elting, in "Albany Med. Annals," April, 1902).

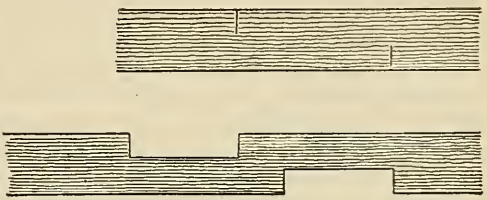

Fig. 529.—Bayer's method of tendon-lengthening.

The first American surgeon to do the operation was Parrish, of New York, who in 1892 transplanted tendons in a case of club-foot. In some cases in which a muscle has been paralyzed surgeons have divided the tendon of the paralyzed muscle and have united its distal end with the tendon of a normal muscle, the normal tendon being split to receive it. It has also been stated that when a muscle or the tendon of a muscle is sutured so as to replace a paralyzed antagonistic muscle, the transplanted structure will actually execute the functions of the paralyzed muscle. For instance, a flexor, when so transplanted, may become an extensor and act under the mental impulse of extension; a pronator may become a supinator (H. A. Wilson, in "American Med.," April 8, 1905). As a matter of fact the surgeon selects a tendon to receive the graft, the muscle of which is nearest in action to the palsied muscle. These principles have been utilized when some or many of the muscles of a limb have been paralyzed, the tendon of an unparalyzed muscle or the tendons of an unparalyzed group of muscles being fastened to the tendons of the paralyzed muscle. It has been shown that the success of the procedure depends upon the accuracy of diagnosis, the division of secondary contractures, the correction of existing deformities, and careful after-treatment. (See the article by Dr. J. Hilton Waterman, in "Med. News," July 12, 1902.) The muscle of the transplanted tendon must not be put under tension. In a paralysis of the lower extremity, as Goldthwait points out, the sartorius usually retains power, and it may be advisable in such a case to divide the sartorius and suture its upper end to the quadriceps above the patella. A strip of the tendo Achillis may be grafted upon the peronei

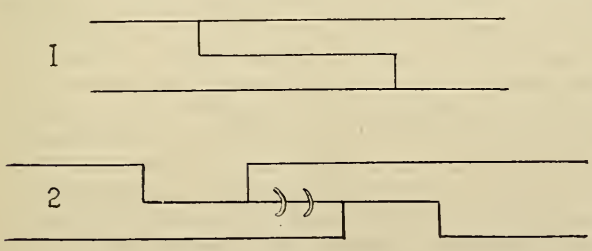

Fig. 529*a*.—Anderson's method of tendon-lengthening.

in certain cases. Unfortunately the suturing of tendon to tendon seldom holds. Experience has shown that it is better, whenever possible, to make a subperiosteal insertion of a tendon. An artificial tendon may be made of silk, being passed from the sound to the paralyzed tendon. This method was devised by Auger in 1875. The silk must have been boiled in paraffin, otherwise it will slough out. The silk eventually becomes surrounded by fibrous tissue. Some maintain that silk is eventually absorbed. Lange showed that tendon regeneration may take place along the strands of silk. Strands of silkworm-gut may be used for the same purpose (Kummell). It is useless to make a silk insert on a tendon in a patient under nine or ten years of age. Coöperation between surgeon and patient is essential if we would develop function, and coöperation is sure to be lacking before that period of life. The consensus of opinion among orthopedic surgeons is that silk tendons should not be used if there is much strain or trauma. Under active use silk will be cast off by a process of noninfective sloughing and, unless sufficient scar tissue has been formed by that time, the result is bound to be a failure. The operation of tendon-transplantation is occasionally of distinct benefit, but I agree with Ridlon, and am not usually sanguine of results. Ridlon wisely reminds us that in such cases much good may perhaps result from the proper use of braces, tenotomy, and hand stretching, followed by prolonged retention in plaster, the patient using his limb actively.

Ridlon points out that most brace treatment is not curative because it only aims to prevent deformity developing, and tenotomy and stretching fail because they only seek to remove existing deformity. The object should be some restoration of function. This is often obtained by following Thomas's direction and "posturing" the limb so as to permit structural shortening of the paralyzed muscles and then fixing them for months.

XXII. ORTHOPEDIC SURGERY

This branch of surgery formerly dealt only with the treatment of deformities by means of mechanical appliances, but of recent years its domain has been enlarged to include the treatment, surgical and mechanical, of deformities, contractures, and many joint diseases.

Torticollis (**wry-neck**) is a condition in which contraction of certain of the neck muscles causes an alteration in the position of the head. The deformity is one sided; the sternocleidomastoid is the muscle chiefly involved, though the trapezius, the splenius, and other muscles sometimes suffer. Acute torticollis, which is rare, is a temporary condition, and results from cold or from injury (see Myalgia). Chronic torticollis may be congenital (due to injury before birth or during birth), may be due to nerve irritation, to an assumed attitude because of eye defect, to polio-encephalitis (Golding Bird), to inflammation of the glands or to disease of the vertebræ, and it may be intermittent, but is usually persistent. The muscle stands out in bold outline, the head is turned to the opposite side, the ear of the affected side is turned toward the shoulder, the chin is thrown forward, and spinal curvature may arise. The corresponding side of the face becomes distorted. Secondary facial changes result from Nature's effort to balance the face and keep the eyes on a level, in accordance with Wolff's law. When the muscular deformity is over-corrected the face again becomes symmetrical. There is no pain. In many cases the head may be restored to its normal position by passive movement or by voluntary effort, but it at once returns to its habitual position. Mikulicz asserts that torticollis is a chronic fibrous myositis, due often to compression during labor. He further says that the lesion known as hematoma of the sternomastoid, which occasionally follows labor, is not hematoma, but thickening due to myositis. D'Arcy Power reported the autopsy on a

child one month of age. The sternomastoid muscle contained a fibrous mass, the result, Power believes, of a hemorrhage into the muscle prior to birth ("Med. Chir. Trans.," vol. lxxvi). Power, Clutton, and Owens have all traced cases of hematoma of the sternomastoid from early infancy to the time when tenotomy was required for torticollis. W. W. Richardson ("Surg., Gynec., and Obstet.," 1906) believes that interstitial myositis is always present, but doubts the causal influence of the lateral position of the head *in utero*. In some cases hereditary influence is evident. One woman gave birth successively to 7 wry-necked children (Nove-Jusserand and Vianny, in "Revue D'-Orthop.," 1906). Many writers advocate the ischemic theory as explanatory of the causation of torticollis. This theory is, that during labor lateral flexion of the head with elongation of the neck or lateral flexion with torsion produces occlusion of the sternomastoid branch of the superior thyroid artery, which vessel supplies the sternocleidomastoid muscle (see Tubby's "Orthop. Surgery"). In congenital torticollis the muscle and the cervical fascia are shortened, and the muscle does not relax under the influence of an anesthetic. In torticollis due to rheumatism and reflex causes the tonically contracted muscle relaxes when the patient is anesthetized. In spasmodic wry-neck the muscle is thrown repeatedly into clonic contractions.

Symptoms.—*Congenital* wry-neck is due to central nervous disease, to spinal deformity, or to injury during birth, and in this form the sternomastoid is shortened, hardened, and atrophied. It may not be noticed for some years because of the short neck of infancy. It is associated with asymmetrical development of the face, and is almost invariably upon the right side. *Spasmodic* wry-neck may present tonic spasm only, intermittent spasm alone, or both may appear alternately. It sometimes arises in those whose occupation demands frequent rotation of the head, but more often no such cause can be discovered. It is probably a disease of the cortical area which presides over rotation of the head. (See article by C. A. Hamann, in "Buffalo Med. Jour.," Dec., 1901.) It is a disease especially of adults; in women it is often linked with hysteria. Pahl ("California State Med. Soc.," 1906) analyzed 68 reported cases. Men and women appeared equally liable, it was most frequent between the ages of twenty and thirty, and the right side was affected in twice as many cases as the left side. The exciting cause may be a cold, a blow, or a mental storm; the predisposing cause is the neurotic temperament. It may be due to enlarged glands, to carious teeth, or to eye-strain. In some rare cases bilateral spasm occurs, the head being pulled backward and the face being turned upward. Clonic spasms may come on unannounced, or they may be preceded by pain and stiffness; the head can be held still for a moment only; there is sometimes pain, always fatigue, but during sleep the contractions cease. The attack will probably pass away, but will recur almost certainly.

Treatment.—Congenital wry-neck is treated by myotenotomy through a superficial incision which is vertical or transverse (see page 823). The muscle and fascia are divided in a line parallel to and just above the clavicle or just below the mastoid attachment. The flaps are raised, access is free to the origin of the muscle, the muscle is readily divided. Any bands should be thoroughly kneaded and stretched and the head should be twisted into a position which over-corrects the deformity. The wounds in the skin and fascia are closed. This incision leaves a trivial scar. After operation plaster of Paris is used to secure fixation and fixation is maintained from four to eight weeks. Early operation favors the establishment of muscular co-ordination before the development of permanent bony deformity of the vertebræ. Some surgeons cut the scalene muscles as well as the sternocleidomastoid. Gerdes Rowland lengthens the sternomastoid and carefully sutures it ("Practitioner," Sept., 1908). The old subcutaneous myotenotomy should be abandoned, as aseptic incision enables the

surgeon to see and to feel all the contracted bands of fascia, muscle, and tendon, and to avoid vital structures (see page 823). In spasmodic wry-neck there is a fair chance of recovery. Pahl's table (*Loc. cit.*) shows that out of 68 cases, 28 recovered, 17 were improved, and 11 were not improved by treatment. Results in 12 were not stated. Treat the neurotic temperament and remove any obvious irritation (eye-strain, carious teeth, enlarged glands). Drugs usually are practically useless, although Chas. S. Potts reported a cure after the hypodermatic use of atropin. The rest cure is sometimes beneficial. Tenotomy is not to be employed. In 1890 Mayo Collier suggested ligation of the spinal accessory nerve with silver wire. In persistent cases stretch or divide and exsect a part of the spinal accessory nerve (Keen). To reach this nerve make an incision along the posterior edge of the sternocleidomastoid muscle, find the nerve as it emerges from under the middle of the muscle, about 1½ inches below the tip of the mastoid process, retract the muscle at this point, and remove at least 1 inch of nerve. Neurectomy of the spinal accessory nerve paralyzes the sternocleidomastoid muscle, in spite of the fact that that muscle has also a nerve-supply from the cervical nerves. The paralysis is followed by atrophy, and if the spasm affected the sternomastoid muscle only the operation will cure the case. Unfortunately, other muscles are usually involved, and cure will only be obtained by performing neurectomy on the nerves which innervate the affected muscles. (For the treatment of rheumatic wry-neck, see Myalgia, page 801.)

Fig. 530.—Dupuytren's contraction of the middle finger.

Dupuytren's contraction was first described by Sir Astley Cooper. In 1831 Dupuytren made the first dissection of a case (Black, in "Brit. Med. Jour.," 1915, 1). It is a fibrosis and contraction of the palmar fascia, of its digital prolongations, and of the fibers joining the fascia and skin without any inflammation of the skin. The process starts in the digital prolongations. Fixed contraction of one or more fingers occurs (Fig. 530). The ring-finger and the little finger most often suffer, but any finger or the thumb may be involved. The condition may be symmetrical. It is far more common in men than in women. The disease arises oftenest in men beyond middle age, but is sometimes met with in youths. The **cause** of this disease is unknown; some refer it to gout, rheumatism, or osteo-arthritis; others, to traumatism, syphilis, organic nervous diseases, arteriosclerosis, reflex irritation, or neuritis. In one-fourth of the cases heredity seems to be influential. If due to traumatism, the right hand should suffer most frequently; but it occurs in the left hand nearly as often as in the right (P. Jansen, in "Arch. f. klin. Chir.," Bd. lxvii, H. 4). Working men are not more liable to it than others. Jansen examined specimens from 7 cases and found connective-tissue hypertrophy and circulatory disturbance, the contraction being a result of the above-named processes.

Symptoms.—Dupuytren's contraction is indicated by a small hard lump or crease which appears over the palmar surface of the metacarpophalangeal joint. This nodule grows and the corresponding finger is gradually pulled down. In some cases the tip of the finger is forced against the palm. The skin becomes dimpled or puckered. In some cases the interphalangeal joints of the contracted finger dislocate.

Treatment.—Fibrolysin, which is a soluble combination of thiosinamin and salicylate of sodium, has been used hypodermatically in Dupuytren's contraction and, it is claimed, with success (Schwalbach). In very slight and early cases the wearing of a splint at night, associated with daily manipulation and massage retards the development of the deformity. In treating Dupuytren's contraction subcutaneous multiple incisions may be made, the tense fascia and the fasciocutaneous fibers being cut. The finger is straightened and is placed upon a straight splint, which is worn continuously for a week or ten days and is worn at night for at least a month. A more satisfactory operation is that of Keen. He divides the skin by a V-shaped cut, the base of the V being downward, lifts up the flap, and dissects out the contracted tissue. A valuable method is that of McCurdy. He makes a long incision which crosses the contracture obliquely, stretches thoroughly, closes the wound, and keeps up mechanical fixation for a time. A cure is most certain to be obtained by Lexer's radical operation. This surgeon excises the entire aponeurosis and considerable portions of the palmar skin adherent to the aponeurosis. In order to cover this wound it may be necessary to slide a pedunculated flap into the raw surface.

Syndactylism (webbed fingers) is always congenital, and may persist through several generations. Simple incision of the web is useless; the operation to be performed is that of Agnew or of Diday (Figs. 531, 532).

Fig. 531.—Agnew's operation for webbed fingers (Pye).

Fig. 532.—Diday's operation for webbed fingers (Pye).

In Agnew's operation a flap of skin from the dorsum is inserted between the fingers and sutured in place.

In Diday's operation a flap is taken from the dorsal surface and another flap is raised from the palmar surface, and each flap is sutured to the finger to which it is attached.

Polydactylism (supernumerary digits) is always congenital, is often hereditary, and is usually symmetrical. There may be an incomplete digit, or there may be an entire and well-developed finger or toe with a metacarpal or metatarsal bone. The connection to the metacarpus or metatarsus may be by a fibrous pedicle only. If the digit is complete, with a metacarpal bone, no operation is required; if it is incomplete or is ill-developed, it should be removed.

Trigger-finger or Jerk-finger (Lock-finger, Snapping-finger).—The patient can usually close the fingers, but on trying to open them one finger remains closed. It can be opened by grasping it with the other hand, but flies open with a snap, like an opening blade of a pen knife (Abbe). In some cases two fingers are involved. In a reported case (Frederick Griffith, "Annals of Surgery," 1904) the ring and middle fingers of the left hand locked at the knuckle-joints on attempting flexion. The locking occurred when about one-third the amount of flexion necessary to grasp an object was achieved. By bending the fingers with the other hand unlocking was accomplished and flexion was finished voluntarily. In attempting extension blocking occurred at the same point and unlocking was accomplished in the same manner. In most cases, but not in all, there is pain when locking occurs. The condition is gradual in onset. Trigger-finger

is often associated with rheumatism (in 52 cases out of 121, according to Necker). It is said by Tubby to be due to enlargement of the flexor tendon, or to contraction of the groove in the transverse ligament in the palm. It may be due to a ganglion, enchondroma, or tenosynovitis. Traumatism or irritation may produce it. The tendon-sheath may be thickened or, according to Marcano, there may be a nodule on the tendon which rubs against the sesamoid bone. It may result from occupation. Abbe seems to prove that the trouble is in the flexor tendon which "crumples up as a tape might crinkle when slack above a slot." It catches under the transverse fibers ("Med. Record," March 27, 1914).

Treatment.—If a ganglion, a loose cartilage, or a tendon nodule exists, treat by excision. A sesamoid bone may be excised. If there is inflammation, use massage and counterirritation. Abbe recommends a very simple and effective operation. Subcutaneous division of the constricting fibers is the plan of Abbe. The cut is in the direction of the tendon ("Med. Record," March 7, 1914). If there is no obvious cause, put a compress over the tunnel in the ligament and apply a splint. A short splint supporting the proximal phalanx and running into the palm may be worn like a finger ring. Prolonged rest so obtained may stop the tendon's tendency to crinkle.

Mallet-finger.—This is called also *drop-finger, dropped phalangette*, and *rupture of the extensor tendon*. It is due to a blow in the direction of flexion when the finger is extended. It is supposed to be due partly to stretching and partly to rupture of the extensor tendon at the point at which it is the posterior ligament of the distal interphalangeal joint. Abbe has shown that baseball players are liable to a condition which is the reverse of this, in which the last phalanx is dislocated backward (*baseball-finger*). Drop-finger is treated by incision and suture of the tendon to the periosteum.

Genu valgum (knock-knee) results from an unnatural growth of the internal femoral condyle or of the internal part of the head of the tibia, or from absorption or atrophy of the external femoral condyle or of the external part of the head of the tibia. Any of these conditions causes the shaft of the femur to curve inward and the internal lateral ligament of the knee-joint to stretch, the knees coming close together and the feet being widely separated. The condition may also be caused by curving of the tibial shaft just below the epiphysis. This deformity is usually noted when the child begins to walk, but it may not appear until puberty or even long after. Knock-knee may arise from rickets, from an occupation demanding prolonged standing, or from flat-foot. It may occur in one knee or in both knees.

Treatment.—Mild rachitic cases of knock-knee may remain in slight deformity, or may get well from improvement of the general health, though they seldom do. In an early case properly applied braces will correct deformity. In a later case operation will be necessary. In ordinary cases simply treat the rickety condition. The patient is forbidden to stand or to walk, and the limb, after being put as straight as can be, is fixed on an external splint and a pad is put over the inner condyle. Later in the case plaster of Paris is used. Some surgeons prefer to immobilize while the leg is flexed to a right angle with the thigh. In a severe case the surgeon can immobilize after forcibly straightening (causing an epiphyseal separation) or after the performance of osteotomy (see page 778). Osteotomy is preferable to fracture by a mechanical appliance (osteoclasis).

Genu varum (bow-legs) is the opposite of knock-knee. It tends much more to self-correction than knock-knee because of the arrangement of the thigh muscles, the powerful adductors acting strongly on the knee and middle of the leg (J. Torrance Rugh, in "Am. Jour. Orthop. Surg.," April, 1908). Usually both legs are bowed *out*, the knees being widely separated, the tibiæ and femora, as a rule, being curved, and the feet being turned in. This disease

in early life is due to rickets, the weight of the body producing the deformity. In older people incurable bow-legs may arise from osteitis deformans.

Treatment.—Some mild cases of genu varum recover as a result of improvement in the health. Ordinary cases are treated by braces, by plaster-of-Paris bandages, and by attention to the general health. Braces usually suffice prior to three and a half years of age. Later, when the bones have hardened in severe deformity, osteotomy is necessary and should be done at the apex fo the curve.

Fig. 533.—Club-hand.

Club-hand (Fig. 533).—A congenital deformity in which the hand deviates from the normal relation to the forearm. It is usually associated with other deformities. In some cases the radius and possibly some of the carpal bones are absent.

Treatment.—By massage and passive motion, by immobilization, by tenotomy or osteotomy, or by bone-grafting.

Talipes (club-foot) is a permanent deviation of the foot into deformity. There are several forms: *talipes equinus* (Fig. 535) is a confirmed plantar flexion; *talipes calcaneus* (Fig. 536) is a confirmed dorsi-flexion; *talipes varus* is a confirmed adduction and *talipes valgus* is a confirmed abduction. Two of these forms may be combined, as in talipes equinovarus (Fig. 537), talipes equinovalgus, talipes calcaneovarus, and talipes calcaneovalgus. The causes of talipes are congenital or acquired. The congenital form may be due to persistence of the fetal form of the foot. There are three theories of the cause of the deformity: viz., the nervous theory, the mechanical theory (intra-uterine pressure), and arrest of development. Acquired cases may arise from infantile paralysis, from spastic contractions, from cicatrices, from traumatisms, from arrest of bony growth following upon the inflammation of bone, or from hysterical contractures.

Fig. 534.—Deformities of hands and feet.

Talipes equinus is rarely congenital. In this condition the patient walks upon the toes and cannot bring the heel to the ground.

Talipes Calcaneus.—The patient walks upon the heel and cannot bring the toes to the ground. In congenital cases, the flexors of the foot are shortened and the tendo Achillis is lengthened.

In paralytic cases the dorsal flexors are normal and the muscles which act upon the tendo Achillis are paralyzed.

Talipes varus is seldom seen without equinus. In this condition the patient walks on the outer edge of the foot.

Talipes valgus is met with in flat-foot. The patient walks on the inner edge of the foot.

Talipes Equinovarus.—The heel is raised and the patient walks upon the outer edge of the foot. This is the usual congenital form.

Talipes equinovalgus is very rarely congenital. The heel is raised and the patient walks upon the inner side of the foot.

Talipes calcaneovarus is a combination of calcaneus and varus.

Talipes calcaneovalgus is a combination of calcaneus and valgus and commonly follows infantile paralysis.

Treatment.—In congenital cases the condition is usually manifest on both sides, and is nearly always talipes equinovarus. It is better that both sides should be affected, as the feet will then be symmetrical through life. Congenital club-foot should be treated in infancy, and when a restoration to position can be effected by the hands of the surgeon, is treated by plaster-of-Paris

FIG. 535.—Talipes equinus (Albert).

FIG. 536.—Talipes calcaneus (Albert).

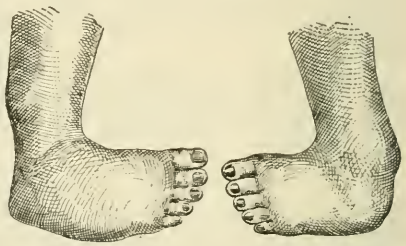

FIG. 537.—Double equinovarus ("American Text-Book of Surgery").

bandages. If a child has begun to walk, it may still be possible to correct the deformity eventually by manipulations, by plaster-of-Paris bandages, or by club-foot shoes, but most cases require tenotomy of the tendo Achillis and other contracted structures before the application of the shoe or the plaster. The club-foot shoe may do good service, but in many instances it is painful and is not so efficient as plaster of Paris. In severe cases, before applying the plaster, the patient is given ether; the surgeon cuts the tendons of the anterior and posterior tibial muscles, the plantar fascia, the tendo Achillis, and the long flexor of the toes, in the order named, and forcibly corrects the deformity. In all cases of congenital club-foot the secret of successful treatment is the daily stretching of the foot after operative correction. In old cases, with alteration in the shape of the bones, cuneiform osteotomy, or the removal of the cuboid or other tarsal bones, may be indicated. Buchanan employs subcutaneous division of all resistant structures. Occasionally, in relapsed and inveterate cases, *astragalectomy* is performed. It is seldom practised upon young children (see page 795). In some cases of talipes calcaneus shortening of the tendo Achillis is advised; but such an operation is only of temporary value, as stretching occurs after two years or more. In talipes due to infantile paralysis the operative treatment is the same, but we should not immobilize in plaster, but rather in some apparatus which can easily be removed to permit the use of massage and electricity. In paralytic cases tendon-transplantation is occasionally employed. This consists in transferring the tendon of an active muscle so that it will take the place of the tendon of a paralyzed muscle. The transferred tendon should always be attached to the periosteum (Tubby and Jones on the "Surgery of Paralysis").

Pes planus (flat-foot) is a condition in which there is loss of the arch of the foot due to muscular paralysis or ligamentous weakness, to prolonged standing, or to trauma. Flat-foot is especially apt to occur in rickets. *Spurious flat-foot*, or *inflammatory flat-foot*, occurs in Pott's fracture and in inflammation of the ankle-joint or of the tendon of the peroneus longus muscle. *Paralytic flat-foot* is seen after infantile paralysis. *Static flat-foot* is due to disproportion between the body weight and the support of that weight. All children are born with pronated feet; the arch usually begins to form soon after birth, but in some individuals it never forms. Flat-foot, according to de Vlaccos, is thus produced: If we suppose a straight line prolonged downward from the center of the leg, most of the astragalus and os calcis will be external to it; hence the body weight presses on the inner side of the foot, and tends to flatten the arch and cause outward rotation, tendencies which are antagonized by the flexors of the toes and by the tibialis posticus muscle. The os calcis is pronated and is pushed to the side, the astragalus moves after the os calcis, and the ligaments are stretched ("Rev. de Chir.," Aug., 1901). A very common cause is contraction of the tendo Achillis. In childhood the condition is seldom recognized, but in an adult with contracted Achilles tendon long hours of standing will quickly precipitate the acute symptoms of flat-foot. Pes planus is productive of much pain upon standing or walking; in fact, the individual may be completely crippled. Pain is quickly relieved upon sitting down. Walking upon the toes is not painful. A marked flat-foot can at once be recognized by wetting the sole of the patient's foot with a colored fluid and causing him to step firmly upon a piece of paper (Fig. 538, B). Beginning flat-foot cannot be thus recognized and is frequently overlooked, the patient being treated for gout or rheumatism. Even a slight case can be detected by carefully observing the inner surface of the foot. When weight is placed upon it, it is seen to descend as the arch falls. A more accurate method is measurement, to find the middle of the foot. In flat-foot the extremity is lengthened. Golding-Bird points out that the middle of the normal foot is the point of articulation of the inner cuneiform and the metatarsal bone of the great toe. In flat-foot the greatest change is in the posterior half of this line. The extent to which the posterior measurement exceeds the anterior is the degree of flat-foot. The excess may reach ¾ inch.

A B

FIG. 538.—Print of a normal foot sole (A) and of a flat-foot sole (B) (Albert).

Treatment.—In *paralytic flat-foot*, which arises from infantile paralysis, employ exercise, electricity, and massage. To maintain a correct position of the ankle and to facilitate normal muscular action, apply suitable braces. In some cases of paralytic flat-foot it is advisable to stiffen permanently the ankle-joint by operation. Operation is not indicated before the twelfth year, because during the earlier years of life union will probably fail to occur. Goldthwait removes the cartilage from the articular surfaces of the astragalus, calcaneus, tibia, and malleoli, and seeks to obtain permanent bony ankylosis. In *static flat-foot* it has long been customary to advise rest in bed for two weeks, and then exercise for several hours a day to increase the arch. The usually recommended exercise has been to rise upon the toes and lower again and again, with the ankles turned outward. The patients rests for a time after each séance of exercise by sitting tailor-fashion with the legs crossed under him or by standing on the outer edges of the feet. Massage is ordered and a special shoe is made to raise the arch of the foot. The shoe must fit the heel snugly and have a firm, broad heel. In some cases it is necessary to use a Thomas heel; in others, a steel shank. The patient's general health is, of course, attended to.

Many orthopedic surgeons have come to regard this usual treatment as unphilosophical and improper for many cases.

It is essential to understand that a static flat-foot may be a fully functionating foot, free from pain and disability, and, therefore, not a subject for treatment. For convenience, flat-foot is divided into rigid and flexible. Either form may be free from pain. The pain of flat-foot is usually the result of excessive use. It must be differentiated from Albert's disease (achillodynia), metatarsalgia, osteophytes on the under surface of the os calcis, and Raynaud's disease. Rigid flat-foot can be made flexible by manipu-

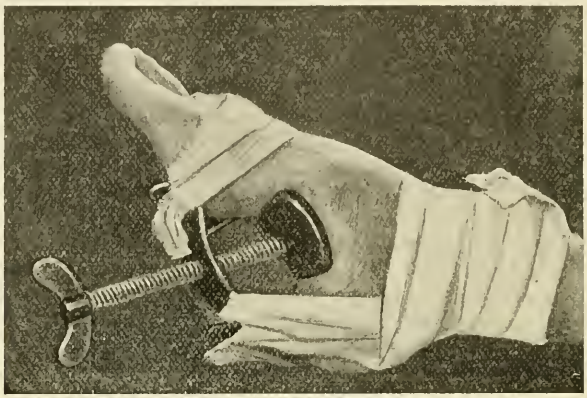

Fig. 539.—H. Augustus Wilson's flat-foot correction screw.

lative measures (according to Whitman's method) or by the employment of H. Augustus Wilson's flat-foot correction screw (Fig. 539). This apparatus pulls down on the posterior part of the os calcis and the distal extremities of the metatarsal bones and pushes up beneath the tarsus. The force employed is very great and much care should be exercised when it is used upon a patient under anesthesia. It is preferable to use it without ether, relying upon the patient to state when the pressure becomes unendurable. A flexible flat-foot is capable of correction by exercises.

Fig. 540.—Whitman's plate to support the arch of the foot in flat-foot (Fowler's "Surgery").

It was formerly customary to prescribe always various forms of steel plates to correct the broken-down arch, but some orthopedic surgeons are discouraging their use, believing that they destroy the muscular control of the foot, and by weakening the foot render it susceptible to sprains and other injuries. It is my belief that steel plates should often be used, but never abused (Fig. 540). When plates are necessary because the patient is heavy or because he must continue a trying occupation, they must be fitted to the individual case and must be

worn until such time as the use of exercise has enabled the patient to maintain properly the body weight with the strengthened arches. If the tendo Achillis is shortened it must be lengthened by operation or else the heel of the shoe must be raised to permit the fullest range of dorsal flexion the tendon allows. When muscle tone is low and there is small chance of restoring it, H. A. Wilson ("Amer. Medicine," May 6, 1905, page 725) advocates the employment of the method devised by Professor Müller ("Central. f. Chir.," January 10, 1903, page 40) for paralytic valgus. It consists of an arthrodesis of the astragaloscaphoid joint, and transplantation of the tendon of the extensor proprius hallucis into a hole drilled free from above downward through the scaphoid. Fixation in plaster of Paris in an overcorrected position is maintained for four weeks and then corrective exercises are employed. The anterior tibial tendon is supplemented in its action by the transplanted tendon.

Gleich shortens the foot and raises the arch by sawing through the os calcis and fastening the posterior part of this bone at a lower level. Trendelenburg advises supramalleolar osteotomy. This operation permits of adduction, and the adducted foot should be put up in an immovable dressing of plaster of Paris. Ogston resects the astragaloscaphoid joint. Golding-Bird and Davy remove the scaphoid bone. Stokes removes a wedge-shaped piece from the head and neck of the astragalus. Rugh has taken a wedge-shaped piece of bone from the inner side and inserted it in the outer side.

Pes cavus (hollow foot) is an increase in the arch of the foot, due, possibly, according to Golding-Bird, to paralysis of the peronei muscles. When the peronei muscles are paralyzed the adductors act unopposed, and secondary contraction of the plantar fascia occurs. Certain it is that a contracted plantar fascia is the chief obstacle to correction. In many cases the cause is the wearing of shoes which are too short for the feet. The pressure made upon the toes causes spasm of the plantar flexors and this spasm permits the fascia to contract.

Treatment.—In a paralytic case a shoe is worn containing a plate of steel in the sole, and pressure is applied over the instep. If equinus exists tenotomy of the Achilles tendon is indicated. If there is calcaneus divide the plantar fascia or perhaps transplant the tendons of peronei and posterior tibial to the os calcis (G. G. Davis, "Am. Jour. Orthop. Surg.," 1913, xi). The operation of Forbes transplants the tendon of extensor longus hallucis to the head of the first metatarsal bone. In all, if the calf muscles are entirely paralyzed and there is marked calcaneus perform astragalectomy. In paralytic cases apply electricity and massage to the paralyzed muscles. If there is no palsy cut with a tenotome the plantar fascia and the tendon of the flexor longus hallucis.

Hallus valgus or **varus,** a displacement of the great toe outward or inward may occur in the young, but it is most frequent in old persons, especially old women. It arises often from wearing pointed shoes, shoes that are too short, or high heels, but may be due to gout or to rheumatic gout. In many cases an exostosis forms in the inner portion of the distal end of the metatarsal bone. In hallux valgus a *bunion* (bursa) is apt to form over the metatarsophalangeal joint and it may inflame or ulcerate.

Treatment.—An arrangement may be worn to straighten the toe and to protect the bunion (see Fig. 525). The prominent and hypertrophied inner portion of the head of the metatarsal bone may be removed by means of a chisel, osteotomy may be performed upon the metatarsal bone, the joint may be excised. Amputation should not be done as it removes the weight-bearing head of the metatarsal bone. H. A. Wilson advocates lateral excision. By means of bone-forceps he cuts away that part of the distal extremity beyond the phalanx, and by a chisel removes the remaining sharp line edge. He places the phalanx in normal position and holds it so for two weeks ("Am. Jour. Orthopedic Surgery," Jan., 1906).

Hammer-toe (Figs. 541 and 542) is a condition in which there is flexion of one or more toes at the first interphalangeal joint. Shattuck shows that this condition is due to contraction of "the plantar fibers of the lateral ligaments of the joint."[1] This disease usually begins in youth and may be congenital. A bunion is apt to form, and the joint may become dislocated.

Treatment.—Subcutaneous division of the lateral ligaments and flexor tendon usually allows straightening of the toe. After the operation the toe must be held in extension for several months by means of a short splint and adhesive plaster. Terrier's plan of treatment consists in making a dorsal flap, removing a bursa if one is found, dividing the extensor tendon, opening the articulation, removing each articular surface by cutting forceps, suturing the soft parts, and applying a plantar splint for two weeks.[2] The base of the proximal phalanx may be removed. Some surgeons simply excise the joint. Amputation should not be performed except perhaps in the case of the little toe. Amputation of a toe weakens the foot.

FIG. 542.—*X*-ray of hammer-toe.

Metatarsalgia (Morton's Disease).—This disease was first described by Dr. Thomas G. Morton, of Philadelphia, in 1876. It is a painful condition of the foot, caused by ligamentous relaxation, which permits the sagging down of the heads of the second, third, or fourth metatarsal bones, two of them or all of them. Morton believed the pain to be due to jamming of a nerve between the heads of the fourth and fifth metatarsal bones. The head of the fifth metatarsal bone is, by lateral pressure, forced against and below the neck of the fourth metatarsal, and as a result the superficial branch of the external plantar nerve and its two digital branches are squeezed. It is usually associated with flat-foot. Loss of the metatarsal arch will jam other nerves than that between the fourth and fifth metatarsals, and will produce a condition similar to Morton's disease, the pain being differently situated. Pain, in Morton's disease, is produced by walking, and the suffering may be so severe that the patient is obliged to sit down at once. When the shoe is removed and the foot is rested the pain soon abates. The pain is felt usually between the fourth and fifth toes and about the head of the fifth and the neck of the fourth metatarsal bones. Pain can be developed by grasping the foot in the hand and squeezing it. If flat-foot exists, there is also pain due to this trouble. The condition is common in golfers and is then called golfer's foot.

FIG. 541.—Hammer-toe.

Treatment.—Mild cases may be cured by wearing well-fitting shoes and an arch support, the use of hot air, proper exercise and massage. The shoe should have a small elevation in the sole to restore the metatarsal arch and so relieve lateral pressure on the nerve. Some cases require a brace. Jones puts a bur on the sole of the shoe so that the weight will be thrown behind the heads of the metatarsal bones. He also raises the heel $\frac{1}{8}$ inch on its inner side, binds a band of adhesive plaster around the base of the metatarsals, directs exercise of the small muscles of the foot and orders massage. If an early case is treated in this manner a cure will be obtained in a few weeks. Severe cases demand resection of the fourth metatarsophalangeal joint, or amputation of the fourth toe, and with it the head of the fourth

[1] "American Text-book of Surgery."
[2] "Rev. de Chir.," July, 1895.

metatarsal bone. Graham, of Washington, has cured cases by excising a portion of the superficial branch of the external plantar nerve.

Coxa Vara and Coxa Valga.—Coxa vara (*incurvation* or *infraction of the neck of the femur*) (Fig. 543) is a disease characterized by bending of the neck of the femur, the femoral neck being depressed below its normal obtuse angle with the shaft, the hip-joint being perfectly healthy, and the condition, as a rule, being unilateral, but sometimes bilateral. This condition was described by Müller in 1889. Coxa vara is first noticed, as a rule, between the thirteenth and twentieth years, and the commonly accepted view has been that the deformity is rachitic, but Kredel has reported 2 congenital cases.[1] Traumatic coxa vara may follow impacted fracture of the neck of the femur in a child. An individual with coxa vara develops a limp, and grows tired after slight exertion, but there is no swelling, no tenderness, and little or no pain. Shortening after a time becomes apparent, the great trochanter can be detected above Nélaton's line, and the head of the bone is in the acetabulum. If the head

Fig. 543.—Congenital dislocation of the hip on one side and coxa vara on the other.

is in the acetabulum it can be recognized as being there by locating the femoral artery ½ inch below Poupart's ligament and making pressure directly backward at that point. The head, if in place, will be felt. The extremity is adducted and usually rotated outward. Abduction is limited. In some cases in which there is joint irritation all joint motions may be distinctly limited.

In a bilateral case there is lordosis, but shortening may not be detected because both legs are the same length. Each great trochanter, however, is above Nélaton's line and the head of each bone is in the acetabulum.

Coxa valga is a condition in which the angle of the neck to the shaft of the femur is more obtuse than normal. The neck may assume a position in line with the long axis of the shaft. It occurs particularly in children who have had infantile palsy, but it may be congenital, may occur in rickets and osteomalacia, and after a prolonged period of disuse of a limb. The patient has pain and a limp, the extremity is lengthened, abducted, and in external rotation there is limitation of adduction and the trochanter is flattened. Coxa valga is usually unilateral, but may be bilateral.

[1] "Centralbl. f. Chir.," Oct. 17, 1896.

Without the *x*-rays the differential diagnosis in coxa vara and coxa valga is often very difficult, and the accompanying table will materially aid in contrasting the conspicuous features of the various conditions with which these two deformities of the neck of the femur may be confounded:

TABLE MODIFIED FROM THAT OF DR. H. AUGUSTUS WILSON

	Hip disease	Infantile paralysis	Congenital dislocation	Psoas abscess	Coxa vara or valga	Knee disease
Age.	Three to fifteen.	Three to fifteen.	Any age.	Three to fifteen.	Any age.	Three to fifteen.
Onset.	Insidious.	Sudden.	From birth.	Insidious.	Childhood.	Insidious.
Pain.	Referred to knee.	None.	None.	Referred to abdomen.	None in hip.	In knee.
History.	Tuberculous.	Inflammatory disease.	Limp from birth.	Tuberculous.	Limp.	Tuberculous
Posture.	Flexion, abduction, external rotation.	Uncontrolled.	Shortening and external rotation.	Flexion, adduction, external rotation.	Great trochanter higher in vara and lower in valga.	Knee flexed.
Muscular rigidity.	Present in all directions.	Absent.	Absent.	In one direction.	None.	About knee.
Temperature.	1 degree high.	Normal.	Normal.	1 degree.	Normal.	1 degree.
Local tenderness.	In hip.	None.	None.	None.	None.	In knee.
Night cries.	Present.	Absent.	Absent.	Present.	Absent.	Present.
Tendency to abscess.	Yes.	No.	No.	Yes.	No.	Yes.
X-ray.	Diseased focus in hip.	Atrophy.	Alteration in joint.	Normal hip.	Alteration in neck angle.	Normal hip, focus in knee.
Muscular atrophy.	Profound.	Profound.	Absent.	Absent.	Absent.	Profound.

The *x*-rays clearly show the deformed bone in either coxa vara or coxa valga.

Treatment.—In coxa vara, as long as bending is progressing, employ rest. When the bone hardens, it may be necessary to perform osteotomy below the trochanters. In coxa valga Galeazzi performs osteotomy through the neck of the femur and allows the trochanter to ascend.

Flail-joints from Infantile Palsy.—In the subacute stage of infantile palsy, there is paralysis but no fever. Neither massage nor electricity are admissible until tenderness has disappeared. Splints are used to antagonize deformity. When the patient is convalescent massage and electricity are of great use and braces are used. After an attack of infantile paralysis involving the entire lower extremity of each side the limbs become limp and swing flail-like when the extremity is made to move, and the joints are much relaxed. In such cases the psoas and iliacus muscles are never completely paralyzed, and the aim of the surgeon is to utilize these muscles in enabling the patient to walk. In many cases the application of apparatus is sufficient. In others ankylosis may be established in the ankles and knees by operation. If ankylosis is established in these joints, the psoas and iliacus muscles become able to move the legs. Tendon transplantations may be performed, tenotomy or osteotomy may be indicated. A joint is stabilized most securely by utilizing as ligaments the tendons of totally paralyzed muscles, attaching them subperiosteally or to the bone (Putti).

XXIII. DISEASES AND INJURIES OF NERVES

Diseases of Nerves

Neuritis, or **inflammation of a nerve,** may be limited or be widely distributed (*multiple neuritis*). The first-mentioned form will here be considered. The causes of neuritis are traumatism, wounds, overaction of muscles, gout, rheumatism, syphilis, fevers, and alcoholism.

The **symptoms** of neuritis are as follows: excessive pain, usually intermittent, in the area of nerve-distribution. The pain is worse at night, is

aggravated by motion and pressure, and occasionally diffuses to adjacent nerve-areas or awakens sympathetic pains in the opposite side of the body. The nerve is very tender. The area of nerve-distribution feels numb and is often swollen. Early in the case the skin is hyperesthetic; later it may become anesthetic. The muscles atrophy and present the reactions of degeneration; that is, the muscles first cease to respond to a *rapidly* interrupted faradic current, and next to one with slower interruptions; faradic excitability diminishes, but galvanic excitability increases. When, in neuritis, faradism produces no contraction, a slowly interrupted galvanic current which is so weak that it would produce no movement in the healthy muscle causes marked response in the degenerated muscle. In health the most vigorous contraction is obtained by closing with the − pole; in degenerated muscles the most vigorous contraction is obtained by closing with the + pole. When voluntary power returns, galvanic excitability declines; but power is often nearly restored before faradic excitability becomes manifest (Buzzard).

The **treatment** of neuritis consists of rest upon splints and the use of an ice-bag early in the case and a hot-water bag later. Blisters over the course of the nerve are of value, especially in traumatic neuritis. Massage and electricity must be used to antagonize degeneration. A descending galvanic current allays pain to some extent. Deep injections of chloroform or cocain may allay pain. Treat the patient's general health, especially any constitutional disease or causative diathesis. The salicylate of ammonium or phenacetin may be given internally. In some cases nerve-stretching is advisable.

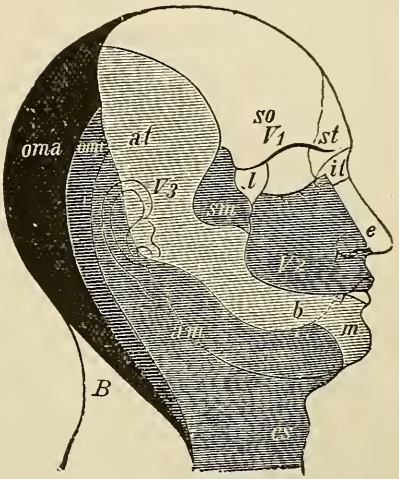

Fig. 544.—Distribution of the cutaneous sensitive nerves upon the head: *oma*, *omi*, The occipit. maj. and minor (from the N. cervical. II and III); *am*, N. auricular magn. (from N. cervic. III); *cs*, N. cervical. superfic. (from N. cervic. III); V_1, first branch of the fifth (*so*, N. supraorbit.; *st*. N. supratrochl.; N. infratrochl.; *e*, N. ethmoid.; *l*, N. lachrymal.); V_2, second branch of the fifth (*sm*, N. subcutan. malæ seu zygomaticus); V_3, third branch of the fifth (*at*, N. auriculotempor.; *b*, N. buccinator; *m*, N. mental.); *B*, posterior branches of the cervical nerves (Seeligmüller).

Neuralgia is manifested by violent paroxysmal pain in the trajectory of a nerve. This disease, unless it is exceedingly severe and persistent, is treated, as a rule, by the physician. Injections of alcohol or osmic acid into the nerve may secure relief or cure. If neuralgia is due to adhesions about the nerve or to the pressure of scar or callus, these conditions should be amended surgically. There is some evidence that neuralgia arises, at least occasionally, from dilatation of the vessels of the sheath and subsequent edema and exudation. If this be the case cure may follow opening the sheath and separating adhesions between the sheath and nerve (Robert M. Simon, in "Brit. Med. Jour.," April 10, 1909). Neuralgia of stumps and scars is a surgical condition, and is due to neuromata, or entanglement of nerve-filaments in a cicatrix. *Tic douloureux* and other intractable neuralgias require careful removal of any cause of reflex irritation. Causal reflex irritation may arise from disease of the stomach, eyes, teeth, uterus, nose, throat, etc. Tic douloureux has been treated by removal of the Gasserian ganglion; intracranial neurectomy of the second and third divisions; section of the sensory root; removal of Meckel's

ganglion; ligation of the common carotid artery; neurectomy of terminal branches of the fifth nerve; division of motor nerves; injections of osmic acid (see page 856); injections of alcohol (see page 856); advancing doses of strychnin (Dana) and purgatives (Esmarch). The distribution of the fifth nerve, the seat of pain in tic douloureux, is shown in Fig. 544.

Sciatica.—This may be acute or chronic, a neuralgia or a neuritis. True sciatica is perineuritis of the sciatic nerve, a very rare lesion. In most cases sciatica is a symptom. Violent and perhaps long-continued pain in the nerve may be a reflex phenomenon. In three cases most obstinate and crippling sciatic pain was cured by removing a diseased appendix. In each case the appendix was posterior. It may be due to pelvic disease, to disease or injury of the sacro-iliac joint, the lumbosacral joint or the lumbar articulations, to disease of the rectum, to traumatism, to exposure to cold or damp, to syphilis, or to alcohol.

Exposure to cold causes the rheumatic form. Indiscretions in diet may instigate a gouty form. In some cases of diabetes violent nerve pain is experienced; the same is true of malaria. Sitting long hours on a hard and ill-shaped bench or chair may be responsible ("Jour. Am. Med. Assoc.," March 18, 1916). Of course focal infection has been blamed (teeth, tonsils, etc.).

Flat-foot causes some cases. Tumor of the nerve or the nerve-sheath causes violent pain.

Treatment.—Seek for any possible cause of reflex irritation and remove it. Remove any cause of nerve pressure. Treat any existing disease or diathesis. Rigid diet, rest in bed, splinting of the extremity, warmth, application of blisters or the actual cautery over the nerve and the high-frequency current do good. If the case does not improve inject salt solution or cocain about the nerve. A very severe and prolonged case may call for nerve-stretching.

Treatment of Neuralgia of Stumps.—Excise the scar; find the bulbous end of the nerve and cut it off. Senn tells us to section the nerve by V-shaped cuts, the apex of the V being toward the body, and to suture the flaps together. Senn's method will prevent recurrence. In some cases reamputation is performed. In entanglement of a nerve in a scar remove a portion of the nerve above the scar and also the neuroma in the scar.

Wounds and Injuries of Nerves

Section of Nerves (as from an incised wound).—After nerve-section sensation and motor power are lost at once. The entire peripheral portion of the nerve degenerates and ceases structurally to be a nerve in a few weeks, but after many months, or even years, the nerve may regenerate. The proximal end degenerates only in the portion immediately adjacent to the section; it rapidly regenerates, and if it does not adhere to the peripheral segment a bulb or enlargement composed of fibrous tissue and small nerve-fibers forms just above the line of section; this bulb adheres to the perineural tissues. The entire distal end degenerates, but new axis-cylinders form in this segment by proliferation of the nuclei on the sheath of Schwann. Union of a divided nerve is brought about by the projection of axis-cylinders from the proximal end or from each end and the fusion of these cylinders. The nearer the two ends are to each other, the better the chance of union. When a nerve has been divided and has not been sutured, abolition of function may be permanent or restoration may occur. Sensation may return in from six weeks to several months. Motor power may never return. If it does return it will do so long after sensory restoration. Restoration of motor power requires from twelve weeks to three and one-half years. It is seldom noted before six months. The return is always slow (John B. Murphy, in "Surg., Gynec., and Obstet.," April, 1907). Failure of return means that the ends are separated by a wide interval or that fascia is interfused between them. In some recorded cases

motion and sensation have returned with great rapidity, due, some have said, to anastomoses with adjacent nerves. Murphy shows that when restoration begins, trophic energy returns even before sensation, and when trophic energy returns the blueness and coldness of the limb lessen.

The nerve-fibers which convey impressions of cutaneous pain and of extreme heat and cold regenerate far more rapidly than those which subserve sensations of light touch and slight degrees of heat and cold.

The investigations of Head and others show that restoration of sensation does not begin at the normal area and spread from there over the anesthetic area, but that the reverse is the case. It begins from the confines of the anesthetic area and spreads toward the normal part.

General Symptoms.—Immediately after nerve-section vasomotor paralysis comes on, and for a few days the paralyzed part presents a temperature higher than normal. It then becomes blue and cold. Pronounced changes occur in the trajectory of a divided nerve. The muscles degenerate, atrophy and shorten, and develop the reactions of degeneration. When union of the nerve occurs the muscles are restored to a normal condition. If the nerve contains sensory fibers, complete anesthesia (to touch, pain, and temperature) usually follows its division; but if a part is supplied by another nerve as well as by the divided one, anesthesia will not be complete. Trophic changes arise in the paralyzed parts. Among these changes are muscular atrophy; glossy skin; cutaneous eruptions; ulcers; dry gangrene; painless felons; falling of the hair; brittleness, furrowing, or casting off of the nails; joint inflammations, and ankylosis. The diagnosis as to which nerve is cut depends upon a study of the distribution of motor and sensory paralysis.

A curious fact that was pointed out by Letiévant is that after division of a nerve blunt pressure may be appreciated over the entire analgesic area. This phenomenon was long thought to be due to nerve anastomoses, the sensory areas from different nerves overlapping. The explanation now given is founded on Sherrington's demonstration that the motor branches of a mixed nerve carry sensory fibers through muscles and tendons, and Head's proof that certain afferent fibers convey impressions of deep sensibility as produced by pressure.

The Symptoms of Division of Nerves.—*Brachial Plexus.*—If one or more cords of the brachial plexus are divided, motor paralysis and anesthesia appear in the limb, the extent of the paralysis and the area of the anesthesia depending upon the cord or cords involved. It should be remembered that the inner cord of the brachial plexus gives origin to the ulnar nerve; the inner and outer cords give branches which fuse to form the median nerve. The posterior cord gives origin to the subscapular, the circumflex, and the musculospiral nerves. The outer cord gives origin to the external anterior thoracic and the musculocutaneous, as well as to the outer trunk of origin of the median.

Avulsion or *rupture of the brachial plexus* is sometimes effected by an injury, when the arm is not lost. Most cases are due to indirect violence and are associated with skeletal injury, for instance, dislocation of the shoulder, fracture of the humerus, or fracture of the clavicle (Frazier and Skillern, paper before Section on Surgery, "Amer. Med. Assoc.," 1911). Bristow ("Annals of Surgery," Sept., 1902) reported 3 cases of avulsion of the plexus and collected 24 more. Frazier and Skillern (Loc. cit.) collected 23 cases of avulsion without skeletal injuries and confirmed by operation. In each of these cases the rupture was between the clavicle and the transverse process of the vertebra. In the case of Frazier and Skillern the rupture was within the dura. The patient was seen by them three months after the accident. He suffered from horrible pain in the arm and hand. Sensations to touch and pain were entirely lost in the hand and forearm and in the arm to 2 or 3 inches above the elbow. From this point to about 4 inches below the shoulder they were much impaired. Sensation was impaired in the entire distribu-

tion of the intercostohumeral nerve, and of the fifth and sixth cervical roots, as well as in the distribution of the brachial plexus. There was flaccid palsy of the entire extremity, including the deltoid. On the injured side the pupil was contracted and the palpebral fissure narrowed. One of Bristow's cases was operated upon the third day after the accident (Loc. cit.). In this case there was complete paralysis of the upper extremity, with the exception of the sensory area of the intercostohumeral and the circumflex nerves. The accident had been inflicted by the patient's forearm becoming entangled in a rope, which was pulled upon by a steam winch. On reaching the hospital he felt severe pain, referred to the arm. There was much swelling in the inner portion of the subclavian triangle, the left pupil was contracted, and it seemed likely that the nerves had been avulsed close to the intervertebral foramina. From the fact that sensation was preserved in the skin of the convexity of the shoulder down to the insertion of the deltoid, Bristow concluded that some fibers of the posterior cord of the plexus had escaped division; but when the operation was performed this conclusion was found to be erroneous. An incision was made, and it was found that the plexus had given way at the point where the four cervical nerves and the last dorsal unite to form the three trunks. In order to reach the lower ends it was necessary to saw the clavicle and divide the two pectoral muscles; and the torn ends of the nerve-trunks were found underneath the clavicle. Suturing was performed. The ends of the sawn clavicle were sutured together, the wound was closed and dressed, and the arm was put up in Sayre's dressing.

After the performance of this operation sensation over the entire upper arm returned. The author once operated upon a patient that had developed paralysis, motor and sensory, after violent stretching of the arm. In the light of Bristow's case I assumed that avulsion of the plexus had probably taken place. Incision disclosed the fact that the plexus was intact, but was surrounded with dense scar-tissue. The tissue was removed, so as to loosen the nerves, which felt like hard cords; but I have lost track of the patient, and do not know the result. My patient was operated upon many months after the injury. I operated upon another case and found intravertebral rupture. I anastomosed two divided nerves to a sound one. The operation was done months after the injury and the patient is apparently slightly improved three months after operation. The location of the seat of injury is of great importance. Lesion within the vertebræ is positively indicated by contraction of the pupil, narrowing of the palpebral fissure, and enophthalmos on the affected side (Frazier and Skillern, "Amer. Med. Assoc.," 1911), but there can be intravertebral injury without these phenomena. The ciliospinal fibers on which these phenomena depend usually accompany the eighth cervical and first thoracic nerves.

Injury above the clavicle will involve the circumflex and musculospiral. As the great pectoral is supplied from both the external and internal cords of the plexus, complete paralysis of the great pectoral proves that both cords are involved, and unimpaired movements of the diaphragm on the side of the lesion (observed with the fluoroscope) show that the cords of the plexus are not divided within the foramina, but well outside of them (John B. Murphy, in "Surg., Gynec., and Obstet.," April, 1907). In all cases of rupture prompt operation is indicated. Long delay means a hopeless prognosis.

In injury without complete rupture the nerves become fibrous and embedded in scar-tissue. If operation is done before scar-tissue forms follow the advice of Frazier and incise the sheaths of the trunks or cords to liberate inflammatory exudate. If scar-tissue has formed, excise it. It may be necessary to excise portions of nerves or trunks with it. If this is done, suture the divided ends together. It may be necessary to do nerve-lengthening, suture à distance, or grafting in of a nerve from a recently amputated limb (if one can be obtained), or of the sciatic of a rabbit. In accessible rupture suture the divided

nerves. In some cases a divided cord or trunk may be anastomosed into a sound one. Ruptures near to, in, or within the intervertebral foramina do not admit of suturing. If a sound nerve is left the divided nerve or nerves should be anastomosed to it. If the entire plexus is ruptured we should consider the plan of Alexinsky (quoted by Frazier and Skillern, Loc. cit.): effect anastomosis between nerves of the injured side and nerves of the sound side. When intractable neuralgia follows rupture the posterior roots may be divided.

Brachial Plexus Palsy.—This can occur in the adult or at birth. In the adult it is due to a fall upon the side of the head or blows over the side and base of the neck (Wm. Sharpe in "Jour. Am. Med. Assoc.," March 18, 1916). It is rare in the adult. It is far more common as a *birth palsy.* Brachial palsy may arise after a difficult delivery. In most cases forceps have been used. Seventy per cent. of Sharpe's 56 cases involved the right arm and 28 per cent. the left arm, 78 per cent. followed head presentation and 22 per cent. breech presentation. It has been pointed out by Clark, Taylor, and Prout ("Am. Jour. Med. Sciences," Oct., 1905) that brachial birth palsy results from tension on the nerve-trunks by overstretching during delivery, the nerve-sheath first rupturing and then the nerve-fibers. When the sheath ruptures hemorrhage occurs, fibrous tissue forms, and the scar presses on the intact, slightly stretched, or actually lacerated nerve, and prevents repair. The authors tell us that the fifth cervical root first gives way, then the sixth, and so on down the plexus if there be sufficient force. In the milder cases the fifth root alone suffers. They call it *brachial birth palsy*, or *laceration palsy*, and sum up the symptoms in a severe case as follows: The arm hangs powerless; abduction at the shoulder is impossible because of deltoid and supraspinatus palsy; the forearm is extended and flexion is impossible because of biceps, brachialis anticus, and supinator longus palsy; palsy of supinator brevis and biceps causes pronation of hand; there is inward rotation of the humerus because of palsy of the supraspinatus, infraspinatus, and teres minor.

In a less severe case in which only the fifth and sixth cervical roots and the suprascapular nerve are involved, the upper arm is paralyzed but only the supinators of the forearm.

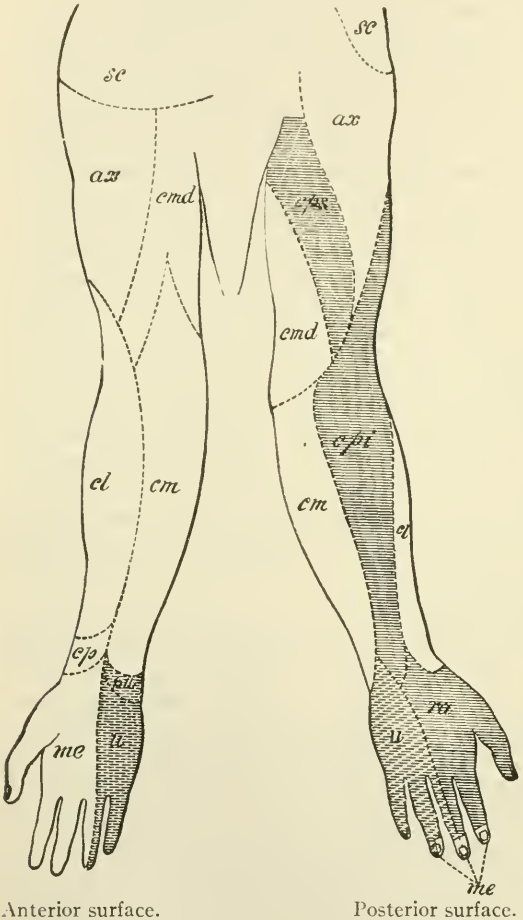
Klumpke's paralysis is a birth palsy in which the forearm alone is involved.

Brachial birth palsy is manifest soon after its infliction by evidences of pain on handling the extremity, the pain being due to neuritis (authors above quoted). The pupils may be unequal. This means injury to the sympathetic and to the eighth cervical or first dorsal which receive communications from the sympathetic (Sever, in "Am. Jour. Orthop. Surg.," 1916, xiv). The same force which caused the nerve injury may also have dislocated the humerus.

The usual plan of treatment is to reduce a dislocation if it exists and fix the arm in a bandage which elevates the shoulder. This relaxes the injured nerve-roots and so favors union. Sharpe (Ibid.) points out that this plan may be efficient in mild cases in which the roots have been merely overstretched or in which the impairment is due to dislocation. This treatment should be restricted to the mild cases. It is not the proper treatment for a case of "total paralysis of the arm, hand and fingers." It is true that improvement may occur even in severe cases, but "improvement rarely continues beyond one year of age, and the end-result is an impaired arm of greater or less severity; a useful arm is seldom obtained" (Sharpe, Ibid.). In a case of total paralysis I am convinced we should follow Sharpe's plan and expose the plexus when the child is one month of age. At this early age very little ether need be given, very little fibrous tissue will be met with, the nerve-ends will not have retracted and the results are always better from early than from late neurorrhaphy.

Posterior (Long) Thoracic Nerve.—Division of this nerve causes paralysis of the serratus magnus muscle, which is made evident by eversion from the thorax and rotation of the scapula when the arm is taken forward (*wing-like scapula*). In paralysis of this muscle the arm cannot be raised above the horizontal.

Suprascapular Nerve.—Division of this nerve produces some anesthesia over the scapula and paralysis of the supraspinatus and the infraspinatus muscles. The supraspinatus is but an adjuvant to the deltoid and palsy of it is not manifestly disabling. Palsy of the infraspinatus renders external rotation of the humerus impossible, and writing becomes most difficult because the pen cannot be moved along the paper. Sewing, too, is greatly interfered with.



Anterior surface. Posterior surface.

FIG. 545.—Distribution of the cutaneous nerves to the shoulder, arm, and hand. The region of the N. radialis is represented by the unbroken hatched line, that of the N. ulnaris by the broken hatched lines. *a*, Anterior, *b*, posterior surface; *sc*, Nn. suprascapular (plexus cervicalis); *ax*, chief branch of N. axillar.; *cps*, *cpi*, Nn. cutanei post. sup. and inf. (from N. radialis); *ra*, terminal branches of N. radialis; *cm*, *cl*, Nn. cutanei medius (also to the plexus) and lateralis (chiefly to the N. medianus); *cp*, N. cutan. palmar., N. rad.; *cmd*, N. cutan. medialis; *mc*, N. medianus; *u*, N. ulnaris; *cpu*, N. cutan. palm. ulnaris (Henle).

Circumflex Nerve.—Division of the circumflex nerve produces paralysis of the deltoid muscle, so that it becomes impossible to lift the arm to a right angle with the body. There is some slight retention of power in the anterior fibers, which are supplied by the anterior thoracic nerve. The skin over the lower part of the muscle is usually anesthetic.

Musculocutaneous Nerve.—Division of this nerve produces paralysis of the biceps and of the brachialis anticus muscles (paralysis of the forearm flexors). This palsy becomes especially evident when the forearm is supinated, because in this position the supinator longus can no longer act as a flexor of the elbow. There is anesthesia of the radial side of the forearm anteriorly and posteriorly.

The Musculospiral or Radial Nerve.—Division of this nerve high up near the plexus causes paralysis of the extensor muscles of the elbow and the wrist, of the supinators, and of the long extensors of the thumb and fingers. When divided near the middle of the humerus, the triceps usually, but not invariably, escapes. If the injury is below the branch going to the supinator longus, that muscle will escape; otherwise it will become paralyzed. The extensor palsy causes wrist-drop and loss of the power of extending the first phalanges of the fingers and thumb; and, as Gowers has pointed out, flexion is reduced to one-third of the normal, the flexors having lost power "from the loss of antergic support." As a rule, in musculospiral palsy there is loss of supination. Sensibility is sometimes greatly affected, and sometimes very slightly. If the

injury is above the level of the musculospiral groove there will be anesthesia in the area supplied by the sensory fibers of the nerve (Fig. 545). If the nerve is injured in the musculospiral groove there are seldom sensory disturbances. Anesthesia rarely occurs in the upper arm in any case, and even after an injury in the groove sensation in the hand may be normal or nearly so. Fig. 546 shows the position of the parts in musculospiral palsy and Figs. 545 and 547 the sensory distribution of the nerve. Fracture of the humerus may cause division of the musculospiral nerve.

The Median Nerve.—After division of this nerve there is paralysis of the pronators; the flexor carpi radialis; the finger flexors, except the ulnar portion of the deep flexor; the abductors, and the flexors of the thumb; and the two radial lumbricales. The forearm can be placed in a position midway between pronation and supination; but further pronation cannot be voluntarily effected. In executing flexion of the wrist a strong deviation toward the ulnar side takes place. The thumb is in a position of extension and abduction, and cannot be brought into apposition with the finger-tips. The second phalanges of the fingers cannot be flexed on the first, and the distal phalanges

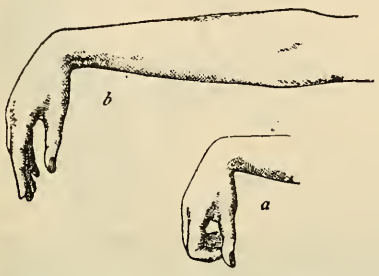


Fig. 546.—Paralysis of musculospiral nerve after fracture of the humerus ("wrist-drop"); but when fingers have been flexed into palm, *a*, they can be extended, *b*, at first interphalangeal joints by lumbricals and interossei, which are supplied by the ulnar and median nerves (Erichsen).

Fig. 547.—Distribution of sensory nerves on the backs of the fingers: *r*, Musculospiral or radial nerve; *u*, ulnar nerve; *m*, median nerve (Krause).

of the first and second fingers cannot be voluntarily flexed. The corresponding phalanges of the third and fourth fingers can be flexed, this being accomplished by the unparalyzed ulnar half of the deep flexor. Flexion of the first phalanges is still possible, as it is accomplished by means of the interossei. The extensor action of the interossei muscles upon the middle and distal phalanges, being unopposed, may eventually cause subluxation. The sensory distribution of the median nerve is shown in Figs. 545 and 547–549. It is the sensory nerve of the radial side of the palm, the front of the thumb, the first and second fingers and half of the third finger, and the back of the last phalanx of the index and the middle finger (Gowers). The sensory changes after median paralysis are quite variable—sometimes widespread and complete, at other times trivial, and occasionally absent. Gowers says that if there is anesthesia it is usually of the palmar surface, but it may also occur on the dorsal aspect of the ends of the first two fingers.

The Ulnar Nerve.—When this nerve is divided there is paralysis of the flexor carpi ulnaris, of the ulnar portion of the deep flexor, of the muscles of the little finger, of the abductor pollicis, and of the inner end of the flexor brevis pollicis (Gowers). It becomes impossible to adduct the thumb, and the majority of the movements of the little finger are abolished. Flexion of the fingers is impossible at the first joints, and extension is impossible at the

other joints; but, as Gowers points out, the loss is slighter in the first two fingers than in the others because the lumbricales of the first two fingers are

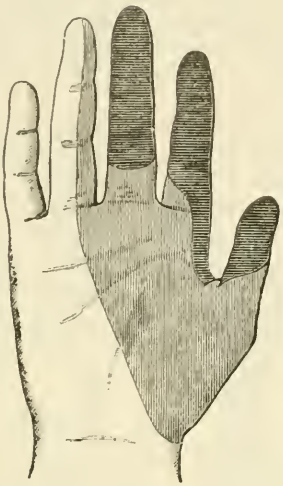

Fig. 548.—Section of median nerve; areas of anesthesia (heavy shading) and of dysesthesia (light shading) on palmar surface of hand (Bowlby).

supplied by the median nerve. Interosseal flexion is impossible, and the opponents of the interossei, acting without normal antagonism, contract and pro-

duce what is known as *claw-hand* (Figs. 550 and 551), a condition in which the first phalanges are overextended and the others are flexed. The sensory loss

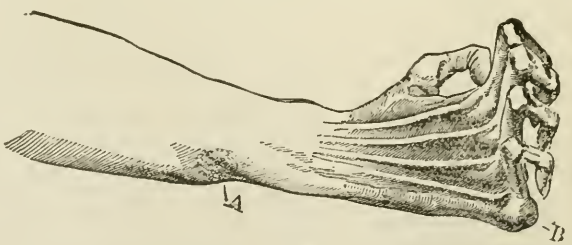

Fig. 551.—Paralysis of ulnar nerve from wound at *A*; contracture of common extensor with posterior luxation of first phalanges; *B*, head of metacarpal bone (Duchenne).

in ulnar paralysis is extremely variable. The sensory distribution is to the ulnar side of the hand, both back and front, involving the little finger, the ring-finger, and the ulnar half of the middle finger (Figs. 545, 547, 552, and 553).

The *lumbar plexus* supplies the cutaneous surface of the lower portion of the abdomen, of the front and the sides of the thigh, and of the inner portion of the leg and foot (Fig. 554). It innervates the flexors and adductors of the hip-joint, the extensors of the knee, and the cremaster muscle. The branches sent to the leg are the obturator and the anterior crural nerves.

The *sacral plexus* supplies the extensors and rotators of the hip, the knee-flexors, and all the muscles of the foot; also the skin of the gluteal region, the back of the thigh, the outer portion and the posterior part of the lower leg, and most of the foot (Gowers) (Fig. 554). Its chief branches are those to the external rotators of the hip—the gluteal nerve, the small sciatic, and the great sciatic.

The Anterior Crural Nerve.—When this nerve is divided the extensor muscles of the knees are paralyzed. The psoas muscle is not affected, even if

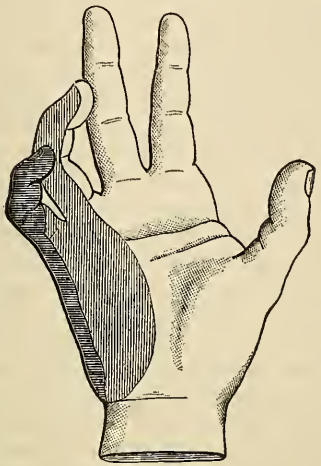

FIG. 552.

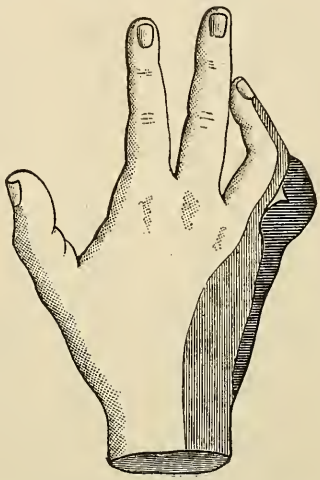

FIG. 553.

FIGS. 552 and 553.—Showing sensory loss and ordinary position in injuries of the ulnar nerve (Bowlby).

the nerve is divided within the abdomen; but high division may produce paralysis of the iliacus muscle. In anterior crural palsy the skin is anesthetic over almost the entire thigh, the inner surface of the leg and foot, and the inner sides of the first and second toes (Fig. 554).

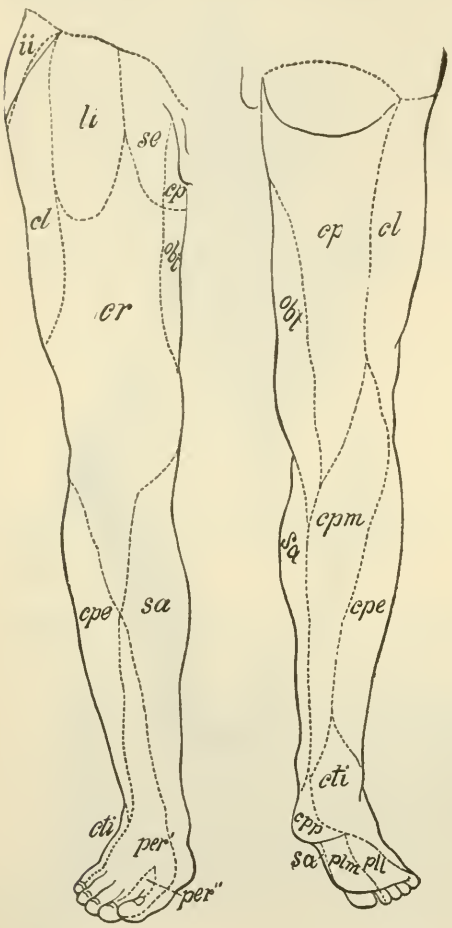
The Obturator Nerve.—In obturator palsy the adductor muscles of the thigh are paralyzed, and, in consequence, the patient is unable to cross one leg over the other. Gowers points out that external rotation of the thigh is also interfered with.

The Superior Gluteal Nerve.—The division of this nerve paralyzes the gluteus medius and the gluteus minimus muscles, and there is "loss of abduction and circumduction of the thigh" (Gowers).

The Small Sciatic Nerve.—Division of this nerve paralyzes the gluteus maximus muscle and produces anesthesia of the upper half of the calf of the leg and of the middle third of the back of the thigh (Gowers) (Fig. 554).

The Great Sciatic Nerve.—If this nerve is divided near the sciatic notch there is a paralysis of the flexor muscles of the leg. These muscles, as Gowers points out, are also extensors of the hip. There is likewise paralysis of all the muscles below the knee. If, however, the injury is below the upper third of the thigh, there is no paralysis of the flexors of the leg. If the nerve is damaged on a level below the small sciatic, there is anesthesia of the outer portion of the leg, of the sole of the foot, and of most of the dorsum of the foot (Fig. 554).

The External Popliteal Nerve.—When this neve is divided, there is paralysis of the tibialis anticus muscle, the extensor longus digitorum, the extensor brevis digitorum, and the peronei; and the patient is unable to flex the ankle and extend the first phalanges of the toes. When he tries to walk he cannot lift the foot from the ground; and eventually there is the development of talipes equinus (Gowers). The anesthesia is manifest on the outer portion of the anterior surface of the leg, and also on the dorsum of the foot (Fig. 554).



Anterior surface. Posterior surface.

Fig. 554.—Distribution of the cutaneous nerves of the lower extremity: *ii*, N. ilio-inguinal. (plex. lumb.); *li*, N. lumbo-inguinal. (to the genitocrural, plex. lumbal.); *se*, N. spermat. ext. (to the genitocrural); *cp*, N. cutan. post. (plex. ischiad.); *cl*, N. cutan. lateral. (plex. lumb.); *cr*, N. cruralis (plex. lumbal.); *obt*, N. obturator. (plex. lumb.); *sa*, N. saphen. (plex. lumbal.); *cpe*, N. commun. peron. (N. peron. tibial.); *cti*, N. commun. tibial; *per'*, *per''*, N. peronæi ram. superfic. et prof.; *cpm*, N. cutan. post. med. (plex. ischiad.); *cpp*, N. cut. plant. propr. (N. tib.); *plm*, *pll*, N. plantar. medial. et lateral. (N. tib.) (Henle).

The Internal Popliteal Nerve.—Damage to this nerve paralyzes the posterior tibial muscle, the flexor longus digitorum, the muscles of the calf, the popliteus muscle, and the muscles of the plantar surface of the foot. The toes become flexed at the two distal joints, and extend at the proximal joints. Walking is greatly interfered with. There is loss of the power of rotating the flexed leg inward, if the damage is above the branch to the popliteus muscle; and extension of the ankle-joint is lost. As the consequence, talipes calcaneus develops (Gowers). The anesthesia is variable, but usually involves the sole of the foot and the outer surface and lower portion of the back of the leg (Fig. 554).

The Plantar Nerves.—Division of the internal plantar nerve paralyzes the short-toe flexor, the two inner lumbricales, and the plantar muscles of the great toe, except the adductor (Gowers). There is anesthesia of the inner portion of the sole of the foot and of the plantar surface of the three inner toes and of half of the fourth toe (Fig. 554).

Division of the external plantar nerve causes paralysis of the muscles of the little toe, of the adductor of the great toe, of all the interossei, of the two outer lumbricales, and of the flexor accessorius (Gowers). There is anesthesia of the skin of the outer half of the sole of the foot, of the little toe, and of half of the fourth toe (Fig. 554).

The Facial Nerve.—This nerve may be divided during the mastoid operation or may be lacerated by a fracture of the petrous portion of the temporal bone, and a peripheral palsy results. The face is asymmetrical and is drawn to the sound side. Asymmetry becomes more marked on attempting to smile

or to show the teeth. Whistling and frowning are impossible. The sense of taste may be less acute or lost on the anterior two thirds of the tongue. There is relaxation of the palate and deviation of the uvula. Reactions of degeneration can be demonstrated in the palsied muscles. In some cases there are sensory disturbances (hyperesthesia or anesthesia) and in some there are vasomotor perturbations on the palsied side. On the paralyzed side the muscles are relaxed, the nasolabial fold is to a great extent gone, the nostril cannot be dilated. The brow wrinkles have been smoothed out, the eyelids cannot be closed; on attempting to close the eye the globe tilts upward and outward. The cornea and conjuntiva inflame, the lower lid droops, and tears run down the cheek.

Treatment.—In every wound in which a nerve or nerves might be damaged make careful search and examination to determine whether such damage is present. Always suspect nerve injury in wounds of the wrist. In all recent cases of nerve-section try, if possible, to suture the ends of the divided nerve. The earlier suture is done the better the chance for restoration of function. For instance, in fracture of the humerus, with division of the musculospiral, operate at once. Primary suture is suture within twenty-four hours of the accident. Within two weeks of the injury it is possible to recognize and save undestroyed fibers and at this period suture is easy. After-care is of the greatest importance in all cases of nerve suture. Suture may fail. There may be partial or complete restoration of function. In 123 reported cases of *primary suture*, 119 were cured in from one day to one year (Willard). The return of sensation may be rapid or may be slow; muscular power returns more slowly than sensation. If the patient is not seen until long after the accident, incise and apply sutures (*secondary sutures*); if the nerve cannot be found, extend the incision, find the trunk above and trace it down, and find the trunk below and follow it up. The results are not nearly so good as are those of primary suture. Long after the accident a considerable amount of scar tissue is found between the nerve ends, this must be removed and the removal creates a gap which when bridged by nerve-suture is responsible for tension on the nerve. The earlier the operation the less the scar tissue, the narrower the gap and the less the tension. After-care for months is highly important. In 130 reported cases of secondary suture 80 per cent. were more or less improved (Willard). Even after primary suture loss of function is bound to occur for a time. After secondary suture sensation may return in a few days, but it may not return until after a much longer period; in any case muscular function is not restored for months. It is usually stated that if return of function is not manifested in six months it will not occur, but Müller had a radial nerve case in which signs of return of function were not noted for eleven months. After partial section of a nerve the ends should be sutured. In performing secondary suture it may be necessary to effect *lengthening* in order to approximate the ends (see page 851). *Transplantation* of a portion of nerve is sometimes practised (*implantation* or *anastomosis*). *Nerve-grafting* is bridging the gap by means of a portion of nerve from one of the lower animals or from a recently amputated human limb. Nerve-transplantation may fail utterly; it may be followed by great improvement, but absolute and perfect restoration of function cannot be obtained. R. Peterson[1] has made a study of the 20 recorded cases of nerve-grafting; 8 of the operations were primary and 12 were secondary. The periods after the injury at which operation was performed varied from forty-eight hours to a year and a quarter; 4 of the 8 primary cases improved; 8 of the 12 cases of secondary operation showed improvement in motion or sensation. The distance between the nerves did not seem to affect the results. No cases recovered completely, but in 1 case sensation returned completely and only the abductors of the thumb remained weak. In most of the cases that were benefited sensation returned by the tenth day and motion

[1] "Amer. Jour. Med. Sciences," April, 1899.

within two and a half months. In one of the successful cases, that of A. W. Mayo Robson,[1] the spinal cord of a rabbit was used. A facial nerve divided in the aqueduct of Fallopius may perhaps be sutured at the site of the injury. This should be attempted as soon as the palsy is observed, as was suggested, I believe, by Frederick Sydenham ("Brit. Med. Jour.," May 8, 1909). If the ends of the divided nerve cannot be approximated, *suture à distance* may be practised, as was done successfully by Sydenham (Ibid.). If suture at the site of injury is impossible the end of the peripheral segment of the divided nerve may be anastomosed to the hypoglossal, glossopharyngeal, or spinal accessory nerve (see page 853).

Pressure upon nerves may arise from callus, scars, a dislocated bone, a tumor, or an external body.

The **symptoms** may be anesthetic, paralytic, or trophic.

The **treatment** is as follows: Remove the cause (reduce a dislocated bone, chisel away callus, excise a scar, etc.); then employ massage, douches, exercise, and electricity.

Dislocation of the Ulnar Nerve at the Elbow.—This condition is very rare. It may occur as a complication of a fracture or a dislocation, or as an uncomplicated condition. It may be produced by violence or by muscular effort, which ruptures the fascia, the function of which is to retain the nerve back of the inner condyle of the humerus. In some cases the symptoms are slight and transitory, the nerve functionating well in its new situation. As a rule, there are pain, numbness, or anesthesia of the ulnar trajectory, some stiffness of the elbow, and stiffness of the little finger and ring-finger. The nerve can be felt in front of the inner condyle of the humerus. In some cases neuritis follows, with trophic changes.

Treatment.—Expose the nerve by an incision, incise the fibrous tissue back of the inner condyle, and press the nerve into the bed prepared for it and hold it in place by sutures of chromic catgut passing through the triceps tendon. Wharton advises suturing also "the margin of the fascial expansion of the triceps tendon superficial to the nerve."[2]

Contusion of Nerves.—The **symptoms** of contusion of nerves may be identical with those of section. Sensation or motion, or both, may be lost. The case may recover in a short time, or the nerve may degenerate as after section.

The **treatment** at first is rest, and later electricity, massage, friction, and douches.

Punctured Wounds of Nerves.—The **symptoms** of punctured wounds of nerves may be partly irritative (hyperesthesia, acute pain, and muscular spasm) and partly paralytic (anesthesia, muscular wasting and paralysis).

The **treatment** after the puncture has healed is the same as that for contusion.

Gunshot Wounds of Peripheral Nerves.—There have been many nerve injuries in this war. On the whole the results of treatment have been disappointing.

The nerves most commonly injured are the musculospiral and ulnar, next to them comes the median and next the sciatic and the external popliteal (Moynihan, Ibid.).

A bullet may split a nerve longitudinally, dividing few or no fibers—may partially divide or completely sever a nerve. It may simply open a sheath. The resultant scar is a *lateral neuroma*. A bruise by a bullet, or the passage of a bullet near a nerve may cause a complete physiological interruption which for weeks cannot be distinguished from anatomical interruption. If the interruption has been physiological and not anatomical, function will

[1] "Amer. Jour. Med. Sciences," April, 1899.

[2] A report of 14 cases of dislocation of the ulnar nerve at the elbow, by H. R. Wharton, "Amer. Jour. Med. Sciences," Oct., 1895.

show positive evidences of restoration in a few weeks. Moynihan says we cannot tell before operation if the nerve was or was not divided ("American Addresses"). When a bullet actually strikes a nerve it produces wide damage to the nerve trunk and much fibrous tissue forms. The fibrous tissue which forms between the ends is a *terminal neuroma.*

If a nerve is injured and pus forms the scar is sure to be enormous and densely hard. A dense scar may cause frightful pain. It is sure to do so in the median nerve.

If a bone has been broken by a bullet, splinters of bone may be driven about and into the nerve. The nerve may grow first to the broken bone or callus may press upon the nerve. Either condition produces violent pain. An intraneural scar may be responsible for pain or palsy. It is called a *central neuroma.*

If early suturing were always possible the results would doubtless be much better. But it is seldom that a surgeon knows a nerve has been completely divided. There is often a very grave associated injury of bone, soft parts or both. The wound must be regarded as infected and suture in a purulent area would be bound to fail. Most of the operations have been done after cicatrization of the wound.

The operation may show no lesion, may show an uncut nerve in a scar, may show a partly divided or a completely divided nerve in a scar.

In some cases even on exposing the nerve we cannot be sure it is divided (Quénut). The hard mass of scar between the ends may be the shape and size of the nerve trunk. Tuffier has been so disappointed with resection of the scar and suturing that he now simply liberates the nerve from the surrounding scar and surrounds it with a sheath. He leaves a bridge of scar the shape and diameter of the nerve and hopes it may be canalized by nerve-fibers. Stoffel not only removes the perineural scar but also the endoneural scar by gently separating the nerve tracts longitudinally. English surgeons believe in suturing (see Neurorrhaphy).

Moynihan's rules are as follows ("American Addresses"): Operation is decided upon:

1. In cases of complete division.
2. In cases of incomplete division where progress ceases.
3. Where there is severe neuralgic pain (*causalgia*).

Operation is deferred:

1. For one month after closure of the wound if the soft parts only were injured.
2. For two or three months after complete closure if bone was involved.
3. Definitely so long as evidences of progressive restoration are found.

Operations Upon Nerves

Neurorrhaphy, or Nerve-suture.—When a nerve has been completely or partially divided by accident it should be sutured at the first possible moment. Round needles are used. If there is no tension the best suture material is fine plain catgut; if there is any tension, lightly chromicized catgut (Sherren, in "Brit. Med. Jour.," Jan. 15, 1910). Sherren points out that if silk or linen is used it interferes with complete recovery and may cause symptoms months after the operation. In primary suture render the part aseptic. Formerly I used the elastic band to secure a bloodless field. Lately I have given it up. It may damage the divided nerve or other nerves and may be followed by oozing of the blood between and about the nerve-ends. Enlarge the incision if necessary. Handle the nerve as little as possible and do not raise it from its bed for any considerable distance. If the ends can readily be approximated, pass two or three sutures through the sheath and connective tissue outside, and tie them (Figs. 555, 556). If the ends cannot be approximated, stretch each end and

then suture. The sutures do not traverse the nerve, but go through the perineurium and adjacent connective tissue. If the nerve is found partially divided the cut fibers are sutured in the same way and the undivided portion is folded upon itself so as to permit approximation. Suture the deep fascia. Arrest bleeding, suture the skin, dress antiseptically, and put the muscles supplied by the injured nerve in a relaxed position and fix the limb on a splint. After union of the wound continue the use of the splint to maintain muscular relaxation as long as the muscles are paralyzed (Ibid.), and use massage, friction, electricity, and the douche. When voluntary power returns remove the splint and insist on active exercise. The operation in some instances fails, but in many cases succeeds. In some few cases sensation returns in a few days, but in most cases does not return for many weeks or months. Sensation is restored before motor power. After successful suturing of a divided median nerve sensations of skin pain and of extreme heat and cold appeared in fifty-six days and were restored in two hundred and seven days. Sensations of light touch and slight degrees of heat and cold appeared in two hundred and sixty days and were not completely restored for one year (Kenneth A. J. Mackenzie, in "Annals of Surg.," July, 1909). *Secondary suture* is performed upon cases long after division of a nerve. If operation is not done for three years or more after division it is very improbable that complete regeneration will ever occur, and yet it is always worth trying, for muscular control has been regained after suturing in 1 case twenty-nine years subsequent to nerve division (Alfred S. Taylor, in "Jour. of Orthopedic Surg.," Nov., 1908). The part is rendered aseptic. An elastic band is not used. An incision is made. The nerve trunk is looked for and identified above and below the point of division. The bulbous upper end is easily found, the lower end is much more difficult to

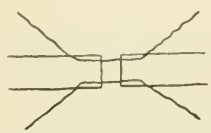


Fig. 555.—Nerve-suture.

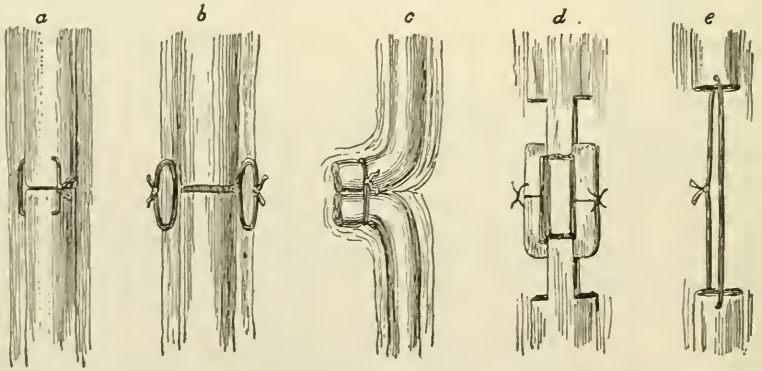

Fig. 556.—Nerve-suture: *a*, Direct; *b*, perineurotic; *c*, paraneurotic; *d*, *e*, neuroplasty (Senn).

locate. The perineural scar is dissected from the nerve with a very sharp knife, scrupulous care being taken to save the nerve from injury, and to avoid squeezing, pulling, twisting and lifting the nerve extensively from its bed.

The bridge of fibrous tissue between the ends in examined. If the distance between the ends is considerable gently stretch each end by making traction up and down on the fibrous bridge. Moynihan ("American Addresses") says: "The fibrous band is now split longitudinally, and then its ends are divided above in one direction, below in the other, so that to each cut end of nerve a fibrous tag is attached by means of which the nerve-ends can be drawn together." "Progressive transverse cuts are now made into the nerve-cells until on the cross-section nothing but nerve fibers are seen. Even the tiniest particle of fibrous tissue must be removed or the operation will fail."

If in spite of the preliminary stretching approximation is not possible some surgeons adopt the expedient shown in Fig. 556, *d*, or that portrayed in Fig. 557. This operation is *neuroplasty* by the *flap method*. Another method is to make a bridge of strands of catgut running from one divided end to the other. We speak of this plan as *suture à distance* (Fig. 556, *e*). The catgut bridge is thought to support the growing reparative material. It does not seem possible to me that either neuroplasty or *suture à distance* can be of any service. In fact Sir Berkley Moynihan says of them that they "are methods with nothing whatever to recommend and with everything to discredit them." ("American Addresses").

Allis suggested shortening the limb by resecting a piece of bone. This has been done successfully by Keen, Rose, and others.

Guelliot suggested *tubulization* after all operations of nerve-suture, that is, erecting barriers along the path of reparative material to save the ends of the nerve from cellular invasion from the perineural structures, which would deviate the new nerve fibers and would block repair. Even a blood-clot might prevent repair. Tubulization is supposed to guide and protect the new fibers. Vanlair uses a piece of artery which has just been removed or surrounds the ends with decalcified bone. Payr uses a tube of absorbable magnesium. Hashimoto and Toknoka use a vein or artery from a recently slaughtered calf, hardened in formalin. Many surgeons have used Cargile membrane. Edinger uses a bit of artery filled with agar jelly.

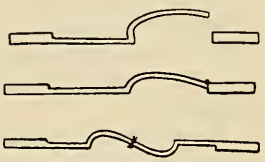

Fig. 557.—Suture of a nerve by splitting the ends (Beach).

Gelatin tubes have been used, silver-foil has been tried, and Cargile membrane has been employed. None of these plans is entirely satisfactory. Murphy covers the line of nerve-suture with fascia, muscle, or fat. In regions where he cannot obtain suitable covering tissue he wraps about the suture line a material composed of equal parts of paraffin and oil of sesame. This mixture can be flattened out very thin ("Surg., Gynec., and Obstet.," April, 1907).

I used to surround the nerve with Cargile membrane but abandoned the practice.

Sir Berkley Moynihan ("American Addresses") questions the value of surrounding the nerve with any protective material, says that such procedures are sometimes harmful, that they prevent free access of blood and cause adhesions and compression of the nerve. He advises us to avoid all such membranes and simply to be certain that "the nerve is laid along the path of uninjured tissues."

Implantation or *anastomosis* is employed in some cases. In this operation the distal end of a palsied nerve is inserted into an adjacent nerve of like or similar function. Letiévant attaches the peripheral portion of a divided nerve into a longitudinal slit in a sound nerve (*end-to-side anastomosis*). Some surgeons have implanted the divided ends into a sound nerve, either splitting the sound nerve or leaving it unsplit.

Moynihan (Ibid.) in speaking of nerve anastomosis says: "All such procedures are worthless and cannot be too strongly condemned. I have never seen any good come of them; indeed, nothing but harm could conceivably result from section of a healthy nerve." The operation of anastomosis is employed after an exsection which leaves a very large gap, for facial palsy, for infantile palsy, for avulsion of the brachial plexus, and for brachial birth palsy.

Nerve-grafting is practised by some. A. W. Mayo Robson used the spinal cord of a rabbit to fill a gap between the ends of the divided median nerve of a man. The restoration of function was almost complete. Some surgeons have grafted in bits of nerve obtained from a recently amputated limb. It makes no difference whether the grafted nerve is motor, sensory,

or mixed. The results of grafting are seldom good. Some use as a graft a bit of cutaneous nerve, for instance the radial, the internal cutaneous of the thigh or an intercostal nerve. Chas. A. Powers ("Transactions of the American Surgical Assoc." 1904) collected 22 cases from literature, 20 from Peterson's paper, 1 case of Durante's, and 1 of his own. In this series there were 3 good results and 3 "fair" results. Robson ("Brit. Med. Jour." Jan. 27, 1917) reports another striking case of nerve-grafting. All the nerves supplying the forearm, except the musculospiral had been cut seven months before. The gap between the ends of the ulnar was bridged by a part of the sciatic nerve of a rabbit. The gap between the ends of the median was bridged by a part of the rabbit's spinal cord. In eleven days sensation began to return. Complete restoration, motor and sensory, was obtained in six months. The bit of nerve grafted does not participate in repair—it is a mere bridge, and acts as would the suture à distance if it worked.

If a divided nerve cannot unite tendon transplantation may be practised. "Tendon transplantation, especially in the case of the musculospiral nerve and the posterior interosseous, gives results which, in point of function, are almost as good as those which come from nerve suture and in point of time are much quicker."

Neurectasy, Neurotomy, and Neurectomy.—*Neurectasy*, or nerve-stretching may be applied to motor, sensory, or mixed nerves. A nerve can be stretched about one-twentieth of its length. Neurectasy has been employed for neuralgia, neuritis, muscular spasm, hyperesthesia, anesthesia, painful ulcer, perforating ulcer, the pains of locomotor ataxia, and many other conditions. The operation, which was once the fashion, seems to benefit some cases, but it is not now thought so highly of as formerly. The incision for neurectasy is identical with the incision for neurectomy or neurotomy of the same nerve. *Neurotomy*, or section of nerve, is performed only upon small and purely sensory nerves (in spasmodic wry-neck a motor nerve is cut). It is performed chiefly for peripheral neuralgia or for some other painful malady. It is almost useless in painful conditions, because sensation, as a rule, soon returns. Paget saw complete return of sensation in four weeks after division of the median nerve. Corning endeavors to prevent this regeneration by inserting oil between the ends. He uses oil of theobroma containing enough paraffin to make the melting-point 105° F. The oil is melted, is injected around the nerve, and cold is applied. The nerve is now sectioned with a canaliculated knife, the ends are separated widely, more oil is injected, and cold is again applied. The theory is that this oil, which is solid at the temperature of the body, devitalizes the nerve at the point of section and acts as a barrier to the passage of regenerating fibers. This method has been applied especially in cervicobrachial neuralgia.[1] *Neurectomy*, or excision of a portion of a nerve-trunk, is applicable to sensory nerves and to painful affections.

Sympathectomy.—*Jonnesco's Operation.*—It has long been known that division of the sympathetic nerve in the neck may produce important changes in the eye and in the cerebral circulation. In 1893 Jaboulay divided the sympathetic on each side for the purpose of treating epilepsy. The removal of the ganglia of the sympathetic was proposed by Baracz; and the operation was first performed by Jonnesco, in 1896, for epilepsy. The operation is performed by some surgeons for epilepsy, for exophthalmic goiter, for glaucoma, and for trifacial neuralgia. In operating for glaucoma the superior cervical ganglion on each side is removed, as it is from this that the sympathetic fibers that pass to the eye are derived. If the operation is done at all, it should be a bilateral one.

This operation is used in epilepsy on the theory that there is an anemic condition of the brain in this disease which is corrected by producing a hypere-

[1] "Medical Record," Dec. 5, 1896.
[2] "Medical Record," Dec. 5, 1896.

mia, and that the hyperemia improves cerebral nutrition. The operation in epilepsy is largely theoretical, although Jonnesco claims 12 per cent. of cures in a large number of operations. In exophthalmic goiter there seems to be some distinct evidence that the operation may be beneficial, but Curtis shows that the mortality is high. Personally, I have not employed it in epilepsy, and at the present time I should not be inclined to do so. In exophthalmic goiter, if any operation is necessary, I perform partial thyroidectomy or ligation of the thyroid arteries; but in progressive glaucoma, which is always so absolutely hopeless, the operation is a justifiable procedure and occasionally seems to have a distinct influence in retarding the development of the disease.

The incision should be made along the posterior margin of the sternocleidomastoid muscle. I have become convinced, in performing two operations of this kind and through studies made upon the dead body, that the ganglion may be more easily reached from behind the sternocleidomastoid than from in front of it. The internal jugular vein and the carotid artery are lifted upward and forward; and the superior ganglion will usually adhere to the under portion of the carotid sheath and be lifted up with it. Theoretically, it is not necessary to open the carotid sheath in this operation, but, practically, this had better be done, so that one may, without any possibility of doubt, distinguish between the pneumogastric and the sympathetic nerve. The moment the nerve is cut the pupil on that side will contract.

Stretching of the Sciatic Nerve.—Some surgeons stretch the sciatic nerve by anesthetizing the patient and holding the leg and thigh in line, strong flexion being made upon the hip, the entire lower extremity being used as a lever. This method, which has caused death, inflicts needless damage, and stretching after an incision has been made is safer and better. The patient lies prone, the thigh and legs being extended. An incision 4 inches in length is made a little external to the middle of the thigh, and going at once through the deep fascia; the biceps muscle is found and is drawn outward; the nerve is discovered between the retracted biceps on the outside and the semitendinosus on the inside, resting upon the adductor magnus muscle. The nerve, which is caught up by the finger, is first pulled down from the spine and then up from the periphery, and finally the hook of a scale is inserted beneath the trunk and the nerve is stretched to the extent of 40 pounds. Very rarely is even a single ligature needed. The wound is sutured and dressed. If the incision is made at a higher level, just below the gluteofemoral crease, the sciatic nerve will be found just at the outer border of the biceps.

Neurectomy of the Infra-orbital Nerve.—This operation was first performed by Abernethy in 1793. The patient lies upon his back, the head being raised a little by pillows. The surgeon stands to the outside of and faces the patient. A curved incision 1½ inches long is made below the lower border of the orbit. The nerve lies in a line dropped from the supra-orbital notch to between the two lower bicuspid teeth and is found upon the levator labii superioris muscle. A piece of silk is passed under the nerve by an aneurysm needle and firmly fastened. The upper border of the incision is drawn upward; the periosteum of the floor of the orbit is elevated and held by a retractor; the roof of the infra-orbital canal is broken through; the nerve is picked up far back by the blunt hook and is divided by scissors, and the entire nerve in front of the section is drawn out by making traction upon the silk. The bleeding in the orbit is checked by pressure. The wound is stitched without drainage.

Neurectomy of the Supra-orbital Nerve.—Before sterilizing the parts shave off the eyebrow. A curved incision 1 inch long discloses the nerve as it emerges from the supra-orbital notch or foramen at the junction of the inner and middle thirds of the eyebrow. The nerve is pulled forward and cut off above and below.

Neurectomy of the Inferior Dental Nerve.—Make a curved incision around the angle of the jaw. Lift the supramaxillary branch of the facial nerve downward (Kocher). Separate the masseter muscle by a periosteum elevator and slight touches of the knife. Chisel an opening in the center of the ascending ramus (Velpeau's rule). This opening exposes the beginning of the dental canal. If necessary, the opening may be enlarged by a rongeur. Pull the nerve out by a hook and remove a piece from it.

Extracranial Operation for Neuralgia of the Fifth Nerve (Tic Douloureux.—Removal of portions of the pain-haunted nerve-trunks sometimes cures the condition and often ameliorates it for a considerable time. Avulsion of a nerve by the method of Thiersch removes a large piece and gives better results especially if the nerve-canal is plugged to prevent regeneration. The nerve is twisted slowly around a blunt forceps and Mayo plugs a canal with a silver screw. Albee and others use a bone-graft. The injection of osmic acid into the peripheral nerves, or of alcohol into the nerves as they emerge from the cranium, may actually cure or secure prolonged relief. The serious operation of removing the ganglion may be performed if peripheral operations and injections fail, or in violent and intractable cases of long standing in which pain is felt in more than one branch. Removal of nerves by ordinary neurectomy often gives comfort for a few months, but rarely gives prolonged relief. In the worst forms of tic douloureux, particularly in those cases in which there are facial spasm and vasomotor phenomena, relief following peripheral operations is usually transitory. If we seek striking benefit by an extracranial operation, it must be thoroughly done.

Injection of Osmic Acid.—As long ago as 1874, Bartholow injected chloroform about and into nerves. Osmic acid was suggested by Billroth and Neuber in 1884. It was strongly advocated by Bennett, of London, in 1897. Osmic acid had been used for many years in a sort of haphazard way, having been injected into tissues about the nerves by means of a hypodermic syringe. Bennett suggested exposure of the nerve and the injection of 5 to 10 min. of a 1 per cent. solution. Acid when so used actually destroys nerve-fibers, and a considerable amount of fibrous tissue forms which intercepts regenerating fibers. It is probable that secondary degenerative changes occur in the nerve-trunks, but they do not ascend and reach the ganglion. Murphy warmly advocates the method. It certainly produces immediate relief by causing anesthesia, but such relief is very seldom, if ever, permanent. I have used it in several cases with satisfaction. In 1 case in which I exposed the ganglion I injected that structure, and the result seemed to be the same as if I had removed the ganglion. In neuralgia of the fifth nerve the painful nerve or nerves should be exposed, and from 5 to 10 min. of a 2 per cent. solution of osmic acid injected into several different parts of the nerve and also between the nerve-sheath and the bony canal (Murphy). The osmic acid method does not seem to grow in favor.

Injections of Alcohol into the Second and Third Division of the Fifth Nerve.—Dr. Matas as long ago as 1889 planned routes to reach the branches of the fifth nerve in order to produce regional anesthesia (Urban Maes Review of Surgical Treatment of Tic Douloureux in Internat. Abst. of Surgery, Oct., 1915). Alcohol injections were introduced by Schlösser in 1903. The injections are made into peripheral branches or divisions of the ganglion, and have even been made into the ganglion. Hartel enters the needle through the foramen ovale and injects the ganglion, a difficult and uncertain procedure. Pollock and Potter suggest injecting the ganglion under fluoroscopy ("Jour. Am. Med. Assoc.," Nov. 14, 1916). Siccard and others have warmly praised the alcohol injection method. It acts similarly to osmic acid. It produces local necrosis of the nerve and fibrosis about it. The necrosis does not tend to ascend (May, "Brit. Med. Jour.," Aug. 31, 1912). It gives relief sometimes after one injection, sometimes after two or more. The permanence of the relief is uncer-

tain. Usually it is complete for six months and then recurrent pain may require renewed injection. Recurrences are milder than the previous condition. Apparent cure may last for three or four years.

I have used the method many times and am satisfied as to its value in proper cases. It is superior to peripheral operations. It is used in very old subjects, feeble subjects, the victims of grave organic disease, and in those who refuse radical operation. In strong young persons removal of the ganglion may still be preferred. In some cases alcohol is used before a ganglion extirpation in order to remove pain and permit of such improvement in health and strength as to make the radical operation safer. Never attempt to make a deep injection about the ophthalmic branch. To do so may damage a great vessel, the optic nerve, the third, fourth, or sixth nerve, or the alcohol may enter the orbit and destroy the eye. If there is pain in the supra-orbital and supratrochlear branches, inject them where they are superficial.

Injection of the Supra-orbital Branch.—Use an ordinary hypodermic needle and inject 10 to 20 min. of the fluid recommended below. Throw the fluid about the nerve at the foramen. After withdrawing the needle make pressure at the puncture. Such pressure is advised by Patrick to stop bleeding, prevent a black eye, keep the tissues exsanguine, and add to the effect ("Jour. Am. Med. Assoc.," Jan. 20, 1912). The lids always swell.

I used for a time 80 per cent. alcohol, each dram of which contained $\frac{1}{6}$ gr. of stovain, but this hardens the tissues so much that they become resistant to reinjection. I now use Patrick's formula, viz.: 2 gr. of muriate of cocain, $2\frac{1}{2}$ drams of alcohol, and distilled water sufficient to make $\frac{1}{2}$ oz. The usual dose is 2 c.c. A special needle is used. It is straight, is graduated in centimeters, and carries a stylet which is flush with the point. The stylet is pulled back slightly while the needle is being driven through the skin and fascia; it is then pushed all the way in. Various plans have been suggested for reaching the nerves (see Dorran plan in "Penna. Med. Jour.," August, 1916). I follow the method of Lévy and Baudoin ("Presse Méd.," April 17, 1906), which is as follows:

Superior Maxillary Division.—Drop a perpendicular from the posterior border of the orbital process of the malar bone (the beginning of the zygoma) to the inferior edge of the zygoma; $\frac{5}{10}$ c.c. back of this point is where the needle should be introduced. It is carried in and very slightly upward. At a depth of 2 cm. the coronoid process may obstruct; at a greater depth, the external pterygoid plate. Either obstruction may be avoided by inclining the needle very slightly forward (never much or alcohol may enter the orbit). At a depth of 5 cm. the needle encounters the nerve as it emerges from the foramen rotundum. The injection usually causes decided but brief pain. If the injection reaches the nerve there will be immediate analgesia throughout its trajectory. This should last two or three days.

Inferior Maxillary Division.—The point for entrance of the needle is at the lower border of the zygoma, 2.5 cm. in front of the anterior root of the zygoma. The needle is carried inward, somewhat backward, and slightly upward. At a depth of 4 cm. the nerve is reached. Be sure the nerve has been reached by finding analgesia throughout its trajectory after injection.

Rose's Method of Neurectomy.[1]—This operation is a modification of the Braun-Lossen method, and is employed when the second division of the fifth nerve is the seat of pain. The infra-orbital nerve is exposed by an incision, a ligature is tied around it, the roof of the infra-orbital canal is opened by a chisel, and the nerve is traced back as far as possible. The wound is then packed temporarily with gauze. The next step in this operation is to open a way into the sphenomaxillary fossa (Fig. 558). The knife is inserted slightly below the external angular process of the frontal bone, is carried back along the

[1] See article by Wm. Rose, "Practitioner," March, 1900.

zygoma, down in front of the ear to just above the angle of the jaw, and then forward for 2 inches. This flap, which is composed of skin and subcutaneous fat only, is dissected forward, and Steno's duct and branches of the facial nerve are not damaged. The flap is wrapped in gauze and temporarily stitched to the side of the nose. The zygoma is exposed by a transverse incision. At the root of the zygoma two holes are drilled ¼ inch apart, and two more holes ¼ inch apart are drilled through the zygomatic process of the malar bone. The zygoma is then divided by a saw (Fig. 559). The posterior saw line runs between the two drill-holes at the root of the zygoma. The anterior cut passes between the two anterior drill-holes. The direction of the first cut is directly downward. The direction of the second cut is downward and forward from above. The arch is freed and detached downward and backward. The exposed tendon of the temporal muscle is retracted backward. The removal of a little fat

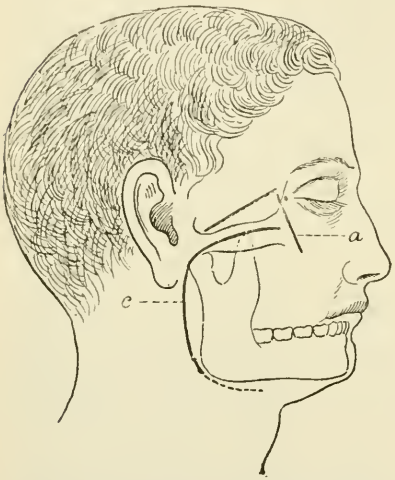

Fig. 558.—*a*, The Braun-Lossen incision; *c*, Rose's incision for reaching the sphenomaxillary fossa (Rose).

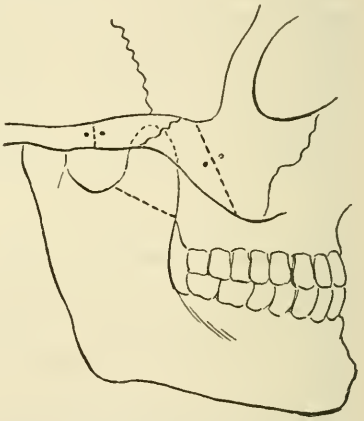

Fig. 559.—Lower jaw and zygoma. Drill-holes and saw-cuts are shown (Rose).

exposes the pterygomaxillary fossa. The internal maxillary artery is exposed, two ligatures are applied, and the vessel is divided between them. The finger feels for the sphenomaxillary and pterygomaxillary fissures. The external pterygoid muscle is separated from the greater wing of the sphenoid and from the root of the external pterygoid process. On the edge of the greater wing of the sphenoid a long prominence is usually detectable. It overhangs the sphenomaxillary fossa and should be cut away by the use of a chisel. The superior maxillary nerve is lifted on a blunt hook, is grasped by forceps, and is twisted off as near the ganglion as possible (Fig. 560). The distal end is drawn upon, and the nerve, having been previously loosened, is drawn back through the infra-orbital canal. The zygomatic arch is wired in place, the temporal fascia is sutured with buried sutures, and the skin-wound is closed. If the pain involved not only the second division, but also the third division, the operation previously described should be performed first, and the third division should be attacked a few weeks later. The third division is reached by removing the coronoid process. The inferior dental and lingual nerves are found, and are traced up to the foramen ovale, and are twisted off close to the ganglion, and the distal portions are removed.

Removal of the Gasserian Ganglion.—This formidable procedure was first suggested by J. Ewing Mears in 1884. Wm. Rose in 1890, was the first surgeon to perform it successfully. It is only undertaken in very severe

cases of tic douloureux, in which the first division is involved, or in cases upon which less grave procedures have failed. Jaboulay and Cavaillin ("Lyon. Med.," May 17, 1908) speak of it as a grave operation of difficult technic which should be left as a final resort. Many operators deny that there is a large mortality after gasserectomy and claim that it is only about 5 per cent. Some operators report a mortality of from 10 to 17 per cent. The greater the experience of the surgeon in this operation, the smaller will be the mortality. Knowledge of the region and parts, dexterity from frequent repetition, and special training count for much. The operation usually cures the pain if the patient recovers from the actual procedure. It is claimed that the pain may recur even after complete removal of the ganglion. I am disposed to think that recurring pain is apt to mean that there was a partial removal. In one case of undoubted complete removal the patient still claims to suffer. The victims of tic are usually elderly, weakened by prolonged suffering and shattered by opiates. They would be poor risks for any operation.

Frazier ("Keen's Surgery," Vol. v) collected 230 cases and finds a mortality of only 3.7 per cent. These figures come from the clinics of men particularly skilled in this operation (clinics of Cushing, Horsley, Frazier, Lexer and so on). The figures of some other writers are far less favorable. In a series of 121 intracranial operations Frazier had but 4 deaths. One hundred and thirteen of the operations were upon the sensory root (Personal Communication). Carson collected 100 cases; Murphy and Neff, 42 cases. The mortality in this group of 142 cases was 15 per cent. Most of the cases reported by Murphy and Neff were operated upon during or after 1899, and in this group the mortality was 10 per cent. ("Progressive Medicine," March, 1903). In Lexer's series of 201 cases, referred to below, the mortality was 17 per cent. In many cases a perfect cure is obtained. In some few the pain returns upon the side operated upon. Occasionally it arises on the side not operated upon. In some cases ulceration of the cornea follows operation. Such ulceration may be trivial, may result in opacity, or may destroy the eye. Paralysis of the abducens occurs in some cases. The hemorrhage may be so profuse as to require packing of the wound and suspension of the operation for a few days. The bleeding may come from the meningeal artery, from the sinus, or from the veins of Santorini. Lexer ("Arch. f. klin. Chir.," Bd. lxv, H. 4) gives a table of 201 cases. Of the survivors, 93.4 per cent. were apparently cured. In two-thirds of the cases the trouble was right sided. In 10 the operation was temporarily abandoned because of hemorrhage. The experience of surgeons in general is that after the removal of the ganglion there is apt to be some atrophy of the tongue and the eye usually becomes insensitive and watery. The masseter muscle will be paralyzed.

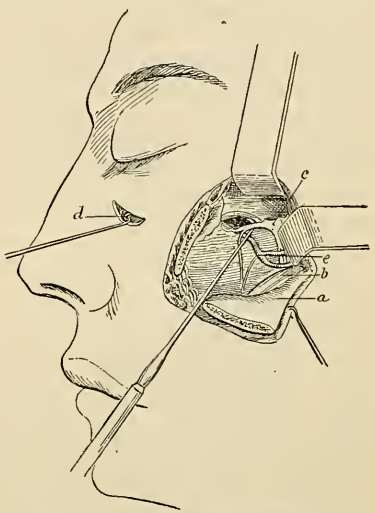

FIG. 560.—*a*, The zygomatic arch, turned down after sawing; *b*, tendon of the temporal muscle retracted; *c*, superior maxillary nerve and Meckel's ganglion; *d*, infra-orbital nerve emerging from canal; *e*, internal maxillary artery.

The Hartley Operation for Removal of the Gasserian Ganglion.—This operation was first performed by Hartley in 1891, five months before Krause performed it. An electric forehead-light is required. Long strips of gauze must be ready for packing in case of hemorrhage. Some operators place the

patient recumbent, with head turned to the opposite side. If the patient is placed semierect venous bleeding will be much lessened, as was pointed out by Lexer. The application of a provisional ligature or clamp to the external carotid artery is advocated by Crile, but this step will not control the venous bleeding, which is the most harassing hemorrhage encountered. Many operators form a large osteoplastic flap in front of the ear (Figs. 561 and 562). I do not believe that an osteoplastic flap is necessary. The temporal fascia is so thick and tense that when the wound in it is carefully sutured protection is perfect and safety is secured. Hemorrhage is to be carefully arrested. Most of the bleeding is venous and from the diploë. It can be arrested by pressure with compresses soaked in hot water, Horsley's wax or plugging the bone spaces with bits of frayed out temporal muscle. It may be found that the meningeal artery has been ruptured. If this accident has happened and the vessel lies in a bony canal, plug with Horsley's wax. If the vessel is bleeding upon the dura, ligate by passing suture-ligatures around it. If it is torn off at the foramen spinosum, pack the foramen with iodoform gauze, and postpone the conclusion of the

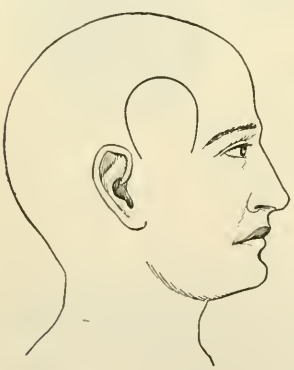

Fig. 561.—Hartley's osteoplastic flap in removal of Gasserian ganglion (Tiffany).

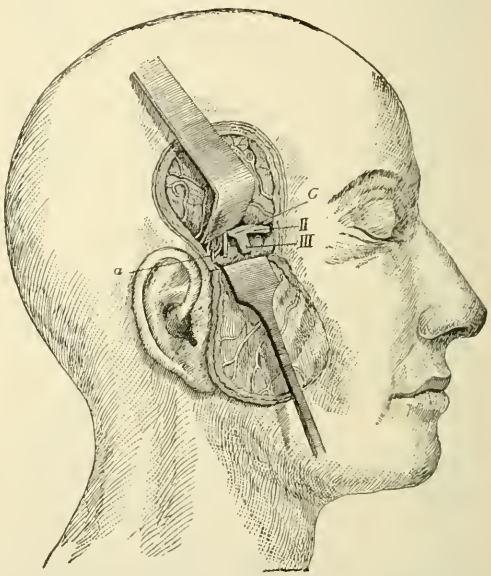

Fig. 562.—Removal of Gasserian ganglion: *a*, Middle meningeal artery; *II*, ophthalmic division; *III*, submaxillary division; *G*, ganglion (Krause).

operation for forty-eight hours. It may be necessary at any stage of this operation to pack the wound and postpone completion for two days. Some surgeons (Krause, Bergmann) ligate the meningeal artery as a routine procedure, but this operation may be difficult and require much time. If the unligated vessel is divided, the hemorrhage can be arrested by gauze packing or by plugging the foramen spinosum with a bit of sterile wood, but it is best to ligate the vessel. If the head and body of the patient were not elevated before they should be now. This position allows the brain to drop posteriorly and renders forcible retraction unnecessary, and, further, it lessens venous bleeding (Lexer). The next step is to lift up the dura and with it the brain (Fig. 562). Find the inferior maxillary nerve and clamp it with hemostatic forceps. Find the superior maxillary nerve and clamp it. Uncover the ganglion. Loosen the nerves from their beds by a dry dissector and divide each one at its foramen of exit. Twist the clamp forceps so as to reel up the nerves. This pulls out the ganglion intact with the motor root and the root of origin, as far back as the pons (Krause's method). Arrest bleeding; close the flap; sew together by a couple of stitches the lids of the affected side in order to keep them temporarily closed, and cover the eye

with a watch-crystal. The eye is to be washed out frequently. Thus irritants are excluded.

Cushing has modified the Hartley operation so as to permit of extradural manipulation below the arch made by the middle meningeal artery and thus lessen the danger of laceration of the artery ("Jour. Amer. Med. Assoc.," April 28, 1900). The anterior arm of the incision of the soft parts is so placed that it does not cut the nerve to the occipitofrontalis muscle. Thus drooping of the lid and oblation of brow wrinkles on that side are avoided. He trephines the wall of the temporal fossa very low down, opens into the skull below the arch of the meningeal vessels, and thus avoids the meningeal at the foramen spinosum of the sphenoid bone and the sulcus arteriosus of the parietal bone.

Horsley's Intradural Method.—An opening is made into the middle fossa of the skull, the dura is opened, and the ganglion is found and removed. This operation is easier than the extradural method, but is believed to be more dangerous.

The Frazier-Spiller Operation of Intracranial Neurotomy of the Sensory Root of the Trigeminus.—This operation was first performed by Frazier in 1901. If experience shows that after division of the sensory root the nerve does not regenerate, and it seems probable that it does not, the operation must be regarded as a valuable addition to our resources. This operation is by many surgeons preferred to removal of the ganglion. The patient is placed semierect. A horseshoe-shaped flap is made, starting at the middle of the zygoma and ending behind and below the helix. The flap is turned down. The temporal fossa is exposed, the bony wall is trephined, at a point slightly posterior to that used by most surgeons to reach the ganglion. The center of this opening is on a line with the point at which the sensory root joins the ganglion. The trephine opening is enlarged to the infratemporal crest by the use of a rongeur. The dura is separated from the base of the skull to the foramen spinosum. The meningeal artery is tied and divided. The dura is divided over the third division and is separated from the upper surface of the ganglion posteriorly. The dural envelope of the ganglion is opened, separated, and the sensory root exposed. The sensory root is then picked up on a blunt hook and divided or avulsed. It is frequently possible, Frazier tells us, to separate the sensory root from the motor root. When the sensory root has been divided the anesthetic is put aside as the parts are now anesthetic. As soon as the reflexes return test the conjunctional reflex to be certain that no sensory fibers retain their continuity. Suture the flap and use a drain of rubber tissue. In this operation we avoid the venous hemorrhage from the foramen ovale and foramen rotundum which is apt to be encountered when removing the ganglion, and escape the bleeding which always occurs when the ganglion is lifted from its seat, and escape the danger of injuring the cavernous sinus, the third, fourth, and sixth nerves, and the motor root. Frazier has had great success with this operation, is convinced that the sensory root does not regenerate and that ulceration of the cornea is less common than after removal of the ganglion.

Abbé's Operation of Intracranial Neurectomy of the Second and Third Divisions.—This operation is preferred by Charles A. Ballance, who opposes exposure of the ganglion or division of the sensory root unless the first division of the nerve is the seat of pain. He advocates this in spite of knowing full well that the pain may return in a few years. He advocates it because of its safety, its simplicity, its freedom from serious hemorrhage, its avoidance of opening the intradural space and of all danger of corneal anesthesia, and also because if pain returns the operation can be repeated. The operation is performed as follows: Ligate the external carotid artery of the diseased side, make a vertical incision over the middle of the zygoma down to the bone. An opening into the skull is made by a mallet and gouge, and this opening is enlarged by a rongeur until it is 1½ inches in diameter. The dura is

lifted from the middle fossa and the nerves are exposed. Each nerve-trunk is clamped, is divided near its foramen of exit, and is separated from the ganglion by cutting or twisting by the forceps. A strip of sterile rubber tissue, 1½ inches in length and ¾ inch in width, is laid over the round foramen and the oval foramen and is pressed into place by gauze. In a few moments the gauze is withdrawn and the ganglion is allowed to descend upon the rubber tissue. The wound is then closed. (See Robert Abbé, in "Annals of Surgery," Jan., 1903.) The rubber tissue is used to block the foramina of exit and prevent future emergence of regenerating nerves. Mayo Robson blocks the foramina by a thin plate of lead or silver, a knob of the plate entering the oval foramen to prevent displacement. Kanavel uses bone-grafts. Mixter used amalgam.

Division of the Auditory Nerve for Tinnitus Aurium and for Aural Vertigo.—This operation was proposed for tinnitus by Krause in 1902. Ballance did it on the right side with success in a most distressing case of painful tinnitus. When the cerebellar hemispheres were displaced by sponges the nerves of the posterior fossa were brought into view. He divided the eighth nerve, but made no attempt to preserve the nerve of Wrisberg. Five months after operation the patient was well except for deafness and deviation of the tongue to the left. (See Ballance, in "Lancet," 1908, vol. ii.) Frazier has divided the auditory nerve for aural vertigo, with partial relief.

Operation for Facial Paralysis of Extracerebral Origin (Facio-accessory Anastomosis and Faciohypoglossal Anastomosis).—(See "Remarks on the Operative Treatment of Facial Palsy of Peripheral Origin," by Chas. A. Ballance, Hamilton A. Ballance, and Purves Stewart, "Brit. Med. Jour.," May 2, 1903; and also the "Surgical Treatment of Facial Paralysis by Nerve Anastomosis," by Harvey Cushing, "Annals of Surgery," May, 1903.) In 1898 Furet suggested to Faure that he should anastomose the peripheral end of a divided facial nerve to that portion of the spinal accessory nerve which goes to the trapezius muscle. Faure did this, but the operation failed. Robert Kennedy, of Glasgow, did the first successful operation. He divided the facial for the relief of spasm and at once anastomosed to a partly divided spinal accessory. The procedure first employed by Ballance was, after noting by galvanism that muscular fiber still remained, to expose the facial nerve at its point of exit from the stylomastoid foramen, to cut the nerve-trunk across as high up as possible, to expose the spinal accessory, and to suture the distal end of the facial into the trunk of the spinal accessory. The spinal accessory was cut half through to make a bed for the end of the facial. The paper of the Ballances and Stewart above referred to recommends end-to-side anastomosis between the divided facial and the hypoglossal. The authors have operated five times for facial palsy. Cushing, Keen, Hackenbruch, Körte, Currie, Beck, Vidal, Girard, Lund, Alt, Frazier, and others have done similar operations. Marked improvement may follow operation even if palsy has lasted for a considerable time. Improvement followed operation in Currie's case, although the palsy was nearly a year old. The period when improvement should be expected is uncertain. Signs of improvement may not be evident for six months or longer. In Cushing's case they began in thirteen days; in Kennedy's case, in seven days. In most cases operation restores facial symmetry when at rest and in many cases during volitional movements. The patient will often become able to close the eye and raise the angle of the mouth. Curious associated movements may occur. In Currie's case when the patient lifted his shoulder there was contraction of the occipitofrontalis muscle ("South African Med. Record," 1907). Grant operated upon a case of traumatic facial paralysis over four months after the injury. He anastomosed the facial to the spinal accessory and the peripheral end of the accessory to the descendens hypoglossi. At the end of fifteen weeks there were feeble association movements of the face and shoulder, which later disappeared. At the end of a year the result was most gratifying ("Jour. Am. Med. Assoc.," Oct. 22, 1910).

Facio-accessory anastomosis does not restore emotional movements, but faciohypoglossal anastomosis may restore them. Küster reports a case which confirms this.

Operation is indicated when a complete facial palsy is of such duration that recovery is not to be hoped for by longer delay. The Ballances and Stewart believe that when palsy has lasted six months without sign of recovery, operation is indicated. A paralysis due to traumatism gives a much better prognosis after operation than does a paralysis due to a septic process (Chas. A. Ballance, Hamilton Ballance, and Purves Stewart, in "Brit. Med. Jour.," May 2, 1903). Murphy has collected 33 cases of anastomosis of the facial nerve with the spinal accessory, hypoglossal, or glossopharyngeal, and Joseph Beck has added 5 cases of his own in which he performed faciohypoglossal anastomosis.

The hypoglossal is preferred to the accessory. Its trunk is larger and its cortical center is adjacent to the facial cortical area. After such an operation associated movements are not observed when the mouth is kept closed, and, if Gowers is correct, the fibers of the facial, which supply the muscles closing the mouth, may take origin from the hypoglossal nucleus (John B. Murphy, in "Surg., Gynec., and Obstet.," April, 1907). Murphy points out that an anastomosis may be end to end, implantation of the facial into a slit in the other nerve, implantation of the facial into a partial transverse division of the other nerve, or end to side (Ibid.).

Operation for Brachial Birth Palsy.—(See article by L. P. Clark, A. S. Taylor, and T. P. Prout, in "Am. Jour. Med. Sciences," Oct., 1905.) These authors report 8 cases of operation with some notable improvements and with 2 deaths. In these cases they found great thickening of the fascia and in some cases fibrous tissue almost completely obscured the remains of lacerated trunks or roots. They advise that the patient be placed recumbent, with a sand-pillow beneath the shoulders and with the head extended and bent toward the opposite shoulder. An incision is made at the posterior border of the sterno-cleidomastoid and the plexus is exposed and explored. Sharpe reports 56 cases upon which he operated ("Jour. Am. Med. Assoc.," March 18, 1916). He makes a transverse skin incision above and parallel to the clavicle and over the supraclavicular space of the posterior triangle. If the lesion is above the clavicle, it is at once attacked; if below that bone, the incision is carried down and the bone is sawed in two. The scar tissue with the lacerated nerves is removed and the nerves or nerve-roots are sutured. The wound is closed, the clavicle being wired if it has been divided. After dressings are applied the head is bent toward the shoulder of the damaged side and fixed with plaster of Paris.

I operated on a case of Dr. Charles S. Potts's in the Philadelphia Hospital. The roots were not torn, but were found embedded in a thin layer of scar which it was possible to remove. The result was good. Nerve anastomosis may be necessary if exsection of scar leaves an unbridgable gap or if nerve-roots have been divided within the foramina.

Operation for Avulsion of the Brachial Plexus.—(See page 842.)

XXIV. DISEASES AND INJURIES OF THE HEAD

Diseases of the Head

In approaching a case of brain disorder, first endeavor to locate the seat of the trouble; next, ascertain the nature of the lesion; and, finally, determine the best plan of treatment, operative or otherwise. In all operations upon the brain the surgeon must be able to determine accurately the situations of certain fissures and convolutions, the finding of the situations of these convolutions and fissures comprising the science of *craniocerebral topography.*

The *regional terms* used in craniocerebral topography are derived from Broca (Fig. 563). The middle meningeal artery is found at the *pterion*, 1¼ inches posterior to the external angular process, on a level with the roof of the

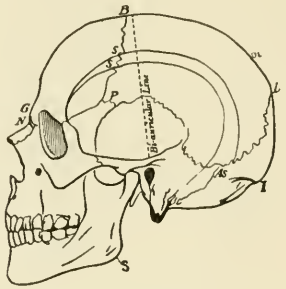

Fig. 563.—Skull, showing the points named by Broca: *As*, Asterion (junction of the occipital, parietal, and temporal bones); basion, middle of anterior wall of foramen magnum; *B*, bregma (junction of the sagittal and coronal sutures); *G*, ophryon (on a level with the superior border of the eyebrows, and corresponding nearly to the glabella, the smooth swelling between the eyebrows); *g*, gonion (angle of the lower jaw); *I*, inion (external occipital protuberance); *L*, lambda (junction of sagittal and lambdoidal sutures); *N*, nasion (junction of the nasal and frontal); *Ob*, obelion (the sagittal between the parietal foramina); *P*, pterion (point of junction of great wing of sphenoid and the frontal, parietal, and squamous bones—this may be H-shaped or K-shaped or "retourné," in which the frontal and temporal just touch); *S*, stephanion; (or, better, the superior stephanion, intersection of ridge for temporal fascia and coronal suture); *S'*, inferior stephanion (intersection of ridge for temporal muscle and coronal suture).

orbit (Fig. 564). The fissures and convolutions of the brain are shown in Figs. 565, 566 and 567. The *fissure of Bichat* is marked by a line on each side drawn from the *inion* to the external auditory process. A line from the *glabella* to the inion overlies the median fissure and the superior longitudinal sinus. The *fissure of Rolando* is very important, as marking the posterior limit of the motor region of the brain. It begins near the median line, ½ inch posterior to the middle of the distance between the inion and glabella (Thane). This fissure

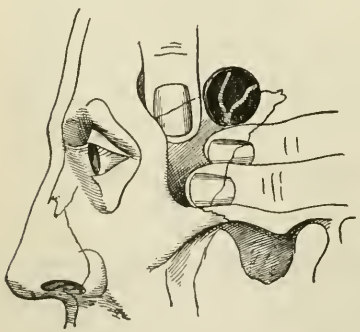

Fig. 564.—The meningeal artery exposed by trephining (after Esmarch).

Fig. 565.—View of the brain from above (Ecker).

runs downward and forward at an angle of 67.5° for a distance of 3⅜ inches. Chiene finds the fissure of Rolando by the following method: He takes a square piece of paper and folds it into a triangle (Fig. 568, 1); the angle B–A–C of this triangle is 45°; the edge D–A is folded back on the dotted line A–E; the angle

D–A–E equals half of 45°, or 22.5°, and the angle C–A–E equals the same (Fig. 568, 2); the paper is unfolded in the line C–A; in the figure thus formed B–A–C = 45° and E–A–C = 22.5°; E–A–B = 67.5°, which is the angle desired. Place the point A in the midline of the head, over the point of origin of the Rolandic fissure; the side A–B is laid along the middle line of the head, and the line A–E corresponds to the fissure of Rolando.[1] Horsley determines the situation of the Rolandic fissure by the use of his metal cyrtometer (Fig. 569). He places the point marked zero over the inioglabellar line and midway between the inion and the glabella. To find the *fissure of Sylvius* (Fig. 566, *S*, *S'*, *S''*), draw a line from the external angular process to the occipital protuberance. The fissure of Sylvius begins on this line 1⅛ inches behind the external angular process; the main branch of the fissure runs toward the parietal eminence; the ascending

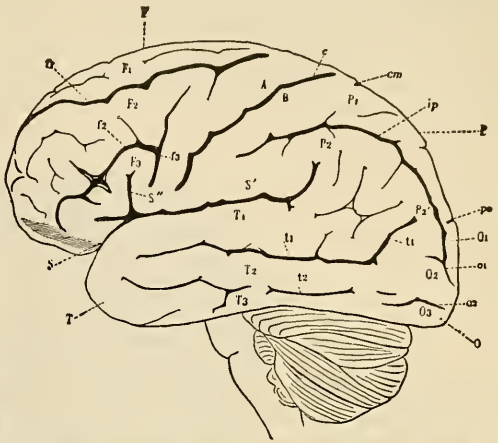

Fig. 566.—Outer surface of the left hemisphere of the brain (Ecker).

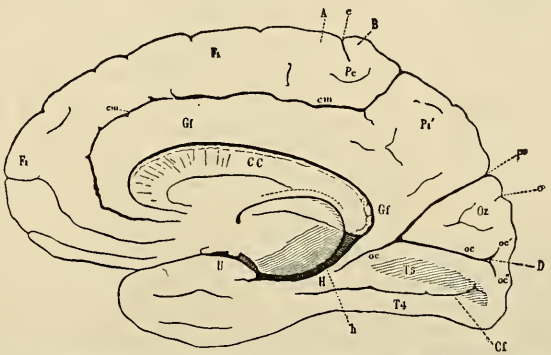

Fig. 567.—Inner surface of the right hemisphere of the brain (Ecker).

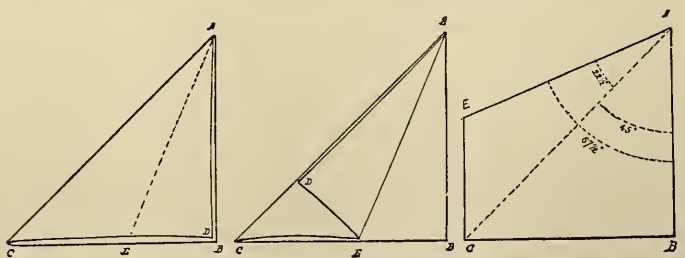

Fig. 568.—Chiene's method of fixing position of Rolandic fissure ("American Text-Book of Surgery").

branch of the fissure corresponds to the squamosphenoidal suture, and continues upward in the same line ½ inch above the suture. The *precentral sulcus* (Fig. 566, F) limits anteriorly the ascending frontal convolution; it runs

[1] "American Text-Book of Surgery."

parallel with and just behind the coronal suture, and a finger's breadth in front of the fissure of Rolando. The *intraparietal fissure* (Figs. 565 and 566, *ip*) limits the ascending parietal convolution posteriorly. It begins opposite the junction of the lower and middle thirds of the fissure of Rolando, passes

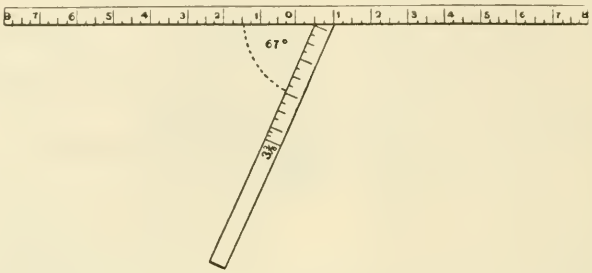

FIG. 569.—Horsley's cyrtometer.

upward in a line parallel with the longitudinal fissure and midway between the Rolandic fissure and the parietal eminence, passes by the parieto-occipital fissure, and downward and backward into the occipital lobe. The motor areas, which on the outer surface are adjacent to the fissure of Rolando, are shown in Figs. 565 and 566.[1] The superior longitudinal sinus is overlaid by a line from the inion to the glabella. The lateral sinus is indicated by a line running from the occipital protuberance horizontally outward to a point 1 inch posteriorly to the external auditory meatus, and from this point by a second line dropped to the mastoid process. The *suprameatal triangle* of Macewen is bounded by the posterior root of the zygoma, the posterior bony wall of the auditory meatus, and a line joining the two. The mastoid antrum is opened through *Macewen's triangle* to avoid injury to the lateral sinus. *Barker's point*, the proper spot to apply the trephine for abscess of the temporosphenoidal lobe, is 1¼ inches above and 1¼ inches behind the middle of the external auditory meatus. Fig. 570 shows clearly the main points of cranio-cerebral topography, obtained by methods approved by many scientists.

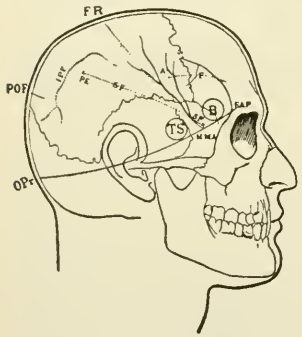

FIG. 570.—Head, skull, and cerebral fissures: B corresponds to Broca's convolution; EAP, external angular process; FR, fissure of Rolando; IF, inferior frontal sulcus; IPF, intraparietal sulcus; MMA, middle meningeal artery; OPr, occipital protuberance; PE, parietal eminence; POF, parieto-occipital fissure; SF, Sylvian fissure; A, its ascending limb; TS, tip of temporosphenoidal lobe. The pterion (to the left of B) is the region where three sutures meet, viz., those bounding the great wing of the sphenoid where it joins the frontal, parietal, and temporal bones (adapted from Marshall by Hare).

Krönlein's method for localizing certain areas is the most generally serviceable (Figs. 571 and 572). A line, known as the base line, Z–M, is carried horizontally backward from the lower border of the orbit through the upper border of the external auditory meatus. Another horizontal line, K–K′, is drawn parallel with this, on a level with the supra-orbital ridge. A line Z–K is erected from the middle of the zygoma to the supra-orbital line. A vertical line is drawn from the articulation of the lower jaw, A, and is prolonged to R. A vertical line is drawn from the posterior border of the mastoid base (M–K′) and is taken to P, the middle line of the skull. A line is drawn from K to P, and between the points R and P′ it overlies the fissure of Rolando. The angle P–K–K′ is

[1] Recent studies indicate that the motor region is entirely in front of the Rolandic fissure.

bisected by the line K–S, which corresponds to the fissure of Sylvius from its point of bifurcation to its posterior termination; K marks the bifurcation of the fissure of Sylvius. To reach the anterior branch of the middle meningeal artery trephine at K; to reach the posterior branch, trephine at K′.

Head Injuries During Labor.—**Caput Succedaneum.**—This condition is edema of the scalp due to prolonged pressure. The edema is circular and circumscribed and occupies the part not subjected to continued pres-

Fig. 571.

Figs. 571 and 572.—Krönlein's method of locating the fissure of Rolando (*R–P′*) and Sylvius (*K–S*); Krönlein's point of trephining for hemorrhage from the middle meningeal (*K–K′*); and von Bergmann's region for trephining for abscess of the temporosphenoidal lobes (*A–a–K′–M*) ("American Text-Book of Surgery").

sure during the uterine contractions of labor. The ring of tissues around which circumferential pressure is exerted by the os uteri project like a cup into the birth canal. The veins become congested and edema results. The parts subjected to pressure may appear normal or may exhibit ecchymoses or even excoriations. The pressure is usually made by the os, and its situation varies with the presentation, but because the most frequent presentation is left occipito-anterior, the common position of the caput is over the superior and

posterior portion of the right parietal bone. In a face presentation great disfigurement may occur. It is seldom that a double caput is encountered. It always means that the presentation has shifted. The worst cases of caput follow prolonged labor. The edematous swelling contains bloody serum, pits on pressure, does not fluctuate, is not limited to the outline of one bone, and the skin above it is usually discolored by ecchymoses. No treatment is necessary, as the condition will disappear in from a few hours to three days.

Cephalhematomata.—By this term we mean extravasations of blood beneath the untorn pericranium. It is supposed by many to be due always to pressure and venous congestion, as is a caput succedaneum. As Cushing points out, the condition cannot result from the venous stasis of prolonged pressure alone. If it did it would always exhibit above it a caput succedaneum, "and this is far from our actual experience" (Harvey Cushing, in "Keen's Surgery," vol. iii). It is certainly due in some cases to bending or breaking of a cranial bone. The condition is said to occur in 1 labor out of 200. In most cases there is but one cephalhematoma, but there may be two, three, or even four. The commonest situation is over the right parietal bone (the common seat of caput succedaneum), and caput succedaneum may be associated with a cephalhematoma. The condition may be bilateral. The blood begins to flow beneath the pericranium during labor and the swelling increases during the first few days after birth; in fact, it is frequently not noticed for two or three days. The swelling is tense and smooth, with a convex outline and when recent feels like a cyst. It may cover but a small portion of a bone or an entire bone, but never extends beyond the bounding sutures. This limitation is due to the fact that the pericranium is attached to the sutures. In the course of a couple of weeks the raised and irritated periosteum begins to produce bone and the ring of hardness usually detected at the margin of the lump at this time is due to the formation of new bone. Bone-plates usually develop over the surface of the swelling. If plates form crepitus can be detected. A shell of bone may eventually surround and cover over the clot, an area of permanent bony thickening remaining. In other cases no bone forms, but the clot gradually disappears. Extradural and even subdural hemorrhage may be associated with a subpericranial bleeding.

Cephalhematomata unassociated with cerebral symptoms usually disappear without operation. If there is no sign of subsidence after two weeks, follow Cushing's rule, evacuate by a puncture-like incision and apply pressure. If suppuration occurs, incision is necessary. Suppuration may occur if the scalp has been excoriated. In cephalhematoma with cerebral symptoms operation is indicated (incision of the scalp and removal of a piece of bone).

Diseases of the Scalp.—The scalp is composed of skin, subcutaneous fat, the occipitofrontalis muscle and aponeurosis, the subaponeurotic cellular tissue, and the pericranium. The scalp is liable to inflammation from various causes, and also to certain diseases—namely, tumors, cysts, warts, moles (local cutaneous hypertrophies), cirsoid aneurysm (see page 496), nevi, and lupus. *Abscesses of the scalp* are common. If an abscess forms beneath the pericranium, the pus diffuses over the area of one bone, being limited by the attachment of the pericranium in the sutures. In cranial osteomyelitis pus may gather between the dura and bone and between the bone and pericranium. The condition is known as *Pott's puffy tumor.* If an abscess forms in the tissue between the occipitofrontalis and the pericranium, it is widely diffused. Treves calls this subaponeurotic connective tissue "the *dangerous area.*" Abscess of the subcutaneous tissue is apt to be limited because of the great amount of fibrous tissue. Abscess beneath the pericranium does not spread beyond the suture lines. It is limited by the sutural membrane which runs from pericranium to dura. Abscess is treated by instant incision at the most dependent part and drainage. In abscess beneath the occipitofrontalis ap-

oneurosis it is necessary to open and drain above the eyebrows, above the superior curved line of the occipital bone, and at each side above the line of origin of the temporal fascia.

Diseases and Malformations of the Bones of the Skull.—The bones of the skull are liable to caries, necrosis, osteitis, periostitis, osteomyelitis, atrophy, hypertrophy, tumors, etc. (See Diseases of Bones.)

Cranial Pneumatocele.—This rare condition is a result of perforation of a bone which permits air to collect beneath the periosteum. It may occur in the mastoid or occipital region or over the frontal region. These protrusions vary greatly in size; and as their shape depends upon the periosteal attachment to sutures in the neighborhood, they vary in shape. The overlying tissues are natural in appearance. The protrusion is tense, but may lessen or disappear on pressure. McArthur ("Jour. Am. Med. Assoc.," May 6, 1905) points out that if diminished by pressure, the patient may hear a sound like rushing air or water in the ear if the protrusion is occipital or mastoid; and in the nose, if it is frontal. An elevated ridge of bone surrounds a pneumatocele. The protrusion is tympanitic on percussion. The condition is due to perforation of the bony wall of an air sinus by disease, injury or rupture. McArthur points out that in half of the reported cases the rupture was not preceded by any history of inflammation or injury. The condition is not dangerous.

Treatment.—Incision, finding the opening in the bone, enlarging it, removing osteophytes; bringing the walls of the cavity together and applying pressure.

Microcephalus.—By "microcephalus" is meant unnatural smallness of the head due to imperfect development. Marked microcephalus is not a common condition, but it is an occasional cause or associate of idiocy. A child may be born with a skull completely ossified even at the fontanels, or the ossification may become complete soon after birth, but in many cases of microcephalus ossification takes place late or not at all. In microcephalus the face is usually fairly well developed; the jaws are prominent; the forehead is flat; the cranium and brain are small; the convolutions of the brain are simpler than is natural; there is apt to be marked asymmetry of the two sides of the brain; internal hydrocephalus may exist; areas of sclerosis and atrophy are common; porencephaly is not unusual. Some patients have perfect motor power; others are slow and incoördinate. Epilepsy, chorea, and athetosis frequently complicate the case. Idiots of this type often present deformities such as cleft palate, strabismus, distorted ears, hypertrophied tongue, deformed genitals or extremities, ill-shaped and irregularly developed teeth. They exhibit irregular muscular movements, are frequently paralyzed in childhood (infantile paraplegia or hemiplegia), and suffer from subsequent contractures. They are active, destructive, excitable, and are liable to be violent and almost demoniacal. As Clouston says, they look impish and unearthly.

Treatment.—Skilled training in a school for the feeble minded or in an institution for idiots is necessary in treating microcephalic idiocy. Idiots have but little power of attention, and sensory impressions give rise to but few concepts, and these are feeble and fleeting. In order to educate the idiot it is highly desirable that speech be acquired, and "the more strongly the attention can be aroused, the more perfect does speech become" (Kirchhoff). The principle of the education of idiots is to stimulate, coördinate, and guide sight, hearing, feeling, taste, and smell.

Lannelongue, of Paris, suggested an operation for idiocy with premature ossification (see Linear Craniotomy, page 936). In this procedure the author has no confidence. Idiocy is a general disorder and not a local brain disease. Soft parts mold bone, and bone does not control soft parts. There is no evidence that the brain is being compressed; in fact, the simplicity of the convolutions suggests the contrary. In many typical cases of microcephalic idiocy

there is no synostosis even years after birth. The operation has been much abused. It is sometimes fatal, and, although a fatality may gratify the family, a surgeon should not be a legal executioner. The remarkable improvement which has been reported in some cases is wrongly supposed to be due to the operation. As a matter of fact, the new surroundings, the strange faces, the firm discipline, the effect of the anesthetic, and the shock of the operation attract the feeble attention and rouse the sluggish senses. Many cases are brought for operation because they are for the time being unusually intractable and excitable, and the return to the usual level of conduct after operation is regarded as a permanent gain, when it is often but a temporary alleviation. We believe that scientific training is the proper treatment, and that the efficiency of training is not increased by the previous performance of craniotomy, and we follow the precept of Agnew, that a surgeon might as well cut a piece out of a turtle's back to make a turtle grow as to cut a piece out of the skull to make the brain grow. It would be as wise to take a piece out of the dome of a cathedral to increase the stature of the dean and chapter.

Diseases and Malformations Involving the Brain.—**Cephaloceles.**—A cephalocele is a congenital protrusion of intracerebral contents through a defect in the skull. These protrusions are covered by skin. The defect through which the protrusion occurs is always in the median line, although in some cases (as at the inner angle of the orbit) the visible protrusion may be at the side. Nearly all such protrusions are either frontal or occipital, although now and then one presents in the pharynx, having emerged from the skull between the body of the sphenoid and the ethmoid.

Frontal cephaloceles are divided into:

1. Nasofrontal—those which are in the region of the glabella.
2. Naso-orbital—those at the inner angle of the orbit.
3. Naso-ethmoidal—those below the nasal bone.

Each one of the above forms passes through the horizontal plate of the ethmoid.

Occipital cephaloceles are divided into:

1. Superior—those above the external occipital protuberance. In these the bony gap may join the posterior fontanel.
2. Inferior—those below the external occipital protuberance. In these the bony gap may join the foramen magnum.

The above regional classification is that advocated in von Bergmann's "System of Practical Surgery" (translated and edited by Wm. T. Bull and Walton Martin).

The commonest form is hydrencephalocele, and all other forms result from retrograde change in this.

Hydrencephalocele.—This is by far the commonest and is also the most dangerous form encountered. The protrusion consists of arachnoid, a layer of brain tissue, and a cavity containing ventricular cerebrospinal fluid and connected with the lateral ventricle. It is, in reality, a protrusion of the lateral ventricle. It is covered by skin—natural skin—unless the protrusion is very large, in which case the skin is more or less atrophied. Beneath the skin is fascia, and beneath this, arachnoid. The pericranium and dura do not cover it, but each has a gap in it and these two tissues join each other around the bone margins.

Encephalocele results from retrograde changes in a hydrencephalocele. The protrusion of the ventricle has become reduced and the hernia consists of a portion of brain covered by arachnoid. Encephalocele is only seen in the nasofrontal region. If there is any fluid in this protrusion it is not in its interior, but on its surface, and results from a cyst of the arachnoid.

Meningocele.—We formerly understood by a meningocele a protrusion of the membranes alone; we now regard it as a condition resulting from retro-

grade changes in a hydrencephalocele. The brain tissue of the latter disappears; beneath the arachnoid is a layer of cells identical with those which line the ventricles; the connection with the ventricle is entirely or almost completely cut off; a cyst forms in the subarachnoid tissue, and thickened pia surrounds the cyst. (See "System of Practical Surgery," by E. von Bergmann, vol. i, translated and edited by Wm. T. Bull and Walton Martin.) The above condition is called by von Bergmann encephalocystomeningocele.

Diagnosis.—The congenital origin and situation make certain that the condition is cephalocele. The bony gap can usually be felt; whether it can or cannot, an *x*-ray picture should be taken. Such a picture may indicate that the mass contains brain matter. The protrusions vary greatly in size and shape. Some are rounded, some are flattened, some are stalked. The skin covering them may be natural, atrophied, filled with vessels, scarred, or ulcerated. Sometimes the cephalocele is very tense; sometimes it is loose. In naturally hairy regions the skin over the summit of the protrusion is bald, but that around the base is hairy. If there is connection between the interior of the protrusion and the ventricle, the mass can be diminished in size by compression. If it shrinks rapidly from compression, the opening into the ventricle is large. In such cases compression of the mass quickly causes signs of cerebral pressure. Lumbar puncture may cause the protrusion to diminish in size; crying may cause it to increase in size. Large cephaloceles fluctuate and perhaps pulsate. Meningocele feels and looks like a cyst (is translucent and fluctuates); it does not usually pulsate, it has a small base, it becomes tense on forcible expiration, and some cases can be very slowly diminished by compression.

Encephalocele is small, opaque, does not fluctuate, has a broad base, does pulsate, becomes tense on forced expiration, and attempts at reduction fail and cause pressure symptoms.

Hydrencephalocele is larger than a meningocele, is translucent, fluctuates, rarely pulsates, is pedunculated, is rendered a little tense on forced expiration, and can be lessened in size by compression, but cannot be reduced.

Treatment.—In von Bergmann's "System of Practical Surgery" we find the wise caution to attempt no operation for an occipital protrusion beneath the protuberance when the cleft enters the foramen magnum and is associated with cleft of the cervical vertebræ—for a condition in which the soft parts are defective and the brain is exposed (*cranioschisis*)—on a case complicated by hydrocephalus or on a case complicated by some other condition which is of necessity fatal. We no longer refuse to operate because the mass contains some brain matter or because it communicates with the ventricle, although if it does so, the prognosis is much worse. For a large hydrencephalocele nothing can be done and early death is inevitable. In rare instances an encephalocele is converted into a meningocele, and the bony aperture closes, thus bringing about a cure. Among the expedients for treating meningocele are electrolysis, injection of Morton's fluid (10 gr. of iodin, 30 gr. of iodid of potassium, 1 oz. of glycerin), pressure, and excision. In cases of cephalocele, when portions of the nerve-centers are not contained in the sac, A. W. Mayo Robson advises the performance of a plastic operation. He ligates the neck of the sac, excises the sac, sutures the skin-flaps separately, and leaves the stump outside the line of superficial sutures. It is usually possible to tell by palpation if nerve-centers are in the sac, but if in doubt, make an exploratory incision, and sweep the finger around inside of the sac.[1] Meningoceles should be operated upon by Robson's plan.

Spurious Meningocele.—It occasionally happens, after a fracture of a child's skull, that cerebrospinal fluid gathers beneath the pericranium and bulges the pericranium and scalp. This condition is called spurious meningocele. When a spurious meningocele forms, the bone must have been

[1] "Amer. Jour. Med. Sciences," Sept., 1895.

broken and the dura and arachnoid ruptured. This protrusion fluctuates, pulsates, and is influenced by respiration. In some cases there is communication with the ventricles of the brain. The parietal and frontal regions are the most usual seats of the trouble. The opening in the skull may close; it may remain stationary; it may actually enlarge by bone-absorption. In some cases the spurious meningocele undergoes spontaneous cure; in some cases rupture occurs; in other cases death takes place as a result of the cerebral injury. (See Joseph Sailer on "Spurious Meningocele," "University Med. Magazine," Sept., 1900).

Treatment.—Close the opening by a plastic operation.

Hydrocephalus.—In *external* hydrocephalus the fluid is on the surface of the brain; in *internal* hydrocephalus the fluid is in the ventricles. Hydrocephalus may be *acute* or *chronic*, *congenital* or *acquired*.

Acute hydrocephalus is usually internal, but may be external. It results from meningitis—usually tuberculous meningitis of the base. The symptoms are headache, elevated temperature, delirium, stupor, convulsions, paralysis, and choked disk.

Treatment of acute hydrocephalus by medical means is of no avail. Tapping of the ventricles may be tried. Drainage of the cisterna magna has been suggested.

Chronic internal hydrocephalus is usually congenital, but may arise after birth in children under seven. In congenital hydrocephalus the condition may be due to circulatory disturbances in the brain of the embryo resulting from uterine disease or injury during pregnancy. Syphilis and alcoholism in parents seem sometimes to be responsible. Chronic acquired hydrocephalus results from inflammation, especially tuberculous inflammation. A tumor pressing on the veins of Galen may cause it. In chronic acquired internal hydrocephalus there is overproduction or underabsorption of cerebrospinal fluid and perhaps both conditions may exist. The usually causative condition is an inflammation of the interior of the ventricles, particularly of the choroid plexuses, and as a consequence venous return is obstructed and oversecretion occurs. In very rare cases one or both foramina of Monro may be closed, and if only one is closed, unilateral hydrocephalus may arise (Alfred S. Taylor, in "Am. Jour. Med. Sciences," August, 1904). The aqueduct of Sylvius, the foramen of Magendie, and the central canal of the cord may be, but seldom are, occluded. Guthrie ("Practitioner," July, 1910) studied 182 cases of meningitis at autopsy. In about 40 per cent. of the tuberculous cases and in 56 per cent. of the non-tuberculous cases hydrocephalus existed. A tumor may cause hydrocephalus by directly obstructing the flow of fluid from the ventricles, but a tumor far away from such a position may cause it by so increasing the intracerebral tension that the brain stem is forced down into the foramen magnum. Such a position of the pons and cerebellum cuts off the flow of cerebrospinal fluid between the subarachnoid spaces of the brain and cord. Thomas produced internal hydrocephalus in animals by injecting into the ventricles an insoluble material known as aleuronat. Chronic inflammation ensued, obstruction and hydrocephalus followed ("Jour. of Exper. Med.," 1914, xix). Thomas says the obstruction may occur in the foramen of Monro or the aqueduct of Sylvius but occurs most frequently in the foramen of Magendie. Drandy and Blackfan ("Beitrag. z. klin. Chir.," 1914, xciii) after elaborate experiments concluded that an obstruction placed in the Sylvian aqueduct causes internal hydrocephalus even after extirpation of both choroid plexuses. This proves that fluid is produced within the ventricles more rapidly than it can be absorbed from them. Internal hydrocephalus also results from ligation of the great vein of Galen near its point of origin but does not from distal ligation of the vein or from ligation of the straight sinus (collaterals save the situation). The chief but not the only source of cerebrospinal fluid is the

choroid plexus of each ventricle. It is formed by processes of secretion and filtration. The amount of the fluid is increased by venous congestion and by the administration of pilocarpin.

Production and absorption should go on hand in hand, the entire amount of the fluid should be changed within twenty-one hours, the lymphatics play only a small part in absorption, the bulk of the fluid is taken up by the blood from the subarachnoid space. There is almost no absorption from the ventricles. If there is not free communication between the ventricles and the subarachnoid space the just balance between absorption and formation is destroyed and fluid accumulates in and distends the ventricles. The communication is made by the valveless foramina in the fourth ventricle, the foramen of Magendie and the two foramina of Key and Retzius (called also the foramina of Luschka). In hydrocephalus the cranium enlarges enormously and the bones of the skull are widely separated. The brain is distended and thinned and the sulci are obliterated. The broad forehead overhangs the eyes; the fontanels are elevated. The fontanels and sutures are open. The child is mentally weak or is an idiot, and very often does not learn to walk or to talk. Convulsions, palsies, and contractures are common, and blindness is frequently present. Such children usually die young. Any case of chronic hydrocephalus may develop evidences of hypopituitarism. In such a case it is probable that the distended third ventricle presses upon the hypophysis. There may be adiposity, undeveloped genitalia, scantiness of hair or, some hairy overgrowth, and optic atrophy. Hemianopsia does not occur a fact which at once marks off these cases from tumors of the hypophysis. (See Lewis J. Pollock, in "Jour. Am. Med. Assoc.," Jan. 30, 1915).

The *treatment* of chronic hydrocephalus is rarely of much avail. Pressure by strapping with adhesive plaster has been tried. Tappings through a fontanel may be performed by means of a trocar (only 2 or 3 oz. of fluid being withdrawn at a time). If much fluid is allowed to flow out, the head must be strapped with adhesive plaster afterward. If the skull ossifies, the lateral ventricles may be tapped after trephining. It has been proposed to drain by tapping the theca of the spinal cord (Quincke). This last operation is called *lumbar puncture* (see pages 969, 970). It will, of course, fail if the foramina in the floor of the fourth ventricle or the aqueduct of Sylvius are blocked. Even if they are open, it is of little service. The operation which promises most was devised by Sutherland and Cheyne, and is known as *intracranial drainage* ("Brit. Med. Jour.," Oct. 15, 1898). Their theory is that in hydrocephalus fluid distends the ventricles because the channels of communication between the ventricles and the subarachnoid spaces are closed. The subarachnoid spaces communicate directly with veins, hence fluid cannot collect under pressure in these spaces. Intracerebral drainage establishes a communication between the subarachnoid space and one ventricle. It is not necessary to operate on both sides in bilateral hydrocephalus, because the lateral ventricles communicate. A small opening is made in the skull. The dura is incised. A number of strands of catgut, which are tied together, are pushed through the brain so that one end of the catgut mass lies in a ventricle and the other end beneath the dura. The dura and scalp are then sutured. Brewer makes an osteoplastic occipital flap, also a dural flap, lifts the cerebral lobe, and pushes a drain of rubber tissue into a lateral ventricle.

The elder Senn passed a rubber tube into the ventricle and put the outer end of the tube beneath the skin of the scalp.

Alfred S. Taylor ("Am. Jour. Med. Sciences," August, 1904) makes an osteoplastic flap with its base over the right mastoid, cuts a dural flap, passes a slender aspirating needle through the second temporosphenoidal convolution into the lateral ventricle, draws off a *little* fluid, and measures the thickness of the brain. He then takes 6 strands of No. 2 forty-day catgut, each strand ½ inch longer than the thickness of the brain. The strands are tied together

with a spiral of catgut, 1¼ inches of the loop being left free. Three layers of Cargile membrane are wrapped about the shaft, but the tip remains free. It is carried into the ventricle along the needle track by thumb forceps, and the loops are slipped here and there, but chiefly downward, under the dura. Cargile membrane is placed between the loops and dura and the dura and skin are sutured. Taylor operated on 6 cases and 2 recovered, with relief of all signs of pressure.

The cisterna magna may be drained. Cotterill actually opened the foramen of Magendie, and the patient distinctly improved ("Lancet," Nov. 12, 1910).

Cushing, after determining by lumbar puncture that the ventricles can be emptied, obtains retroperitoneal drainage by a combined laparotomy and laminectomy. Marmion establishes drainage from the ventricles into the highly lymphatic tissues about the parotid gland ("Zentralb. für Chirurgie," August 12, 1911), and Payr, with the internal jugular vein by means of a transplanted artery or vein ("Archiv. für Klin. Chirurgie," August 26, 1911).

Puncture of the corpus callosum has been recommended by Anton, Ringel, Tillmann, Stieda, Bramann and others. The operation is called *ventriculostomy*.

The mortality is said to be less than 2 per cent. Any relief must be temporary as the puncture cannot be kept open. The operation is performed as follows, according to Bramann: Expose the skull 1 inch posterior to the coronal suture and in the middle line. Make a small opening in the skull and make a small dural opening near to the margin of the sinus. Pass a cannula or sinus forceps into the longitudinal fissure. Carry it vertically downward guided by the falx and push it through the corpus collosum. Open the blades of the forceps or remove the mandrin of the cannula, enlarge the opening by moving the instrument gently to and fro, remove the instrument and close the scalp wound (Binnie's "Operative Surgery").

Injuries of the Head

One of the most important subjects in surgery is that of head injuries. The frequency of their occurrence, their great fatality, the extraordinary recoveries that are sometimes encountered, the common difficulty in diagnosis, the drama which often leads to or accompanies them, combine to surround these cases with a peculiar interest.

Gross says: "It was long ago remarked by Mr. Pott, and the observation has been verified a thousand times since, that there is no lesion of the head so trifling, on the one hand, as not to endanger life, or so severe, on the other, that it may not be followed by recovery" ("A System of Surgery").

Liston, in his Lectures on the "Operations of Surgery," sets forth the same idea more concisely. He says: "It has been said, and truly, that no injury of the head is too slight to be despised, or too great to be despaired of."

After every injury of the head an *x*-ray examination should be made. In many cases a fracture cannot be detected by any other method.

After any head injury symptoms and signs of compression should be watched for most carefully. If they arise they are to be regarded as commands for surgical interference. Choked disk is an early and important sign of pressure.

Lumbar puncture should be performed after head injuries. Bloody cerebrospinal fluid is very significant though we can obtain clear fluid in some cases of subdural hemorrhage.

Caput Succedaneum.—(See page 867.)

Cephalhematoma.—(See page 868.)

Scalp-wounds bleed profusely because the scalp is very vascular, because many of the blood-vessels are in fibrous tissue and cannot contract and retract, and because even blunt force splits the scalp almost like an incision. Scalp-wounds are treated as are other wounds. Even a large piece of scalp with only a narrow pedicle may not slough; hence try to save any piece that has an attach-

ment. Always shave a wide area and disinfect the shaved area and the wound. Arrest hemorrhage, and exercise great care in cleansing the wound and the parts about it. Stitch the wound with silkworm-gut. Very few sutures are needed if the wound is longitudinal, but many are required if it is transverse. Deep vessels are ligated. The permanent arrest of hemorrhage from the skin and subcutaneous tissue is rarely effected by ligatures, but rather by sutures judiciously placed. If drainage is required, use a few strands of silkworm-gut; but drainage is rarely used unless we know the wound to be grossly infected. Wet antiseptic dressings are used for the first few days and moderate pressure is applied by wet gauze bandages. Avulsion of the Scalp is discussed on page 301.

Contusions of the Head.—Scalp swelling from hemorrhage is usually considerable. The patient may be stunned or dazed. The swelling of *hematoma of the scalp* must not be mistaken for *fracture* with depression. In hematoma there is a central depression; hard pressure on the center finds bone on a level with the general contour of the bone, and the margin of a hematoma is circular, is not quite hard, and is elevated above the general contour. In depressed fracture the edge is on a level with the central depression, is below the level of the general bony contour, and the margin is sharp and irregular. The treatment is by bandage-pressure. Should suppuration arise, at once incise.

Concussion, Contusion, and Laceration of the Brain.[1]—For many years it was customary to regard concussion as a condition produced by molecular vibrations in the nervous substance of the brain. Duret's classical observations profoundly modified surgical thought, and led to the opinion that in concussion of the brain there is injury to the brain itself, a rupture of cerebral vessels brought about by the advance and recession of waves of cerebrospinal fluid. This wave, it is thought, first flows in the direction of the force. Keen says that there may be slight brain injuries which can properly be called "concussions," but it is better to consider concussion as synonymous with laceration of the brain. Kocher considers concussion as identical with *contusion of the brain*. It seems, however, highly improbable that slight cases of concussion are accompanied by vascular rupture or organic mischief; the symptoms are too transitory and reaction too rapid and complete to permit of any such view. Experiments on animals show we can develop concussion without laceration or contusion. Autopsies have been carefully made in some cases of death from concussion, and no organic lesion has been discovered. It is quite true that the same force which causes the concussion may cause contusion or multiple lacerations, and a severe force is apt to do so. But we are not then justified in assuming that concussion is contusion or laceration: we should rather conclude that the individual had both concussion and a demonstrable injury. Both conditions arise from violence, but the two conditions are not identical. I believe, with von Bergmann, that there is such a condition as concussion, which may be pure concussion or, may be associated with organic damage, and even if a man dies and is found to have an organic injury, the concussion may have caused or, at least, have hastened the fatal result. I believe, with von Bergmann, that it is not repeated waves of force from the blow, but the concussion of the blow itself that does the harm. The brain is momentarily displaced by the blow. The blow acts on the entire brain; the centers are first stimulated and then depressed, and in fatal cases are not only depressed, but are paralyzed. The cause of concussion is violent force, either direct (as a blow upon the head) or indirect (as a fall upon the buttocks). This force momentarily displaces the brain, giving rise to stimulation and then to exhaustion of the nerve-centers, and perhaps to rupture of vascular twigs, large vessels, or even the membranes. In the less severe cases concussion only exists; in the more severe cases there is also contusion or laceration or compression soon arises.

As von Bergmann points out, the entire cortex in concussion is momentarily

[1] See the author in "U. S. Naval Bulletin," Vol. x, No. 3.

stimulated and then depressed. The momentary stimulation exists when a man "sees stars" as a result of a blow. The depression or exhaustion is manifested by heaviness, dulness, stupor, perhaps by unconsciousness. The stimulation of the medullary centers, von Bergmann points out, lasts longer, as a rule, than the stimulation of the cortex, and is manifested particularly by a slow pulse. If the pulse grows rapid and weaker, the pneumogastric center is becoming exhausted and the patient is in danger of death. In slight cases of concussion the cortex only may be involved, the medullary center escaping. In rapidly fatal cases of concussion the medullary centers are quickly paralyzed.

Symptoms.—In a very trivial case the patient "sees stars," is slightly and momentarily dazed and confused, is for a time pale, weak, giddy and nauseated, and the pulse is temporarily slow and weak, but he is otherwise unaffected. In a rather slight case of brain concussion the patient may or may not fall; his face is pale; he feels weak, giddy, nauseated, and confused, but he soon reacts, and often vomits. The pulse is slow for a time and then becomes normal. In a severe case he falls down and lies in a state of complete muscular relaxation. He cannot stand up. The extremities are cold; the skin is pale and cold; the pulse is small and slow. The face is ghastly, the skin is cold to the touch and lacks the flush and heat noted in compression. The slow pulse is due to stimulation of the pneumogastric center; the respiration varies, being sometimes deep, sometimes superficial, sometimes rapid, sometimes irregular, but not stertorous. He seems unconscious, but can usually be roused to monosyllabic response by shouting, pinching, or holding a bright light near his face. He does not originate an idea, does not volunteer a word, scarcely moves a muscle. Occasionally, however, there is complete unconsciousness. The urine and feces are often passed involuntarily. The pupils may be unaltered, may be dilated or contracted, may be equal or unequal, but in any case they will react to light. Paralysis rarely exists, but if there be paralysis, it is temporary. The temperature at first is subnormal. In a very severe concussion in which there is great danger of death the pulse is very rapid, small, weak, and probably irregular because of exhaustion of the medullary center, and the patient is absolutely unconscious because of depression of the cortex. If there is a severe cortical laceration there will be twitchings or even general convulsions, or the patient will lie curled up with limbs flexed and eyelids shut, and will resist all attempts to open his eyes or mouth or to move his limbs (A. Pearce Gould). Erichsen called this condition "cerebral irritability." If a patient with very severe concussion and very rapid pulse is recovering, the pulse will become slower. If a patient with severe concussion and a slow pulse is improving, the pulse will become normally rapid; if he is getting worse, it will become abnormally rapid and weaker. Always perform lumbar puncture and make ophthalmoscopic examinations at intervals of from 6 to 12 hours. Bloody cerebrospinal fluid and choked disk are significant—the first of subdural bleeding the second of compression. How long may concussion last? As von Bergmann well says: Concussion is transient in its manifestations. It is a matter of a few minutes or, at most, a few hours, and any prolongation of severe symptoms beyond this time, especially if they are intensifying as time goes on, indicates an associated injury. When the patient reacts from concussion he will probably vomit. Within twenty-four hours he usually improves, but is feverish and complains of headache and lassitude, sometimes becomes delirious, and in rare cases develops mania. If the patient in concussion recedes from, instead of advances toward, recovery, coma will set in or inflammation will develop. The prognosis is always uncertain. Any concussion producing more than very temporary unconsciousness is almost surely a serious injury, because considerable laceration has probably occurred. Recovery from concussion may be complete and permanent, but, on the contrary, the entire nature may undergo a change.

Such a change, which may not be evident for weeks or months, is apt to be manifested by egotism, selfishness, censoriousness, mendacity, great irritability, outbreaks of violent rage about trivial things, and forgetfulness. The forgetfulness is particularly as to recent events. There are headaches, insomnia, attacks of depression, lassitude, and vertigo. Such a patient is very susceptible to alcohol, the heat of the sun, and physical or mental strain. He can do nothing requiring mental effort.

After concussion a patient may develop hysteria, epilepsy, amnesia, or actual insanity. A condition resembling Korsakow's psychosis may develop (a condition of confusion with gaps in memory which are filled up spontaneously by fabrications, the patient also having multiple neuritis), confusional insanity, or mania may arise, or a condition like hallucinatory paranoia or mental weakness, which may resemble paresis. Concussion may pervert or wipe out all memory of the causative accident and also, strange to say, of a varying period preceding the accident. The loss of memory of the accident is permanent; the amnesia for a period preceding the accident may be permanent or may only be temporary. Statements made regarding an accident by one who has had concussion must be received with many grains of salt. A man may tell a story he believes himself, and yet it may be a mass of dream fancies without a word or with scarcely a word of truth. Victims of arteriosclerosis are particularly apt to develop mental trouble and neurasthenia. Régis insists upon this.

After concussion we may find sugar in the urine. We may find it also from fracture of the skull, compression of the brain, tumor of the brain, etc. It used to be thought that *traumatic diabetes* was the result of vasomotor disturbances which flooded the liver with blood and took quantities of glycogen into the circulation. From the islands of Langerhans in the pancreas comes a secretion which exerts control over carbohydrate metabolism. If that secretion is absent or is present in small amount the tissues cannot assimilate carbohydrates, those materials appear in the blood, the tissues break down, the glycogen stored up in the liver is swept into the circulation and diabetes exists.[1] The administration of adrenalin, puts sugar in the urine, so does pituitary disease, so may thyroid disease.

Hypersecretion from these glands antagonizes the internal secretion of the pancreas and so causes diabetes. Traumatic diabetes is probably due to incoördination between the ductless glands. In all probability sugar in the urine after a head injury means that there is irritation of the floor of the fourth ventricle and also to the nerves that go to the suprarenals, and that as a result there is an increased formation of suprarenal secretion.

Hypertraumatic diabetes is usually temporary. If it should last for a long time organic disease of the pancreas may arise and genuine diabetes begin.

Traumatic polyuria is common after head injury. Polyuria results from jarring compression or irritation of the posterior portion of the hypophysis cerebri. The excess of secretion causes polyuria. Traumatic polyuria is more common after fracture of the base than after pure concussion. When it occurs after fracture of the base there may have been actual laceration of or compression upon the pituitary body.

Treatment.—In treating brain concussion bring about reaction by the administration of aromatic spirits of ammonia (no alcohol, as this agent excites the brain), by pouring a few drops of ammonia on a handkerchief and holding it near the nose, by surrounding the patient (who lies in bed with his head on a pillow) with hot bottles, by hot irrigation of the head, by the application of mustard over the heart, and by the administration of enemata of hot coffee or of hot saline fluid. Do not pour fluid into the patient's mouth until he becomes able to swallow easily. If he cannot easily swallow, rely on hot enemata and hypodermatic injections of strychnin. Place the patient in bed in a quiet room

[1] The author in U. S. Naval Bulletin, Vol. 10, No. 3, 1916.

and watch him. If reaction is inordinate, apply cold to the head, give arterial sedatives and diuretics, and purge. For some days or for some weeks, according to the case, insist on a very quiet life. For many weeks after a grave concussion a patient must be kept away from business and be watched, because of the possibility of an abscess of the brain arising, and because of the liability of such patients to develop hysteria, neurasthenia, or insanity. Give a plain diet containing a minimum of meat, administer an occasional purgative, and secure sleep. Sleep can often be obtained by some simple expedient, such as the administration of warm milk, placing a hot-water bag to the abdomen or feet, or applying a mustard plaster for a short time to the back of the neck. In cases in which obstinate wakefulness exists, it becomes necessary to give bromid, chloral, sulphonal, trional, or some other hypnotic. Morphin is avoided because it is thought to increase venous congestion of the brain, but the elder Gross often used it, especially in cerebral irritation. If signs of compression arise, it is best to trephine, as the compressing agent may be a clot (see page 881). If inflammation arises, some surgeons will not trephine; but most regard it as wise and proper, especially if the damage seems to be localized, to incise the scalp and inspect the bone. If a fracture is discovered and the symptoms are serious, perform an exploratory trephining, open the dura, and secure drainage for inflammatory products. Personally, I believe that trephining for drainage is indicated in such cases even when there is no fracture.

In any severe concussion of the brain with contusion of the scalp the surgeon should at once incise the scalp and inspect the bone.

Compression of the Brain.—The combination of symptoms indicative of cerebral compression may be present in a number of different conditions. We find these symptoms in abscess of the brain, tumor of the brain, intracranial hemorrhage, foreign bodies, inflammatory exudate, and fracture of the skull with marked depression. The symptoms of compression are expressive of impairment of the functions of the entire brain by insufficient and imperfect circulation of blood, this impairment of circulation being the result of a lessening in capacity of the cavity containing the brain, its membranes, the blood-vessels, and the cerebrospinal fluid (von Bergmann). Duret injected wax within the cranium of an animal and showed that a diminution of 5 per cent. in the intracranial capacity produced somnolence, and a diminution of 8 per cent. caused death. If a brain tumor, abscess, blood-clot, or portion of depressed bone occupies space previously given to brain matter, vessels, etc., there is less room within the skull to contain the special structures. The bones cannot yield, the brain is incompressible, so the cerebrospinal fluid is displaced, the vessels are squeezed, and the circulation is greatly impeded. Pressure upon either arteries or veins causes the condition called compression (Fig. 573). This condition of cerebral pressure or compression is one of anemia. In reality it is compression of the vessels which feed the brain with blood, and such compression grievously disturbs the normal relationship between the blood-supply of the brain and the circulation of cerebrospinal fluid. Compression begins in obstruction to the onflow of venous blood. It extends gradually to the arteries. The circulation is slowed, and because of slow circulation the activity of the centers is finally inhibited. It is stated by Cushing that the rise which occurs in the blood-pressure is conservative and is expressive of Nature's effort to maintain the circulation in the compressed medullary centers. Increased vascular tension is made manifest by estimating the blood-pressure and observing venous stasis in the optic disk. Increased tension of cerebrospinal fluid is shown by lumbar puncture. The fluid flows out rapidly or jets out. The cortex is temporarily stimulated and then depressed, because of impairment of nutrition. The medullary centers are first stimulated. The respiratory center is stimulated by retention of CO_2 in the blood, then the vasomotor center is stimulated, then the vagus, and finally, perhaps, the convulsive center

(von Bergmann's "System of Practical Surgery"). The stimulation of the cerebral centers is followed after a time by weakening or actual paralysis. The centers are said to suffer in regular order, viz., the cortex, the corona radiata, the gray matter of the cord, and, finally, the medulla (Huguenin). As von Bergmann points out, by the time the convulsive center becomes stimulated the cortex is usually exhausted and the patient is unconscious. In compression the sensitive cortex first feels the effect and feels it most gravely, and the cortical impairment may last long after other trouble has passed. In some cases the cortex alone seems to be distinctly involved. When the vagus center is stimulated the pulse becomes slow; later, as the center becomes exhausted, it becomes rapid and weak, and this change has the same unfavorable significance as in concussion. If death occurs it results from paralysis of respiration and not of circulation. The displaceable cerebrospinal fluid is a great safeguard against compression, but Cushing has shown us that in intracranial obstruction of the venous circulation the flow of cerebrospinal fluid into the space about the cord is prevented because the medulla and cerebellum are jammed down in the foramen magnum.

Symptoms.—*Pressure symptoms* are divided into those occurring during the period of stimulation and those occurring during the period of increasing exhaustion. The symptoms of the first stage are headache, vomiting, flushing of the face, contraction of the pupils, choked disk, mental excitement, elevation of blood-pressure, restlessness, and slowing of the pulse. The pulse becomes slow, regular, and strong. The symptoms of the second stage are heaviness, dulness, drowsiness, passing into stupor, and finally into coma. The respirations are stertorous and after a time become Cheyne-Stokes. The pulse is weak, intermittent, compressible, and increasingly rapid. There are involuntary evacuations of feces and urine, and finally paralysis of respiration which causes death, the heart beating for a time after respiration has ceased (von Bergmann's "System of Practical Surgery").

The *headache* usually present in the first stage of compression is intense, persistent, sometimes general and sometimes more or less localized, and often aggravated by percussion of the cranium. It persists even in delirium, and the patient ceases to appreciate it only when unconsciousness begins. The *vomiting* is usually without nausea and is due to stimulation of the medullary center. At first vomiting may arise from taking food, but it soon continues independent of food. The tongue is probably clean. Cerebral vomiting is usually associated with severe headache. *Restlessness* is a pressure symptom in the stage of stimulation, and the patient rolls his head, tosses his body, and groans with pain. The *heart* does not begin to slow until the patient begins to be dull and drowsy, or until stupor arises, when the pulse slows and the tension rises. Finally it becomes very slow—perhaps less than 50 or even 40 in a minute. A very slow pulse is ominous as edema of the medulla is apt to arise. If the condition grows worse, the slow pulse after a time suddenly becomes rapid and of low tension, instead of slow and of high tension, a most unfavorable sign, indicating exhaustion and approaching paralysis of the vagus. In the stage of stimulation the patient is excited, unstable, delirious, and the condition of delirium gradually gives way to drowsiness, stupor, and coma. In some cases of compression there is distinct protrusion of the eyeballs. Before the patient becomes unconscious the pupils are contracted. When the patient is comatose, they are usually dilated, but may be contracted. In coma the pupils respond slowly to light or not at all. If the conjunctival reflex is gone, they will not respond at all (Gowers). In a lesion making unilateral compression toward the base the pupil on the side of the compressing cause is apt to be much dilated and even immobile. *Choked disk* begins in the stage of stimulation and continues to the end. That choked disk is due to intracranial pressure seems demonstrated by numerous operation reports, especially by Cushing, of

Harvard, in which relief of pressure abated choked disk (see page 912). The existence of choked disk is determined by the use of the ophthalmoscope. In every case of traumatism repeated ophthalmoscopic examinations should be made. The respirations become stertorous or snoring as coma develops because of the vibrations of the relaxed palate in the air-current, and the cheeks flap during expiration. As the activity of the respiratory center fails from increasing anemia, the respirations become shallow and infrequent, or, perhaps, of the Cheyne-Stokes type. Gowers defines Cheyne-Stokes breathing as "alternating periods of decreasing and increasing depth of breathing, separated by a pause" ("Lectures on Diseases of the Brain"). The *unconsciousness of compression* may be sudden or gradual, may be partial or complete. Apoplexy and many traumatisms cause immediate unconsciousness: the irritation of such a sudden lesion at once inhibits the cortex. A meningeal hemorrhage causes a gradually increasing unconsciousness. A brain tumor may cause heaviness, dulness, stupor, or, perhaps, after a long time, even coma. If compression comes on gradually, the brain more or less accommodates itself, and unconsciousness, if it occurs at all, is considerably deferred. A sudden increase of pressure may produce immediate unconsciousness. *Stupor* is partial unconsciousness, a condition in which a person lies as though asleep, though he arouses partially and temporarily when positively spoken to. In profound coma the limb reflexes are usually but not always diminished or lost. The superficial reflexes are impaired or lost. The muscles are flaccid and swallowing is impossible. In coma there is incontinence of feces and either incontinence or retention of urine. There may be the incontinence of retention. The *temperature* of a patient suffering from compression varies. In traumatic cases it may be at first subnormal and later normal or elevated. In inflammatory conditions it is elevated, except in abscess of the brain, in which it is subnormal, for a time at least, in half the cases. After an apoplexy it is for a time subnormal, but as shock passes away it becomes somewhat elevated. Any sudden compression causes shock and temporarily subnormal temperature. Lesions of the pons and medulla cause elevation—perhaps remarkable elevation—of temperature. In great or sudden brain compression complete coma always exists and there is no voluntary movement. In cerebral compression *paralysis* may exist, which may be very limited (monoplegia), may be of one side (hemiplegia), or may be general. In hemorrhage into the interior of the brain the unconsciousness is immediate or nearly so. In bleeding from the middle meningeal artery a period of consciousness intervenes between the injury and the coma, during which period blood collects and the coma comes on gradually. In compression from depressed fracture or from a foreign body the symptoms usually come on at once, but they may be deferred for some hours. Compression from inflammation or pus begins gradually after a considerable time has elapsed. The symptoms described as pressure symptoms are those of pure compression. When traumatism causes the condition, the compression symptoms are mingled with those of concussion, or perhaps of contusion or hemorrhage. The brain adjacent to any lesion causing compression suffers more than the brain distant from it. The blood-supply of the entire brain is affected, but the adjacent brain has its capillaries particularly and directly compressed. Hence limited paralysis is sometimes produced by compressing lesions. The course of compression depends on the nature and persistence of the cause. Great temporary pressure may produce no permanent harm. Moderately severe pressure may be recovered from even after weeks of stupor. Great pressure, sufficient to induce coma, if not relieved quickly, will cause death. Persistent cerebral symptoms after a head injury, when no obvious lesion can be made out, are probably due to edema of the brain.

Determination of the Cause of Coma in a Patient.— A diagnosis must be made between coma due to brain injury and the comatose condition of

apoplexy, uremia, epilepsy, hysteria, diabetes, opium-poisoning, gas-poisoning, meningitis, lobar pneumonia, and alcoholic intoxication. In hospital practice cases of unconsciousness without a known history are frequent. In attempting to diagnosticate, examine carefully for any evidence of traumatism, and inquire as to how and where the patient was found, if any fit occurred, and if a bottle or a pill-box was found near by or in the pockets. The surgeon should himself examine the pockets. Smell the breath to notice alcohol or opium, but always remember that an alcoholic is often a victim of Bright's disease, that a man with Bright's disease is liable to apoplexy, that a man may be stricken with apoplexy while he is drunk, and may fracture his skull by falling when under the influence of opium or of alcohol. The odor of acetone (violets) on the breath or in the urine indicates the existence of diabetes. Draw the urine with the catheter if any water is in the bladder. Examine the urine for albumin, acetone, and sugar, and take the specific gravity. In doubtful cases of coma have an ophthalmologist use the ophthalmoscope. He might find optic atrophy, indicative of Bright's disease, or choked disk, indicating compression. The cerebrospinal fluid obtained by lumbar puncture should contain blood if hemorrhage has taken place beneath the cerebral dura or in a ventricle of the brain. This test is valuable in fracture of the base of the skull, for in this condition cerebrospinal fluid is usually bloody. In *postepileptic coma* the temperature is never below normal, there are no unilateral symptoms, the condition resembles sleep, and after a time the patient can be aroused or comes to of himself. *Hysterical coma* occurs in boys and women; there are no objective symptoms, and the patient, though swallowing what is put into his mouth, cannot be aroused. In *uremia*, besides the condition of the urine (and always remember that a person with albuminuria is apt to develop apoplexy), there is a persistent subnormal temperature, and convulsions are prone to occur. There is perhaps edema of the legs, but paralysis and stertor are absent. In *apoplexy* hemiplegia exists, and the initial temperature is for a short time subnormal. A single convulsion may have ushered in the case. *Alcoholic unconsciousness* is often diagnosticated when apoplexy really exists. A man will smell of alcohol who has had one drink, but one drink will not produce coma; hence the smell of alcohol is not conclusive. In any case of doubt some hours of watching will clear up the diagnosis. Regard a doubtful case as serious until the truth is clear. In *opium-poisoning* the pupils are contracted to a pin-point, the respirations are usually slow, shallow and quiet, and may be stertorous, but there is no paralysis. Always remember that hemorrhage into the pons will produce pin-point pupils, but it also causes paralysis (crossed paralysis if in the lower half of the pons) and high temperature with sweating. In opium-poisoning the temperature is subnormal. In *diabetic coma* the pupils will react to a very bright light, the temperature is subnormal, and the breath and the urine smell of acetone. (See Acidosis, page 1348, and Diabetic Coma, page 191.) An ophthalmoscopic examination and lumbar puncture may furnish explanations of a doubtful case.

Treatment of Brain Compression.—The treatment of brain compression depends on the cause. Hemorrhage (extradural or subdural) requires trephining and arrest of bleeding; coma from depressed fracture demands trephining and elevation; foreign bodies must be removed; abscesses must be evacuated; some tumors are to be removed. In many tumor cases the growth is not removed, but a decompression operation is performed (see page 937). In cerebral compression, if death is threatened by respiratory failure, institute artificial respiration and at once trephine over the supposed region of compression. Horsley has shown that irrigation of the head with hot water is of great value in bringing about reaction from shock in cases of brain injury.

Intracranial hemorrhage may be either *spontaneous* or *traumatic*. In the vast majority of instances spontaneous hemorrhage comes from the lenticulostriate artery (Charcot's artery of cerebral hemorrhage), and produces apoplexy, a disease in the province of the physician, except in some ingravescent cases, for which ligation of the common carotid on the same side as the rupture has been advised. In adults traumatism is almost always the cause of a meningeal hemorrhage. The blood may flow from a sinus, from the middle meningeal artery or one of its branches, or from vessels of the pia. Traumatism during delivery is an occasional cause of hemorrhage from the middle meningeal artery (Richardière) and a not unusual cause of hemorrhage from cortical veins. Violent paroxysms of coughing in whooping-cough occasionally produce extradural hemorrhage or subdural hemorrhage. Geo. S. Brown reported such a case. He diagnosticated the condition and operated successfully ("New York Med. Jour.," April 25, 1903).

Fig. 573.—Fracture of skull with middle meningeal hemorrhage. Compression of brain by blood (Scudder).

Traumatic Intracranial Hemorrhage.— Hemorrhage may take place–(1) between the bone and the dura (*extradural*); (2) between the dura and the brain (*subdural*), and (3) in the brain substance (*cerebral*).

Extradural meningeal hemorrhage arises usually from the middle meningeal artery or from one of its branches. A spicule of bone may penetrate a venous sinus and produce extradural hemorrhage, or a sinus may rupture. Rupture of the meningeal artery or one of its branches is usually, but not always, accompanied by fracture (Fig. 573); in fact, in some cases not even a bruise can be found (Fig. 574). The ruptured vessel may be upon the opposite side to that on which the force was applied, hence the evidence of scalp injury is not a certain sign of the side of the skull involved. The accident may or may not cause temporary unconsciousness; but even if it does, from this unconsciousness the patient almost always reacts unless there are other grave injuries, and there is usually a *distinct period of consciousness* between the accident and the lasting coma, the coma being due to pressure from a continually increasing mass of extravasated blood (Fig. 575). If the main trunk or a large branch has been ruptured the period of consciousness will be short; if a small branch has been ruptured the period of consciousness will be prolonged for hours or perhaps for days. As the clot forms and enlarges the patient becomes heavy, dull, stupid, and sleepy; he sleeps so soundly he can scarcely be aroused, and snores loudly, and finally passes into stupor and then into coma. The other signs of this condition are paralysis of the side opposite the blood-clot (not necessarily of the side opposite the point of application of the force, for the artery may rupture from contre-coup on the uninjured side); this paralysis is apt at first to be localized, but it gradually and progressively widens its domain. If the clot extends toward the base, the pupil on the same side as the clot ceases to react to light, and the immobile pupil dilates widely. If the clot be on the left side, aphasia may be noted. As the clot enlarges adjacent centers become involved. The face becomes paralyzed, then the arm, and finally the leg. Not unusually epileptiform attacks occur, starting in discharges from the centers which are irritated by the advancing clot before their function is abolished by pressure. The pulse becomes full, strong, usually slow, but occasionally frequent; the breathing becomes stertorous; the temperature rises, that of the paralyzed side exceeding that of the sound side. In a compound fracture the pressure of escaping blood may force brain matter out of the wound. In extradural hemorrhage from a sinus the symptoms

cannot be differentiated from those produced by arterial rupture. If there is no free bleeding beneath the dura the fluid obtained by lumbar puncture will be clear. The ophthalmoscope discloses an early and reliable sign of pressure. The *x*-rays make a fracture evident.

Treatment:—In treating extradural hemorrhage localize the clot, not by the seat of the wound or contusion, but entirely by the symptoms. In a doubtful case endeavor to bring about reaction; but if the state of shock deepens or does not improve and if pressure symptoms increase, operate at once. To reach the middle meningeal artery or its arterior branch trephine 1¼ inches back of the external angular process, at the level of the upper border of the orbit (see Fig. 564, 571, 572). If the incision does not expose the clot, trephine again at the level of the upper border of the orbit and just below the parietal eminence (see Figs. 571, 572). The first incision gives access to the main trunk and to the anterior branch; the second incision exposes the posterior branch. If signs indicate that the clot is traveling to the base, the trephine should be used ½ inch lower than the point first directed. Arrest bleeding by a suture ligature or by packing (see page 515), and always open the dura and inspect the brain. By this procedure we may discover a subdural hemorrhage which otherwise might be missed. Drainage must be employed.

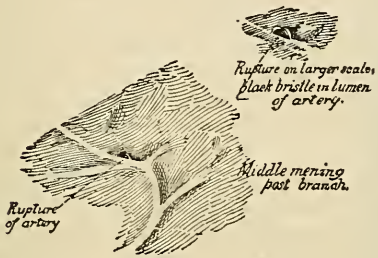

Fig. 574.—A case of rupture of middle meningeal artery. Preparation of dura. In the Warren Museum. The specimen is viewed from the outer side (Scudder).

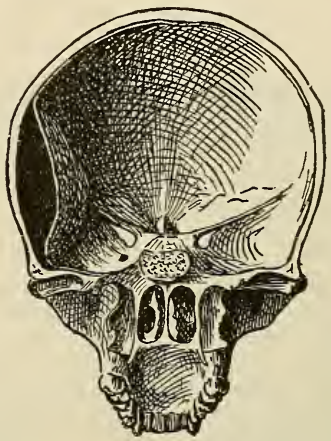

Fig. 575.—Frontal section of skull. Middle meningeal hemorrhage. The dura bulges inward toward the skull cavity (diagram) (Scudder).

Subdural meningeal hemorrhage is usually due to depressed fracture and rupture of the middle cerebral artery or of a number of small vessels.

The *symptoms* are identical with those of extradural bleeding, but are usually very rapid in onset and are accompanied by a more distinct drop in temperature and graver depression. The cerebrospinal fluid obtained by lumbar puncture is usually bloody, but, strange to say, is sometimes clear.

I have fancied that headache is more violent before the onset of unconsciousness than it is in extradural hemorrhage. Pressure is detected early by ophthalmoscopic examination.

The *treatment* is trephining for exploration at a point 1¼ inches back of the external angular process, enlarging the opening upward and backward by a rongeur, opening the dura and turning out the clot. Hemorrhage is arrested by light pressure with a piece of freshly cut muscle or by ligating the bleeding point. Elevate any depression of bone, and stitch the dura by catgut. Hemorrhage from internal pachymeningitis requires the same treatment.

Cerebral Hemorrhage.—The *symptoms* of cerebral hemorrhage are identical with those of apoplexy. The *treatment* is the same as that for apoplexy, except in ingravescent cases, when the common carotid on the same side as the clot may be ligated.

Rupture of a sinus may arise without a bone injury, but is usually due to a compound fracture. A sinus may be wounded during a brain operation. The **treatment,** if the rupture happens from fracture, is trephining. Enlarge the bone opening by the rongeur, cut a piece of muscle from the temporal or some other muscle and hold it for a time against the bleeding point. If this fails apply a lateral ligature or a suture ligature or catch the rent with hemostatic forceps, leaving them in place for three or four days. A gauze plug is a last resort. Its use may cause palsy and be followed by infection. Elevate depressed bone. If during an operation a sinus should be wounded, use a lateral ligature, a suture-ligament, or control hemorrhage by packing.

Intracranial Hemorrhage in the Newborn.—Certainly most of the cases of birth palsy seen in children are the result of subdural and subarachnoid hemorrhage at birth and damage of the cortical motor area. In such conditions there is spastic paralysis of the hemiplegic type, or if both hemispheres suffered there is plastic diplegia and usually amentia (Cushing, in "Amer. Jour. Med. Sciences," Oct., 1905). In some cases there is hemorrhage beneath the tentorium due to rupture of that shelf. It has not been the custom to operate for hemorrhage in the newborn; most of the cases do not die, but remain for life weakened and paralyzed, choreic, epileptic, or idiotic.

The hemorrhage in cases of birth palsy is, as Cushing points out, usually venous and due to "rupture of some of the delicate and poorly supported venous radicles of the cerebral cortex" (Ibid.). It may result from traumatism due to bone overlapping or forceps pressure during parturition, or may arise during asphyxia after birth. Cushing discovered in examining stillborn infants and infants that died soon after birth that many of them died from cortical hemorrhage. In some the extravasations were very large, in fact, completely overlying a cerebral hemisphere. In some they were much smaller. In one the clot was in the cerebellar fossa.

The vessels usually torn are on one side and are the unsupported venous radicles which enter the longitudinal sinus, hence the leg center of one side is the cortical area most apt to be gravely damaged. If the vessels of both sides are torn, a bilateral cortical lesion results. The sinus itself may be ruptured.

Symptoms of Hemorrhage in the Newborn.—In Cushing's masterly paper (Ibid.) the symptoms of recent hemorrhage are set forth. There is the history of a long and difficult labor, forceps perhaps having been used, or a history of postpartum asphyxiation. The head of the child may be unusually large. The birth-canal may be unusually small, as is found in contracted pelvis. The non-distensible soft parts of a primipara in middle life may be responsible. Syphilis and eclampsia predispose. In some cases none of the above-named causes are evident. In them the condition may result from the alteration in pressure when the head emerges from the os uteri. In hemorrhage of the convexity the fontanel bulges and perhaps does not pulsate. The fluid obtained by lumbar puncture contains blood-corpuscles. There is usually twitching and, as a rule, convulsions occur. They may occur soon after birth or several days later. When they occur soon, they may be general; when they occur later, they may be unilateral. Paralysis is rare in the early days after birth. There may be alterations in the circulation and respiration. Pupillary alteration and ocular palsy seldom occur. If the hemorrhage is below the tentorium the fontanel still pulsates, the neck muscles are rigid, stupor exists, and the respirations are very irregular. If the child is not operated upon it may die or it may apparently recover. If it apparently recovers after a considerable hemorrhage, several months may pass before ominous symptoms are recognized. The late manifestations of the disease may be "spastic palsies, or blindness, or deafness, or feeble-mindedness, or, in severe cases, even complete amentia" (Cushing). Epilepsy may be a result.

Treatment.—If the motor area is involved osteoplastic craniotomy should be performed in the parietal region, on one side or both, according to the unilateral or bilateral nature of the hemorrhage; opening of the dura; washing out and turning out the clot; suturing the dura and closing the scalp without drainage. Both sides may require operation. Cushing reports 16 cases of operation with 7 recoveries. He says chloroform should be given and that the parietal bone can be cut with blunt, curved scissors. If the hemorrhage is beneath the tentorium no operation is recommended although some surgeons advise lumbar puncture.

For slight cases of spastic paralysis following hemorrhage tendon lengthening may be all that is required. Those cases, "particularly of the hemiplegic and paraplegic types, which show signs of increased intracranial pressure by an ophthalmoscopic examination, are the cases that can be very much improved" by cranial decompression (Sharpe and Farrell, in "Jour. Am. Med. Assoc.," Feb. 6, 1915).

Fractures of the skull may be *simple*, *compound*, *depressed*, *non-depressed*, or *punctured*. *Fracture by diastasis* means separation of a suture or of sutures by violence. A fracture of the skull may be produced by a *bending* force, by a *bursting* force, or by an *explosive* force (see Gunshot-wounds).

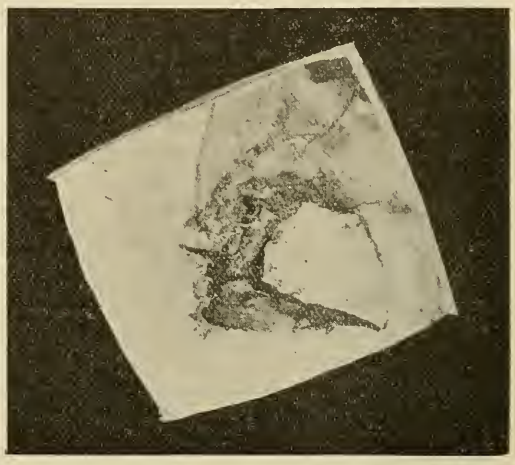

Fig. 576.—Fracture of the vault with extensive depression of the inner table ("American Text-Book of Surgery").

A bending force is usually applied by the forcible impact of a body of small area. It produces a fracture and seldom causes distant injuries. The fracture may be of the inner table only, or of both tables. If both tables are fractured the broken bone is displaced and remains so.

In fracture by bursting, lines of fracture run to distant points from the seat of application of the force. Such an injury is inflicted by the impact of a flat surface of considerable area. In some cases we have a force which first is bending in character, but causes bursting also to occur, because there is no rebound.

Falls of large heavy objects or falls on the head, blows on the head from large flat objects, crushes in railroad accidents, etc., may burst the skull. In bursting fracture there is often widespread injury. The skull may be fractured during labor.

Fractures are divided into fractures of the *vault*, usually due to direct force, and fractures of the *base*, due to extension of fractures of the vault, to indirect violence (a fall upon the feet, the buttocks, or the vault), to forcing of the condyles of the lower jaw against or through the base, or to foreign bodies breaking through the orbit, vault of the pharynx, the ear, or the roof of the nostrils. *Fracture by contre-coup* was the name long given to a fracture which was supposed to occur on the side opposite the point of application of the violence. It is very doubtful if such a fracture ever occurs. I have seen meningeal hemorrhage by contre-coup, but not fracture. Fractures of the skull are uncommon in early youth, but they are much more frequent in the aged. Usually the entire thickness of the bone is fractured, but either the outer

or the inner table (Fig. 576) may be broken alone. In complete fractures the inner table is broken more extensively than is the outer table, because the inner table is the more brittle, because the force diffuses, and also, as Agnew taught, because the inner table is part of a smaller curve than is the outer table, and violence forces bone-elements together at the outer table, but tears them asunder at the inner table (Figs. 577, 578).

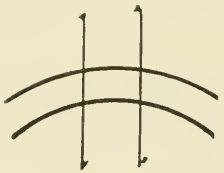

Fig. 577.—Section of outer and inner tables, with two parallel lines (after Agnew).

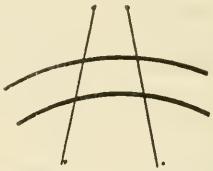

Fig. 578.—Greater yielding of the inner table than of the outer after the application of violence (after Agnew).

Fractures of the Vault.—In every suspected fracture examine with the *x*-rays and *suspect* fracture in every head injury. A fracture may involve the vault alone, but in over 60 per cent. of such fractures the base is involved. A fracture of the vault of the skull may be simple and undepressed, or it may be depressed (Fig. 576), compound, or comminuted (Fig. 579). A mere crack may exist in a bone, and if a rent exists in the soft parts, a bit of dirt or a hair may be caught in the crack. Fractures of the vault arise from direct force. A *fissure* may escape recognition, although in some cases percussion gives a "cracked-pot" sound. This is known as *Macewen's sign*. The stethoscope is placed upon the glabella. Percussion with fingers or percussion hammer is begun over the parietal eminence and approaches the stethoscope. The same procedure is carried out on the opposite side of the head. Those who would employ this method must make a study on percussion of normal skulls at different ages, etc. (see H. B. Wilcox, in "Arch. Pediatrics," 1915, xxxii. He has thoroughly discussed this sign). Any considerable depression can be detected. In a simple fracture occasionally the cerebrospinal fluid collects under the scalp and forms a tumor which pulsates and becomes tense on forcible expiration (see Spurious Meningocele, page 871). Compound fracture can be readily recognized, but do not mistake a suture, a Wormian bone, or a tear in the pericranium for a fracture. A fracture bleeds, a suture does not. Even a narrow fracture is marked by a dark line of blood which *sponging will not remove*. Fracture of the inner table alone can only be suspected unless the *x*-rays make it evident. The prognosis of fracture of the vault depends upon the extent of intracranial injury rather than upon the extent of bone injury. Simple fractures may unite by bone; compound fractures with loss of bone unite by fibrous tissue only. The dangers may be *immediate* (hemorrhage, brain injury, and septic inflammation) or be *distant* (epilepsy, insanity, and persistent headache). In an open fracture the danger of infection is added to the danger of brain injury. A spinal tap may give valuable information. Bloody fluid means bleeding beneath the dura. In simple fracture if we decide against immediate operation have an ophthalmologist watch the eye grounds for signs of beginning pressure.

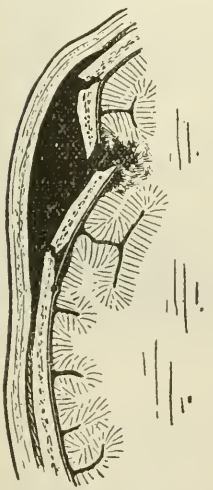

Fig. 579.—Fracture of skull with depressed fragments. Compression of brain by bone (Scudder).

Treatment.—The mortality of fracture of the skull was formerly much greater than at present. Before the days of antisepsis it was 51 per cent. (Harte). Trephining is performed much oftener than was once the custom, and is vastly safer. Out of 26 trephined cases, 3 died (Harte). In any case of fracture of the skull endeavor to bring about reaction before operating, unless the signs of pressure continually increase or the evidences of shock remain unimproved or become graver. A *simple fracture without depression* and *without brain symptoms* is treated expectantly (by rest, quiet, low diet, purgation, moderate elevation of and cold to the head, and arterial sedatives). A *simple fracture with moderate depression* and *without cerebral symptoms* is treated expectantly, and so also is a *simple fracture* in which *symptoms existed but are abating*. *Simple fracture with marked depression* requires immediate trephining, even when brain symptoms are absent. We make an exception in young children, and wait a while before trephining, in the expectation that the expansile brain will lift the depressed but elastic bone up to the level. Trephining in cases in which no symptoms exist, although there is marked depression, often prevents disastrous consequences arising in the future, and is known as *preventive trephining* (Agnew, Keen, Horsley, Macewen, von Bergmann, and others). In all *compound fractures* shave and asepticize the entire scalp, enlarge the incision, and explore the bone. If a fissure exists, it must be asepticized, and if a hair or other foreign body is found in it, in order to effect removal and secure asepsis the outer table of the skull at this spot must be cut away by a chisel, the fissure being thus converted into a broad groove. In a *compound fracture with much depression* trephine, elevate, and irrigate. In any fracture trephine if distinct symptoms exist. In punctured wounds of the brain (*punctured fractures*) *always* trephine, open the dura, and disinfect. In a comminuted fracture the usual custom is to remove loose fragments. Schaak has recently advocated their reimplantation ("Archiv für klin. Chir.," April 6, 1912). My usual custom has been to remove them. In any case of fracture of the vault in which trephining has been performed it is wise to open the dura and examine the brain. In an open fracture and after every operation of trephining in which the dura has been opened administer urotropin in order to make the cerebrospinal fluid bactericidal.

Fractures of the Base.—A fracture of the base of the skull may exist in only one of the three fossæ, in two of them, or it may involve all. Figure 580 shows an extensive fracture of the base of the skull. The middle fossa is oftenest involved. Fracture of the posterior fossa is the most fatal. These fractures may be due to direct violence, to indirect force, and to extension of a fracture of the vault. Extension from the vault is always by the shortest route. Fractures of the base may extend up into the vault, and do so in over 80 per cent. of cases. Fracture by direct violence may arise from the penetration of the nasal roof, the orbital roof, or the pharyngeal roof by a foreign body. The posterior fossa may suffer from a fracture by direct violence applied to the neck. Fractures by indirect force may arise from blows upon the frontal bone (the orbital portion of the frontal or the cribriform process of the ethmoid breaking), from falls upon the chin (the condyle of the jaw breaking the middle fossa), or from falls upon the buttocks, the knees, or the feet (fracture occurring in the posterior fossa). The base is not broken by contre-coup.

Symptoms.—Fractures of the base of the skull are apt to be compound. A solution of continuity in the pharynx, roof of the nares, orbit, or ear permits access of air to the seat of fracture and allows blood and cerebrospinal fluid to flow externally. In *fracture of the anterior fossa* the fracture may be compound because of laceration of the mucous membrane of the nares or of the conjunctiva. Blood may run from the nose, its source being the vessels of the mucous membrane or the dura, the fracture being compound. Epistaxis does not prove the fracture to be compound, but only suggests it; but if the

epistaxis is prolonged, the probability is greatly increased; and if the flow of blood is succeeded by a flow of cerebrospinal fluid the diagnosis of compound fracture is positive. A flow of cerebrospinal fluid from the nose is seldom observed or at least the fluid is seldom recognized. Cerebrospinal fluid appears only when the mucous membrane, the dura, and the arachnoid are each lacerated. In fractures of the anterior fossa blood is apt to flow into the orbit, producing *subconjunctival ecchymosis*, and perhaps pushing the globe of the eye forward. Some blood is often swallowed and vomited. In the middle fossa the bones are very thin and fractures are far more common in this region than in other parts of the base. In *fractures of the middle fossa* blood may flow from one ear or both ears. Blood obtains exit through a tear in the tympanum, its source being the vessels of the tympanum, the meningeal vessels, or a sinus. Blood may flow through the Eustachian tube and come from the nose, may be spat up, or may be swallowed and vomited. In some cases a quantity of cerebrospinal fluid flows from the ear, the discharge being increased by expiratory effort and a position which favors gravity. Cerebrospinal fluid is at first blood-stained, but later becomes clear. The flow of clear cerebrospinal fluid occurs in only a small minority of the cases. The cerebrospinal fluid must not be confused with either blood-serum or liquor Cotunnii. The cerebrospinal fluid, if it flows at all, is always present in large amount; the liquor Cotunnii can be present only in minute amount. Blood-serum is highly albuminous; cerebrospinal fluid is a serous fluid of very low specific gravity, it is devoid of formed elements, never shows more than a trace of albumin, and contains considerable chlorid of sodium and a carbohydrate now known to be a dextrose which reduces the copper of Fehling's solution and reacts to Trommer's and to Moore's tests, but does not refract polarized light nor easily ferment with yeast. Treves[1] states that cerebrospinal fluid cannot flow from the ear in fractures of the middle fossa—(1) unless the line of fracture crosses the internal meatus; (2) unless the prolongation of the membranes into the meatus is torn; (3) unless a communication exists between the internal ear and tympanum, and (4) unless the drum-membrane is torn. Miles, of Edinburgh,[2] claims that bleeding from the ear followed by a flow of cerebrospinal fluid is not pathognomonic of fracture of the middle fossa of the base. He maintains that when the drum is ruptured we may have these signs; when bone is not broken the chief source of the blood being the vessels of the pia and temporosphenoidal lobe, the blood and cerebrospinal fluid flowing inside the sheath of the auditory nerve, passing into the vestibule, through the lamina cribrosa, and from the vestibule into the

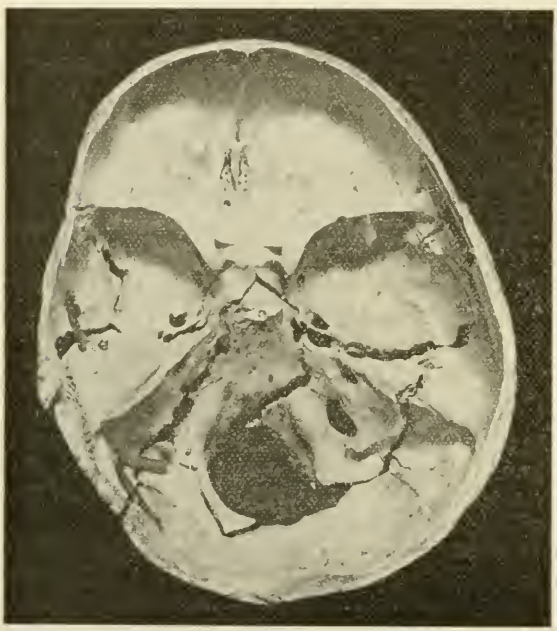

FIG. 580.—Extensive fracture of the base of the skull ("American Text-Book of Surgery").

[1] "Applied Anatomy."

[2] "Edinburgh Med. Jour.," Nov., 1895.

middle ear, finding exits from this space by way of the Eustachian tube and also through the rent in the drum-membrane. Profuse mucous discharge may flow from the ear after an injury without fracture when the drum is ruptured, the fluid coming from the cells of the mastoid. It must be understood that fracture of the base may exist when there is no flow of blood or of serous fluid. A fracture of the middle fossa is usually compound, made so, even when the drum is not ruptured, by the Eustachian tube, and there is often paralysis of the seventh or eighth nerve or of both of them. In *fracture of the posterior fossa* there is usually respiratory derangement and blood accumulates beneath the deep fascia and produces discoloration in the line of the posterior auricular artery (*Battle's sign*), the discoloration first appearing near the tip of the mastoid. The discoloratio appears in the line of nerves and vessels which emerge from the deep fascia, the vessels passing through openings and the extravasated blood emerging from the same openings. Fractures of the posterior fossa are apt to be compound through the pharynx, and in such cases the patient spits or vomits blood. Fractures of the posterior fossa are more fatal than fractures in either of the other fossæ because of the adjacency of vital centers. Fractures of the base are apt to be associated with *paralysis of cranial nerves*. The palsy indicates the situation of the fracture. In fracture of the anterior fossa the olfactory nerve may suffer. In fracture of the middle fossa the facial nerve most often suffers. The eighth is sometimes injured. Other nerves which may suffer alone or in combination in fracture of the base are the abducens, the motor oculi communis, the trigeminus, the pneumogastric, the optic, the spinal accessory, the hypoglossal, and the glossopharyngeal. *Optic neuritis* often arises after the first week. In fractures of the base the temperature is subnormal during the shock, rises to 100° to 101° F., falls again to about normal, and remains normal or subnormal unless there is inflammation or sepsis. Lumbar puncture may obtain bloody fluid. Such a finding means subarachnoid bleeding and indicates fracture. In any fracture injury of the brain may exist. Such an injury will be made manifest by symptoms, and we may or may not be able to diagnosticate and localize it. The prognosis is greatly influenced by the nature and extent of the intracranial damage. Harte ("Annals of Surgery," Oct., 1901) has collected 46 positive cases of fracture of the base of the skull from the records of the Pennsylvania Hospital; 35.5 per cent. recovered. Ransohoff collected 190 cases of fracture of the base of the skull. The mortality was 65 per cent. Over one-half of the fatalities were within twelve hours. Only 15 per cent. died after the second day. Of 98 cases with profound coma and respiratory disturbance 70 per cent. died ("Annals of Surgery," July, 1910). According to Hartley, in cases treated expectantly the mortality is 90 per cent., in cases treated by operation it is less than 35 per cent. ("Am. Jour. of Surgery," Dec., 1910).

Treatment.—In fracture of the base I now perform a subtemporal decompression, usually on both sides, as Cushing advocates. This is, first of all, exploratory, and may disclose a bleeding meningeal artery. After the dura is opened it enables us to evacuate fluid causing pressure and in which bacteria could multiply, and to prevent recurrence of pressure after the wound has been closed. If there is bleeding under the dura the brain should be lifted to let the blood out, and a drain of rubber tissue should be inserted. If there is only brain edema no drain is required. In some cases drainage has been obtained from the anterior fossa by breaking through the cribriform plate and introducing a tube by way of the nostril (Allis), and from the middle fossa by trephining above and behind the external auditory meatus. In a compound fracture of the orbit disinfect and drain. It may be necessary to trephine the roof of the orbit to secure drainage.

In addition to performing decompression I always give urotropin, as advised by surgeons in Johns Hopkins Hospital (S. J. Crowe, in "The Johns

Hopkins Hospital Bulletin," April, 1909). This drug renders the cerebrospinal fluid bactericidal. Other methods of treatment are secondary to the above. My experience is that this plan saves many cases which would otherwise perish. In treating a compound fracture of the base of the skull disinfect any cavity involved. In fractures of the middle fossa with ruptured drum clean the ear mechanically, wash it out by a stream of warm salt solution (turn the head toward the affected side while washing, so that the solution will not run down the Eustachian tube), insufflate iodoform, insert a piece of iodoform gauze, and apply an antiseptic dressing. Several times daily the ear is to be irrigated and insufflated with iodoform. The nasopharynx must be frequently irrigated by normal salt solution or boric acid solution and insufflated with iodoform. The conjunctival sac is frequently irrigated by boric acid solution. If after a head injury blood accumulates back of the drum, this membrane should be incised to permit of drainage and disinfection. In fractures of both the middle and anterior fossæ and in fractures of the posterior fossa communicating with the pharynx, the nasopharynx must always be cleaned. The exact method depends on the choice of the surgeon. We may wash out these cavities frequently by hot water, next by peroxid of hydrogen, and finally by boric acid solution, or can simply use normal salt solution. After washing, insufflate the nasopharynx with iodoform. Repeat the cleansing at regular intervals and also cleanse the conjunctival sac frequently. In fracture of the posterior fossa examine to see if the fracture is compound, into the pharynx, and if it is, cleanse with great care the nasopharynx and mouth, as previously directed. In a very extensive fracture of the base, besides use of the methods set forth above, the entire head should be shaved and a plaster-of-Paris cap applied. A patient with fracture of the base must be put into a quiet and darkened room and kept upon a low diet, sleep being secured, and the bowels and bladder being attended to. If we are uncertain as to whether a fracture exists or not, keep the patient quiet, in a darkened room and on a low diet. Attend to the bladder, keep the bowels loose, examine the nasopharynx with a mirror and the ear-drum through a speculum, and make a lumbar puncture.

Obstetric Depressions of the Skull.—These lesions seem to have been first studied by Danyau in 1849. The depression may be of the parietal or frontal bone and may or may not be accompanied by fracture. It may have been caused by the promontory of the mother's sacrum or by obstetric forceps. A slight depression does no harm, because it is gradually and spontaneously corrected. A marked depression, especially if accompanied by fracture, places the child in danger of epilepsy, idiocy, and non-development of body, and requires treatment. The usual treatment is trephining and elevation. Some claim to elevate by an apparatus making pneumatic suction. Some make a small incision, insert a screw (Heine's screw), and elevate by making traction on the screw. Hanch elevated by means of a corkscrew. (See Frazier, in "Progressive Medicine," March, 1913.)

Wounds of the brain are produced by violence and especially by foreign bodies (knives, bullets, etc.). Except when due to penetration of a fontanel in a child or of a parietal foramen in adults, wounds of the brain are accompanied by fracture of the skull. These wounds are very dangerous; foreign bodies (bone, hair, clothing, etc.) are often lodged in the brain, hemorrhage is usually severe, and without proper treatment sepsis is almost inevitable. Such cases are very fatal, though some astonishing recoveries are on record. Figs. 581 and 582 show gunshot-fractures of the skull.

The **symptoms** of a brain wound may be slight and long deferred or may be immediate and overwhelming; they depend upon the site and extent of the injury. Localizing symptoms may exist, and encephalitis with coma is apt to arise. Abscess may follow.

In treating wounds of the brain always shave the entire scalp and examine the weapon, if possible, to see if a piece has been broken off. Antisepticize, enlarge the wound, trephine, arrest bleeding, elevate any depression, remove foreign bodies, irrigate the wound with salt solution, drain by gauze, suture the dura, dress, and administer urotropin.

Wounds in War.—When the bullet of a military rifle, fired at very close range, crosses the brain it may blow the skull into fragments, but often it does not, but produces fracture of the skull and wound of the brain. The "explosive effect" is far less marked in the head of a living man than in the head of a corpse and may even be absent when the range has been only 100 yards. At moderate range, at the point of initial contact of the bullet with the skull, a fracture is produced, the opening is slightly larger than the bullet, and short

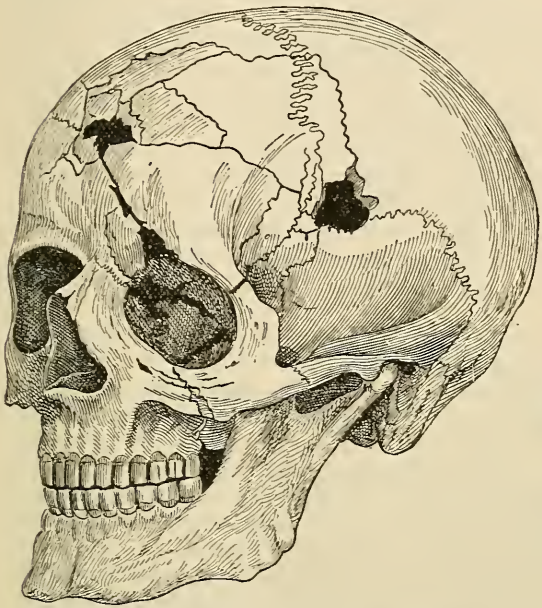

Fig. 581.—Extensively comminuted gunshot-fracture of the skull (after von Bergmann).

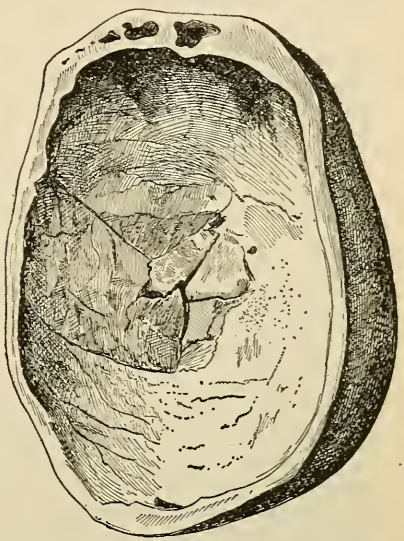

Fig. 582.—Gunshot-fracture of internal table of the skull (after von Bergmann).

fissures commonly radiate from it. Fragments from the internal table are usually displaced and driven into the brain. The wound of exit is more irregular and is apt to exhibit more and longer fissures than the wound of entrance. When a bullet strikes a glancing blow (*tangential wound*) it may fracture the outer table alone; it may produce a "gutter-fracture" (two scalp openings, and "a gutter ploughed" through one or both tables of a portion of the skull, as O'Reilly expressed it), *very seldom* a fracture of the inner table only, *penetration* of the skull, and lodgment of the bullet, or *perforation* of the skull, the bullet passing through the head and emerging. Nearly half the cases are instances of perforating wound. A piece of shrapnel case, a bit of explosive shell, or a shrapnel bullet, may fracture the skull, may lodge or may tear all the way through the head. The base may be fractured by a penetrating or a perforating wound or fracture of the vault may track into the base. There is usually much splintering, in which the inner table suffers most. There may be or may not be depression.

In all of these injuries there are usually great shock and concussion, but concussion symptoms may be absent, Some of the patients walk to the first dressing station. The patient may die at once or almost at once, but if he be

alive a few hours after the injury he has still to face the chances of hemorrhage and the danger of infection and resulting inflammation. The danger depends on the brain injury and the amount of infection and not on the extent of the bone damage. The symptoms vary according to the part of the brain injured and the extent of the damage. In some cases there are no brain symptoms.

In practically all cases bone-fragments are driven into the brain, and as the scalp is a dirty region, the wound is more or less infected. All wounds received in trench warfare are regarded as infected. All wounds from shell fragments, even those inflicted in open fighting, are infected.

Injuries of sinuses, especially of the superior longitudinal sinus, are common. Serious injury may be caused directly by the projectile or may be due to bone-fragments. Injury of the superior longitudinal sinus is due in most cases to tangential wounds in which there is usually a gutter-fracture, the inner table being splintered more extensively than the outer table. A bullet or shell fragment which merely grazes the bone may produce a gutter-fracture.

A tangential injury of the vertex, may give rise to a symptom which Holmes and Sargent ("Brit. Med. Jour." Oct. 2, 1915) call the *longitudinal sinus syndrome*. There may or may not be fracture or depression and the sinus or some of its large tributaries may or may not be torn. In some cases there is contusion of the brain and in consequence anemia of a considerable area or of considerable areas. In some cases there is no hemorrhage but the blood in some of the parasinoidal sinuses and large cerebral veins is in a condition of stasis. The characteristic symptom is bilateral spastic paraplegia coming on at once after the injury, the lower extremities being more seriously involved than the upper extremities.

In a tangential injury by a rifle bullet there is practically always a fracture. In a tangential injury by a shell fragment there may or may not be a fracture.

A bullet lodged in the brain may remain fixed, or may shift its position with the movements of the patient. In a case of my own a bullet which lay in the longitudinal fissure against the falx cerebri made a half revolution on its short axis when the patient became recumbent and resumed its former position when the patient sat up. Dr. Manges demonstrated these movements by *x*-ray studies. A bullet in the brain may gradually shift its position and come to inhabit a location a considerable distance away from its original habitat. Probably it could not do this in an undamaged brain but it may do it in a damaged brain. As a patient usually lies supine the bullet usually tends to move toward the occiput. Villvandré and Morgan ("Archiv. of Radiology and Electrotherapeutics," June, 1916) report a number of cases in which *x*-ray pictures, taken from time to time, showed that bullets did move. The above facts show that *x*-ray localization must be practised just before operation and with the patient in the exact position he is to occupy during the operation.

The mortality from these injuries is very large. In the war between the States 4350 cases were recorded in the Northern hospitals and the mortality (including mortality from late complications), was 59.2 per cent. In the Franco-Prussian War it was 51.3 per cent. In the Boer War, among the British it was only 33.1 per cent., a very notable improvement. (See "Military Surgery," by Surgeon General Robert M. O'Reilly, U. S. A., in "Keen's Surgery," vol. iv.) In the Russo-Japanese War the mortality seems to have been something over 37 per cent. The mortality from cranial injuries in this war does not seem to be better than that of 40 odd years ago, and has been far greater than that of the Boer and of the Russo-Japanese War. Rehn calls the brain surgery of this war "a sad chapter."

In estimating mortality those killed outright and those dying before reaching the hospital are not counted by makers of statistics. Much brain matter may ooze out from such a wound. There may be severe or fatal hemorrhage. Meningitis or abscess may follow. Cerebral hernia (Fig. 586) and

fungus cerebri (Fig. 587) are common after these injuries, especially if much bone has been destroyed by the injury or removed by the surgeon. Various late complications may develop (abscess, softening, paralysis, epilepsy, insanity, aphasia, etc.).

Treatment of Wounds in War.—During this war enormous numbers of men have received head injuries in spite of steel helmets (about one-fourth of those wounded in the trenches). About 25 per cent. of head injuries were injuries of the cranium. A great majority of those who receive cranial wounds by bullets or shell fragments, perish at once or very soon. Comparatively few of those with such wounds reach the first-aid station. Fewer still reach the field hospital and fewer still the evacuation hospital, because some die in transit. Cushing believes that not more than 25 per cent. of those with cranial injuries are operated upon.

Tuffier claims that 50 per cent. of those operated upon recover but admits that an unknown number die later from secondary troubles ("Surgery, Gynecology and Obstetrics," 1915, xxi).

In Lapointe's 127 cases the mortality was 58.75 per cent. (cited by Cushing, in "Military Surgery," June, 1916). It is true that some reports show a remarkable improvement on the ghastly figures cited above but the general conclusion must be that the mortality has been enormous. In cases operated upon *early* and *completely* the results have been better. Gayet ("Lyon. Chir.," 1915, xii) reports 198 cases operated upon within six hours of injury and claims 100 recoveries. Cushing speaks of them as "presumptive recoveries" (Ibid.).

Early in the war many fractures were overlooked. Roberts tells us that over 40 per cent. of cases with supposed scalp wounds had fractured skulls ("Brit. Med. Jour." Oct. 2, 1915). In many cases of fracture the symptoms at first may be so trivial that the patients walk to the first dressing station. If the fracture escapes recognition it is probable that a grave, perhaps a fatal, condition will arise. As a general proposition the earlier operation is done the better, provided the operation can be done completely. In the first dressing station and in a field hospital thorough operation is impossible. It is seldom possible in an evacuation hospital, and even if possible the patient must be moved in a day or two, which is too soon for safety. It has been found safer to move victims of skull injury upon whom no operation has been done than to move them soon after a trephining. The rapid pulse and the lowered tension of those upon whom operation has been performed recently, militate strongly against recovery.

The custom among most surgeons was to operate very early, even in the absence of an *x*-ray apparatus. The method was to enlarge the wound, trephine if necessary, elevate depressed fragments, remove as well as possible all bone-fragments lodged in the brain, drain with iodoform gauze, and as soon as possible send the patient to a rear hospital. When such a case reaches a base hospital there may still be a lodged projectile, there may be bone-fragments yet in the brain, infection may have developed or be developing and infection will probably prove fatal. Such an operation was incomplete, delayed the transfer of the patient to a place where a complete operation could have been done. Preliminary operations have had a mortality of over 45 per cent. Cushing (Ibid.) says "preliminary and necessarily incomplete measures," taken when "the field hospital equipment is primitive," gravely lessen the chance of permanent recovery. When such a preliminary operation has been done the surgeon in the base hospital finds it a most difficult problem to determine what should be done, a difficulty enhanced by the usual absence of records showing what has been done, information essential to determine the proper method of treating the case. The operation should be done as soon as the patient reaches a hospital where there is a surgeon experienced in brain work, where there is ample equipment (*x*-ray apparatus, electro-

magnet, etc.), where there are experienced assistants, where there are trained nurses, where a neurologist can be had for consultation, where the patient can be kept in bed the proper time (about three weeks). If these things can be had

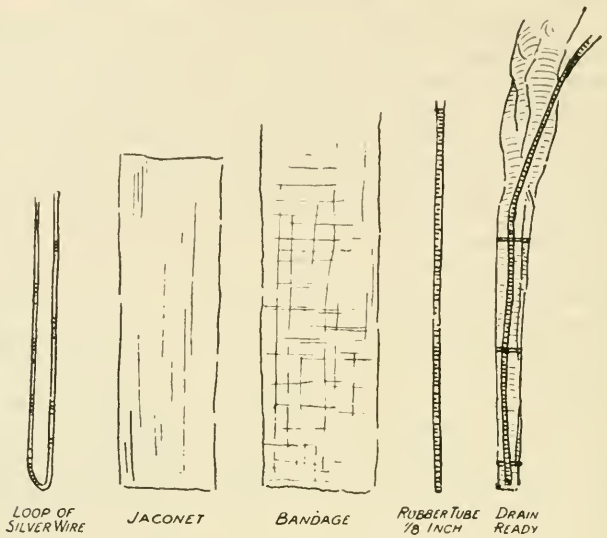

FIG. 583.—Materials for making capillary drains for drainage of the brain (Hull, "Surgery in War").

near the front operate near the front. If they cannot be obtained until a base hospital is reached send the man to the base hospital. By following this plan cases will seldom be operated upon until between two to four days after the injury, yet in spite of the delay the results are better than those of imperfect operations done promptly. Before operation, an *x*-ray should be taken and if a projectile is lodged it should be located. The scalp should be shaved and asepticized. Many operations are done under local anesthesia. The wound in the scalp (including the pericranium) should be excised by elliptical incisions. A large flap (with the gunshot wound within its margins) should be laid down to permit of exploration. The old custom of enlarging the original wound should be abandoned. The exploration through a large opening is necessary. It enables the surgeon to see a fracture. In 40 per cent. of supposed scalp wounds fracture exists. The excision of both the wound in the bone and the wound in the scalp is imperative. Extirpate completely both the scalp wound and the bone wound. Cushing removes the entire wound in the bone cutting completely around it. It prevents infection from pus organisms, gas bacilli, etc. When the wound is not excised late infection is common. If extirpation of the wounds is delayed for three or four days it is of little use. Excision enables us to

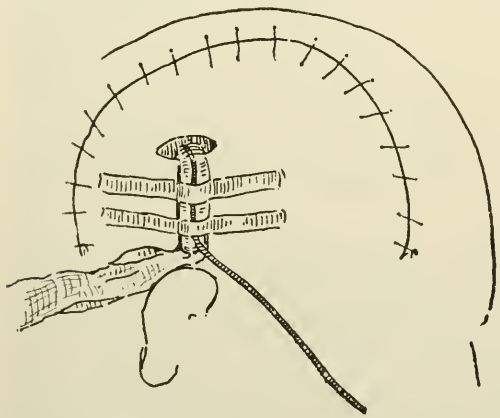

FIG. 584.—The drain has been bent to the required depth and fixed to the scalp by plaster. Two sutures placed about 3 inches from the wound forms a better method of fixing the drain. By placing the sutures at a distance from the wound the drain is made very flexible and moves freely with the pulsating brain without exerting injurious pressure (Hull, "Surgery in War").

dispense with drainage in many cases. Without excision prolonged drainage is always necessary. Brief drainage combats infection. Prolonged drainage opens the doors to infection. If drainage is prolonged until the hair grows above the skin, infection is inevitable. If a wound injures the dura and involves the brain drainage is always necessary. A metal tube blocks up. A rubber tube blocks up and, sooner or later, is forced out upon the dressings. Gauze dams up pus and thus aids in the development of meningitis or abscess. Drainage may be made by rubber tissue. It should emerge from the angles of the flap and not from the region of the gunshot-wound. The most serviceable drain is made as follows (see "Surgery in War," by Major Hull, R. A. M. C.).

Take a piece of stout silver wire much larger than the depth of the wound. Bend it into the shape of a hair-pin. Wrap it with rubber tissue. Surround it with a gauze bandage, and let the free end of the bandage be long. Fix to the bandage by ligatures a Carrel tube. Carry the appliance to the depth of the wound, bend the free end so as to keep the other end from stabbing the brain under the instigation of movements, fix the bent part to the scalp by adhesive plaster to keep the appliance from being forced out and from slipping out. At intervals run hypertonic salt solution (5 per cent.) through the tube. The saline fluid is delivered in the very depths of the wound, attracts to that region currents of water and fluid proteins from the tissue, establishes a flow of infection from the brain into the wound rather than from the wound into the brain, and takes the infected material to the surface by capillary attraction.

In a case in which there are no cerebral symptoms and in which after excision of the wound inspection of the bone shows no sign of fracture it is not necessary to open the skull unless cerebral symptoms develop.

In a tangential wound with a gutter-fracture of the outer table it is practically certain that the inner table is splintered and trephining should be done. Tangential wounds of the vertex are often responsible for the condition manifested by the *sinus syndrome.* Clots form in parasinoidal and perhaps in the longitudinal sinus. There may be hemorrhage caused by bone-fragments tearing the vessel. In some cases there is paralysis of both legs. In other cases there is spastic paraplegia. If the damage is in front of the fissure of Rolando sensation will be normal. If it is back of the fissure wide areas of anesthesia may exist.

If sure no fracture exists operation is not required. If fracture exists trephine. If there is a depressed fracture without dural injury, trephine, remove depressed bone, and close without drainage the wound left by excision. Hull ("Surgery in War") points out the indications for opening an unlacerated dura. He tells us to open it if there are definite signs of "interference with brain function, or of increased intracranial pressure, if the dura, on exposure, is found to be muddy looking, if there is loss of pulsation, or if there is circumscribed loss of elasticity." In such a case brain matter is probably pulpified and may cause pressure by acting as a foreign body, may lead to abscess and may lead to the formation of a large and irritating scar. A small crucial incision is made in the dura and the disorganized brain matter runs out. If sound brain matter does not bulge, close the dura and scalp wound without drainage. If there is marked intracranial pressure do a decompression.

When the skull is fractured and the dura lacerated but there is no foreign body in the brain we may regard the brain wound as aseptic. In such a case Hull (Ibid.) advises us to excise the scalp wound, trephine, enlarge the opening, remove bone-fragments, cut away ragged parts of the dura, close the dural gap by suturing in it a piece of aponeurosis, and close the scalp wound without drainage. If operation is not performed early on such cases fatal infection will arise. Hull says (Ibid.): "A larger proportion of cranial operations for the relief of gunshot-wounds come under this heading than under any other." When a foreign body has entered into the brain sepsis exists. Localization of the body is made by the *x*-rays. The scalp wound is excised, the skull is

opened freely, bone-fragments are removed from under the dura and from in the brain. If the wound in the brain is large enough to admit the finger, the custom has been for the surgeon to insert the finger, *gently* seek for the bullet striving to avoid injuring sound brain tissue. The bullet is removed with scoop or forceps. If the wound is small a soft catheter is carried down to the bullet and the forceps are carried along the catheter as a guide. By sticking close to the catheter damage to the brain is avoided. The wound is disinfected by dichloramin-T. Such a case must be drained (see page 894). If the bullet was shown by the *x*-rays to have crossed the brain and lie near the skull it is usually wise to trephine the opposite side, and remove the foreign body. If a bullet or shell fragment passes right through the head, trephine each side and drain from each side.

Trephining may be necessary after any head injury because of hemorrhage. In most cases hemorrhage can be arrested by cutting out a piece of muscle, laying it on the bleeding point and holding it there for a time with light pressure. In other cases a suture-ligature, a ligature or a lateral ligature is used. Gauze pressure is to be used under the dura only if we are driven to it. If after any cranial operation high intracranial pressure becomes evident, and if lumbar puncture fails to control it, perform decompression. Abadie is an advocate of the extraction of projectiles in two stages ("Bull. Soc. de chir. de Par.," 1916, xlii). If the bullet is far from the point of entrance, or if for any reason the point of entrance is not the correct route for approach he trephines over the projectile, opens the dura, temporarily closes the wound, and in a day or two searches for the bullet with aid of a fluoroscope. For the second operation ether is not given.

Wounds from Revolver Bullets.—The bullet may strike the skull and glance (if fired at an angle) with or without the production of a fracture. A small bullet (No. .22) may even strike perpendicularly and fail to enter, sometimes causing a fracture and sometimes not doing so. Even a No. .22 may enter the skull. I removed a bullet of this size which had entered and crossed the skull and lodged beneath the cortex on the opposite side of the brain. A bullet may cause a "gutter-fracture"—may enter the cranium and lodge—or may cause a complete perforation. A revolver bullet is much more apt to lodge than a military bullet.

The wound of entrance is small; the wound of exit is larger. At the wound of entrance the inner table is more extensively fractured than the outer table; at the wound of exit the outer table is more widely broken than the inner table. In these cases there is always great shock and usually concussion, and concussion symptoms may exist even when the bullet has not entered the brain. In moderate concussion the action of the heart is retarded; in severe concussion it is accelerated (see page 876). A bullet may be lodged within the cranium when merely a fracture without a bullet-hole can be detected. In these cases the bullet produced a fracture and entered the cranium, and then the depressed bone flew back into place (von Bergmann). In such cases, if complete perforation occurs, the one existing opening in the bone is the opening of exit. A bullet may lodge in the bone, between the dura and the bone, between the dura and brain, in the brain, between the dura and the brain or the dura and the bone of the opposite side, or in the bone of the opposite side, in the nasal fossa, maxillary antrum, or orbit. Always examine the side of the head opposite to the wound of entrance to determine if there is a wound of exit or any bulging or fracture. A bullet may pass across the brain and be deflected from the inner surface of the skull. Ruth does not believe the bullet can rebound from the opposite wall.[1] If certain regions are injured, localizing symptoms may arise. Much brain matter may ooze out from the wound. Loss of brain matter sometimes causes great impairment of function, some-

[1] See the instructive article by Fowler, in "Annals of Surgery," Nov., 1895.

times little or none. The secondary symptoms of gunshot-wounds of the head are varied and uncertain, and may not be observed at all before death. Fowler wisely points out that a patient with a gunshot-wound of the head may have also received other injuries, and the other injuries may be in part, at least, responsible for cerebral symptoms.

Treatment of Wounds from Revolver Bullets.—Endeavor to bring about reaction (see Concussion). In severe cases apply heat to the head and make artificial respiration. It will sometimes be necessary to operate while artificial respiration is being made. In treating gunshot-wounds of the head shave and antisepticize the whole scalp, excise the wound, turn down a large flap and proceed as indicated on pages 894 and 895, disinfect the entire track of the ball, and arrest hemorrhage at the wounds of entrance and exit, using the rongeur to expose the bleeding points if the bullet be large, employing the trephine if it be small. If the bullet has emerged and has been picked up, examine it to see if it is entire. The bullet, if retained, is to be sought for. The *x*-rays are invaluable in locating the missile. Place the head in such a position that the track of the ball will be vertical, then introduce Fluhrer's aluminum probe or Senn's probe, and let it find its way by gravity. The probe may find the ball near the wound of entrance, in which case extract the ball with forceps; or the probe may find the ball near the opposite side of the head, in which case make a counteropening through the bone at a point the probe would touch if it were pushed entirely

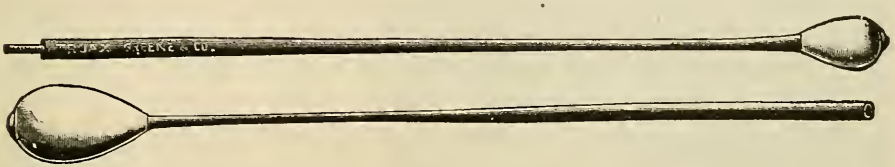

Fig. 585.—Senn's modification of Nélaton's bullet-probe.

across. Take a new and *clean* rubber catheter (No. 9, French), insert a stylet, and carry the catheter through the wound (Keen). Knowing the depth of the ball, search for it around the catheter-tube as an axis, and when found, extract it. In some cases it is advisable to search for and remove the ball with the aid of the fluoroscope (page 310). After extraction drain the wound as shown on page 894. When a counteropening exists, drain from each side. If the ball cannot be detected, drain from the depths of the wound. After dressing always place the head in a position favorable to drainage. Fluhrer tells us that when a counteropening fails to disclose the bullet, use the new opening as a doorway through which to search for the ball. He believes the bullet is not unusually deflected. The angle of deflection is somewhat greater than the angle of incidence, and the bullet is apt to fall a little toward the base. Splinters of bone are often driven into the brain by a bullet, and these should be removed whether the ball is found or not. Several varieties of probes have been recommended. Fluhrer uses a large-sized aluminum probe. Senn used an instrument shaped like the Nélaton probe, but of the same diameter as the bullet (Fig. 585). (Of course, the porcelain probe will not show a black mark from contact with a hard-jacketed bullet.) Fowler uses a graduated pressure probe; so long as the pressure is within the limits of the spring, as shown by the scale, the probe is in the bullet-track. Girdner's telephonic probe has been used as an aid to localization. Bullets are now certainly located by the Röntgen rays. There can be no doubt that many gunshot-wounds have been recovered from without operation, and it is beyond question that many deaths follow operation (about 33⅓ per cent., according to Hahn). Von Bergmann was so impressed with these facts that he did not operate when cerebral symptoms were absent. I usually operate.

Prolapse of the Brain and Hernia of the Brain.—In a compound fracture, especially a gunshot-fracture, with torn dura and pia, brain matter may emerge from the wound. In fracture of the base, brain matter may enter the orbit, the nose, or the ear. A flow of brain matter may continue from a wound for many hours. A week or more after an injury a portion of the brain may protrude or prolapse. To this condition the term *prolapse of the brain* should be applied. In many instances the protrusion is covered with pia, but if the pia has been torn or cut, it will not be a covering. This protrusion emerges from the opening in the skull, mounts up, growing larger and larger, until it may become the size of a fist. It usually pulsates. When bare it is soft, lobulated, of a dirty-white color, pulsating, painless to the touch, often bleeding, and sometimes discharging cerebrospinal fluid. Death may soon follow such protrusion, but the protruding mass may become necrotic and slough off, a granulating surface remaining, which heals. *Hernia cerebri* (Fig. 586) sometimes follows operations upon the brain or injuries of the skull and dura, when large pieces of bone have been removed or when the dura has been widely cut or torn and has not been carefully sutured. It is due to brain edema. The protrusion may become strangulated in the dural opening or adherent to the margins of the opening. The hernia begins a few hours after the injury. Many cases of gunshot-wounds develop herniæ. It is most common in the parietal region and is uncommon in the frontal and occipital regions. The condition is not due entirely to increased pressure else lumbar puncture would be distinctly instead of slightly beneficial. The chief lesion is congestion and edema of the damaged and protruding brain. In some cases abscess exists. Hernia of the brain is protrusion through the dura, but not through the scalp, the scalp wound being healed above the protrusion. In a decompression operation we deliberately create a hernia of the brain. Prolapse of the brain is treated by antiseptic dressings and perhaps by a decompression operation. Skin-grafting benefits some cases. Pressure is dangerous. Excision by the knife or cautery seldom does any good. Hernia in some cases can be treated by repeated lumbar punctures, in some others by craniotomy of the opposite side of the skull. Probably the best treatment is removal of bone-fragments and incision of the dural margin of the opening, followed by the use of Dakin's oil and by compression. If epileptiform convulsions arise make repeated lumbar punctures (Marchack, in "Presse Méd.," 1916). If abscess exists it must be drained.

Fig. 586.—Hernia cerebri under scalp after operation for brain tumor (W. W. Keen).

Fungus Cerebri (Fig. 587).—When the brain is exposed, a granuloma may grow from the neuroglia and fungate through the opening in the skull. This condition is fungus cerebri and is not composed of brain matter. It is due to infection of the brain, and is most frequent when a bit of bone or some other foreign body is retained. A fungus is soft to the touch, is livid in hue, bleeds easily, frequently contains multiple foci of suppuration, and pulsates. It often attains the size of a small orange. It is treated by removing the granulations and any foreign body, and applying, with moderate pressure, aseptic dressing soaked in alcohol. After healing, a depression marks the site of the fungus.

Traumatic inflammation of the brain and its membranes is divided into *encephalitis* or *cerebritis*, inflammation of the cerebrum; *cerebellitis*, inflammation of the cerebellum; *meningitis*, inflammation of the meninges; *arachnitis*, inflammation of the arachnoid; *pachymeningitis*, inflammation of the dura; and *leptomeningitis*, inflammation of the arachnoid and pia.

Meningitis.—Of recent years our views regarding meningitides have changed. We no longer regard each form as a separate and distinct disease, but we regard all the forms as different phases of one disease, that disease being a reaction to infection on the part of the membranes of the brain and cord. We must still, for clinical convenience, classify meningitides into many types. We speak of meningitis as serous or purulent, local or diffuse. We speak of it as basilar, leptomeningitis, etc., or as tuberculous, meningococcic, etc. But, after all, meningitis is an infection for which many varieties of bacteria may be responsible, and in which there are many different routes for the entrance of the causal micro-organisms, but the effects of these organisms upon the tissues are similar and the variety of the symptoms produced depends upon the region diseased and the power and nature of the toxins.

Fig. 587.—Fungus cerebri (W. W. Keen).

This view has been most ably set forth by Kopetzky ("The Laryngoscope," June, 1912). The same careful observer points out that in every form of meningitis there is increased tension of the cerebrospinal fluid and poisoning of the central nervous system by toxins and products of tissue metabolism.

The chief factors in causing increased tension of cerebrospinal fluid are edema of brain tissue and edema of the membranes.

Kopetzky ("The Laryngoscope," June, 1912) further points out that very early in the progress of every case of meningitis there is a disappearance from the cerebrospinal fluid of the copper-reducing substance dextrose. Bacteria are greedy for carbohydrates and eat up dextrose. The disappearance of dextrose is highly significant of the existence of meningitis. Its reappearance indicates abatement of the inflammation.

Treatment.—Kopetzky (Ibid.) in acute cases advocates the administration of serum or antitoxin and the early performance of an operation to reduce intracranial tension. If operations were done early, before pus had time to be imprisoned between the convolutions, results of operation would be much better. Lumbar puncture is of high diagnostic, but of small therapeutical value. The fluid obtained by puncture contains polymorphonuclear leukocytes. Drainage of the spinal theca by lumbar laminectomy is practised by some. The most promising operation is one which drains the cisterna magna (see Haynes's Operation, page 938). Radical drainage has saved many lives.

Pachymeningitis Externa.—Inflammation of the external layer of the dura is called *pachymeningitis externa*. It may arise from tumor, caries, necrosis, middle-ear disease, sunstroke, or traumatism. Syphilis is a not unusual cause. The other membranes may become involved. Suppuration may arise, having extended by contiguity from neighboring parts.

The **symptoms** of pachymeningitis externa are uncertain. They resemble often those of leptomeningitis (see below). Pressure symptoms may arise. Headache is always present. Paralysis may or may not exist. If pus forms, the ordinary constitutional symptoms of suppuration are evident (high temperature and sweats), not the usual symptoms of abscess in the brain. In a severe case the other membranes become involved.

The **treatment** consists in removing the cause (carious bone, pus, middle-ear disease). In pachymeningitis from traumatism it is sometimes advisable to trephine in order to drain inflammatory products; in a case with localizing symptoms always trephine; in an ordinary case, without pus and with no evidences of traumatism, use wet cups back of the mastoid processes, apply an ice-bag to the head, and purge by means of calomel. Administer iodid of potassium in most cases. If sunstroke is the cause, treat according to ordinary medical rules.

Pachymeningitis Interna.—This term means inflammation of the inner layer of the dura. Inflammation may extend from the pia or from the outer layer of the dura. The disease is most often met with in infants and in the chronic insane, but may occur in those not insane in late middle age or beginning old age. The form known as *hematoma of the dura mater*, or *pachymeningitis interna hæmorrhagica*, may arise during infectious disease (typhoid fever or rheumatism), in persons of the hemorrhagic diathesis, in diseases causing atrophy of the brain, in chronic diseases of the heart and kidneys, and in syphilitics. Among the exciting causes are traumatism, inflammation in adjacent parts, and, especially, the abuse of alcohol. In this disease blood is extravasated on the inner surface of the dura. Many observers do not class hemorrhagic pachymeningitis as inflammation, but regard the hemorrhage as primary.

The **symptoms** of internal pachymeningitis are very chronic, come on gradually, are not characteristic, and may be absent. They consist usually of mental irritability or excitement, followed perhaps by hebetude and persistent headache; and apoplectiform attacks, with contraction of the pupils, slow pulse, and vomiting; there may also be muscular rigidity and spasm of the extremities. Choked disk is not infrequent; localizing symptoms may be made out, and coma is apt to arise. Cranial nerves are seldom affected.

The **treatment** is operation, which removes the clot. This is unpromising, but Munro saved 1 case out of 5 ("Chicago Med. Recorder," Dec., 1902).

Acute leptomeningitis is a purulent inflammation of the soft membranes of the brain. The pathological changes can be noted in the pia and in the brain substance. The brain is edematous, the pia purulent, the convolutions are flattened, the ventricles are distended with fluid, and hemorrhages occur into the brain substance. Pus may be localized upon the pia, but it is usually diffused over one hemisphere or over both. Various organisms may be found, especially streptococci, staphylococci, and diplococci. In some cases we find the Bacillus pyocyaneus or the Bacillus pyocyaneus fœtidus, which is identical with the colon bacillus and with the Bacillus meningitidis purulentæ (Park). Saprophytic organisms are occasionally present. This disease may be acute or chronic, and a severe case is spoken of as *encephalitis*. *Secondary leptomeningitis* is apt to affect the convexity; *primary leptomeningitis* is apt to affect the base.

The **causes** of leptomeningitis are epidemic cerebrospinal fever, tuberculosis, acute general diseases (pneumonia, typhoid, erysipelas, and rheumatism), bone diseases, traumatism, middle-ear disease, syphilis, and sunstroke. In diplococcic meningitis the tissues of the *pia* and the cerebrospinal fluid contain diplococci identical with pneumococci. Infection may take place by various avenues. It may pass from the pharynx by way of the Eustachian tube to the ear, or from the nose to the frontal sinus or ethmoid sinuses (Hirt),

and from these situations to the brain. It may pass from the middle ear or mastoid to the membranes of the brain. In fractures at the base the organisms enter by way of the pharynx and the Eustachian tube, or the ear. The **symptoms** of acute leptomeningitis early in the case are: rising blood-pressure (determined by the sphygmomanometer), edema of the optic papillæ, absence of carbohydrates from the cerebrospinal fluid (obtained by lumbar puncture), "an irritable or clouding sensorium" (Irving S. Haynes, in "The Laryngoscope," June, 1912). The same author adds that vagus pulse and respirations irregular in depth and rate may also be present. As the case progresses there are violent headache persisting during delirium, flushing of the face, rigidity of the neck, cerebral vomiting, a pulse small and irregular in force and frequency, but often slow, elevated temperature, leukocytosis, photophobia, contraction and perhaps inequality of the pupils, intolerance of sound, hyperesthesia of the skin and muscles, and delirium passing into stupor and coma. There are rigidity of the muscles of the neck, retraction of the head, retraction of the abdominal muscles (boat-shaped abdomen), inability to extend the legs when sitting up, though it can be done when recumbent. If, while lying down, the thigh is flexed on the belly the leg cannot be extended on the thigh (*Kernig's sign*). If a dull point is drawn along the skin a red line follows it (*tache cérébrale*). A chill or a succession of chills may occur. Choked disk, strabismus, and nystagmus are not unusual. Twitching convulsions or paralyses may occur. Death is the rule within one week. In a case of meningitis the fluid obtained by lumbar puncture may contain bacteria and may be actually purulent. The presence of numerous leukocytes is usual, there being an excess of polymorphonuclear forms in pyogenic infections.

Treatment.—Flexner's serum is valuable in cerebrospinal meningitis, a condition caused by the Diplococcus intracellularis, but is useless in all other conditions. Lumbar puncture is of immense diagnostic importance, but is useless therapeutically. It is not entirely safe. The rapid withdrawal of fluid may cause death by allowing the foramen magnum to be plugged by the brain stem. Ordinary trephining with tapping of the ventricle is practically useless. An operation which promises is the exposure and drainage of the cisterna magna (see page 938). If employed it should be done early, that is, when what we regard as early symptoms are present. Late operations are of no avail. Any causal condition, for instance, suppurative otitis media, must also be treated by operation. After operating administer urotropin. Should the patient recover, he must be guarded for a long time from physical exertion, mental excitement, worry, irritation, constipation, and insomnia.

Chronic Leptomeningitis (*or Chronic Encephalitis*).—The causes of chronic leptomeningitis are the same as those of the acute form. If traumatism is the cause, the inflammation arises at a later period than it would in acute encephalitis. The symptoms of concussion follow a head injury. Days, or even weeks, after the accident a series of symptoms may occur, namely, localized pain at the seat of injury, often accentuated by tapping; listlessness; irritability; apathy regarding business affairs and home obligations, or profound depression and hypochondria with inability to attend to business. Choked disk may exist. In any case acute encephalitis may arise, with or without a chill. The **treatment** of this disease is symptomatic unless local symptoms exist. Always trephine if localizing symptoms are found. Intense local pain justifies trephining.

Tuberculous Meningitis (Acute Hydrocephalus; Water on the Brain).—This inflammatory condition is due to the bacilli of tuberculosis. In a child affected with tuberculous meningitis there is often a record of a fall, the injury acting as an exciting cause by establishing an area of least resistance. Prodromal symptoms lasting several weeks are common (restlessness, irritability, anorexia, loss of flesh, change of character). The attention

of the physician is attracted to the meninges by a convulsion or, what is more common, by headache, fever, and vomiting. The fever is persistent, but irregular. The child cries out from pain (*the hydrencephalic cry*) and the bowels are constipated. The pulse is rapid in the beginning, but later becomes slow, irregular, and of high tension. The pupils are contracted, there is muscular twitching, and the sleep is impaired. The temperature is about 103° F. There is usually edema of the optic papillæ and carbohydrate disappears from the cerebrospinal fluid (see page 899). In the second period of the disease the vomiting ceases, constipation becomes more marked, the belly retracts, headache is not so violent, and the patient lies in a soporose condition interspersed with episodes of delirium. In this stage the pupils dilate and are often unequal, the head is retracted, convulsions occur or limited rigidity is noted, the respirations are sighing, and if a finger-nail is drawn along the skin, a red line develops (the *tache cérébrale*, due to vasomotor paresis). Kernig's sign is present (see page 901). Squint and consequent double vision are usual. In the last stage coma becomes absolute and general convulsions or limited spasms are apt to occur. Optic neuritis exists, and the child passes to death along a road identical with that of typhoid collapse. In many cases the examination of cerebrospinal fluid withdrawn by lumbar puncture throws light upon the diagnosis. The fluid is turbid, is devoid of carbohydrate and usually contains an excess of lymphocytes. In most cases it contains the bacilli. It may be sterile. Sterile fluid from a patient with symptoms of meningitis suggests that the condition is tuberculous. In children the base of the brain is usually involved, and the disease is apt to last from two to four weeks; in adults the convexity is usually involved, and death is apt to occur in a few days. When the meningitis is basilar, occipital headache, rigidity of the neck, and vomiting are severe, paralysis of various cranial nerves may occur, and there may be hemiparesis from pressure on the crus. Absence of leukocytosis points to a tuberculous cause for a meningitis. The existence of leukocytosis does not disprove the tuberculous cause of the disease.

The **treatment** is like that for traumatic meningitis. The operation of trephining, perhaps with tapping a ventricle, seldom offers any chance of improvement, and never does unless the process is limited in area and confined to the convexity. Lumbar puncture is performed for diagnostic rather than for therapeutic reasons. Draining the cisterna magna should be tried (see page 938).

Abscess of the brain is a localized collection of pus. The bacteria which may be found are noted upon page 900 (Acute Leptomeningitis). The **causes** are suppurative otitis media (in half of all the cases), fracture of the skull, osteomyelitis of the cranial bones, erysipelas of the scalp, subaponeurotic abscess of the scalp, abscess of the lung, gangrene of the lung, empyema, concussion or wound of the brain, and general infections. As Ballance points out, abscess of the brain complicating head injury is not really an abscess of the brain unless the wounding material entered into the brain substance. In most cases the abscess is "a local meningeal suppuration with participation of the adjacent brain cortex, a meningocortical abscess rather than a brain abscess proper" ("Some Points in the Surgery of the Brain," by Chas. A. Ballance). General infections may cause abscess (pyemia, tuberculosis, and specific fevers). A tuberculous mass may caseate (tuberculous abscess). The abscess may be between the dura and the skull (extradural), between the dura and brain, adhesions forming and preventing general leptomeningitis (subdural), or in the brain substance (cerebral or cerebellar). Leptomeningitis may arise because no adhesions are created, because septic clots form in veins or sinuses, or because infected blood regurgitates into the sinuses (Park). A traumatic abscess is generally beneath the area to which the traumatism was applied, but it may be on the opposite side. The source of infection may be the

nose, the orbit, or the middle ear (see page 900). Roswell Park says infection may pass along blood-vessels, lymph-vessels, nerve-sheaths, or the prolongations of the membranes which extend outside of the skull. An acute inflammation of the middle ear rarely causes abscess, because an acute inflammation in sound tissue causes the formation of granulation tissue, which acts as a barrier to infection. Chronic inflammation of the middle ear is the most frequent cause of abscess. Park tells us that if the roof of the tympanum is involved, it may perforate and abscess of the middle fossa may form; if the tympanum is perforated toward the mastoid antrum, the abscess arises in the temporosphenoidal lobe; if the perforation is toward the sigmoid groove the abscess forms in the cerebellum.[1]

Chronic bone disease is seldom followed by spreading meningitis, often by abscess. When infection reaches the brain by direct extension from a suppurating bone it must pass through the membranes, but it is usually limited by adhesions. The cortex is very vascular, strongly resists infection, and is seldom extensively destroyed, but the white matter is far less resistant and abscess tends to form in it (Ballance, Ibid.). In some cases of abscess of the temporosphenoidal lobe following ear disease the cortex seems normal, in others the membranes and cortex are fused over a narrow area which constitutes the stalk of an abscess in the white substance of the lobe. This is the *mushroom abscess* of Ballance. An abscess may increase rapidly in size and finally break into a ventricle or through the cortex. It may become encapsulated and latent. A slowly-growing abscess may push aside nerve-fibers as does an encapsulated tumor, but a rapidly growing abscess destroys them.

In the cerebrum, multiple abscesses, except in cases of general infection, are seldom seen. In the cerebellum they are not uncommon. One or several abscesses may arise from a primary one. If they are adjacent to the primary one they are called satellite abscesses and tend to break into the older purulent area.

Ballance, in considering the onset of abscess, adopts the views as to the five types set forth by Brissaud and Souques. These types are as follows (Ballance, Ibid.):

(1) A subacute evolution. In this there is a febrile onset, like the onset of a specific fever, with headache, vomiting, and elevated temperature. After a few days there comes a remission, the period of delusive calm. In this period symptoms are absent or trivial. Though there may be progressive emaciation, there is no elevation of temperature in this period.

Suddenly convulsions occur which are followed by coma, or coma arises without antecedent convulsions. The patient may die in coma or the coma may pass away, "the symptoms indicating a local brain lesion" (Ballance, "Some Points in the Surgery of the Brain"). In this stage elevated temperature may appear again.

(2) Evolution with violent general infection, the symptoms of abscess being merged and usually lost in the symptoms of general infection.

(3) Evolution with complete latency. The patient presents no symptoms until a few hours before death, or he may die suddenly without a symptom having been observed. In this connection Ballance speaks of the difference between "symptoms not noticed and symptoms not present" (Ibid.).

(4) Only when symptoms were not present does he use the term "complete latency" to indicate the condition. Ransohoff has reported the case of a boy in whom an abscess in the frontal lobe was latent for three years, and another case in a man, due to gunshot-injury, in whom the abscess was latent for four and a half years and in which nearly ten years elapsed between the injury and death ("Annals of Surgery," July, 1909).

(5) Onset not to be distinguished from a brain tumor.

(6) Onset with headache and fever, or with mental excitement. Then

[1] Park, in "Chicago Med. Record," Feb., 1895.

the patient appears to get completely well and remains so for weeks, for months, or for a year or more. This condition may occur in abscess secondary to influenza (Ibid.).

Symptoms of Abscess of the Cerebral Substance or of the Cerebellum.—The symptoms due to pus formation are as follows: There is an initial rise of temperature, but (except in extradural abscess) the temperature may quickly become normal or even subnormal. Years ago Sir Samuel Wilks called attention to the depression of temperature frequently noted in cerebral abscess. Subnormal temperature is not nearly so common as is supposed. It has been present in about one-half of the cases I have seen. Toward the end of the case the temperature may rise and the fever become linked with delirium. Surface elevation of temperature over the seat of the abscess is occasionally observed. A chill may occur, but seldom does. Anorexia and vomiting are present. Urinary chlorids are diminished and the phosphates are increased (Somerville). Certain symptoms are due to pressure: Headache is the earliest symptom. Headache is at first general, then local, and grows worse later in the case, and exists even in delirium; this fact distinguishes it from the headache of fever, which ceases in delirium; pulse is full, re ular, and, in the absence of complications, becomes very slow; respiration tends to alterations of rhythm and the Cheyne-Stokes type; drowsiness lapses into stupor and stupor passes into coma; paralysis of the sphincters takes place; superficial reflexes gradually disappear on the side opposite to the lesion; convulsions are common; sensation is rarely impaired, and paralysis of the basal nerves may occur (third and sixth especially). The pupil on the same side as the abscess is sometimes dilated and fixed. Choked disk is not invariably found. It may be more marked on the same side as the abscess. It is more moderate in degree than in meningitis. Localizing symptoms, spasmodic and paralytic, depend upon the center which is irritated or destroyed. In abscess of the temporosphenoidal lobe hemiplegia of the opposite side is apt to develop. The face is most and first involved, next the arm, next the trunk, and finally the leg (Sir Victor Horsley, "Lancet," Jan. 27, 1912). In an abscess far posterior the motor palsy may be so slight as to almost escape recognition, but there is loss of the sense of position of a limb and loss of power to localize touch. In cerebellar abscess there are vertigo, vomiting, occipital headache, rigidity of the postcervical muscles, and incoördination. Choked disk may be present or absent. A cerebral or a cerebellar abscess causes a decidedly high leukocytosis.

Meningitis arises soon after an accident; a *traumatic abscess* cannot arise until more than a week has elapsed after an accident, and many weeks may elapse. Meningitis presents high temperature and the general symptoms before outlined. *Mastoid disease* may occasion cerebral symptoms without abscess, or it may cause abscess. It is curious that in some cases of mastoid disease without brain abscess choked disk arises. In *sinus-thrombosis* there is septic temperature, the veins of the face and neck are enlarged, and a clot can usually be felt in the jugular. A *tumor* grows slowly, may present localizing symptoms, and double choked disk is frequently present. In tumor the temperature is apt to be normal. There is no symptom and no group of symptoms positively significant of abscess in contrast to tumor. If abscess and tumor occur together the diagnosis is impossible. There are 34 such cases on record (Hirschman, in "Zeitschr. für Ohrenh.," 1914, lxxi).

Treatment.—If abscess is due to ear disease with implication of the mastoid cells, at once open and clear out the mastoid (see Fig. 599), and after doing this proceed to trephine the skull in order to reach the abscess. In any case, if symptoms of abscess exist, trephine the skull at once. If localizing symptoms are present, open over the suspected region. If localizing symptoms are not present, and the cause is ear disease, trephine at Barker's point (see Fig. 599).

If no pus is found between the bone and dura, open the membrane. When the dura is opened, if the abscess is subdural, pus will be evacuated; if the abscess is in the brain substance, the brain will bulge very much and will not pulsate. A grooved director is plunged into the brain, in the direction of the abscess, for 2 or 2½ inches. It is pointed to the external angular process of the opposite side. If pus is not found, withdraw the director and introduce it near the first point, and point it to the nostril of the opposite side. If pus is not found, withdraw the director and introduce it again, pointing it to the angle of the jaw of the opposite side. When pus is discovered, incise the brain with a knife, enlarge the opening by inserting a closed pair of forceps and withdrawing the instrument with the blades open. Scrape away the granulation tissue lining the abscess-cavity, irrigate with hot salt solution, and introduce a rubber drainage-tube and suture it to the scalp; stitch the dura, but leave an ample opening for the tube; bring the tube out through a button-hole in the scalp, and after the first two days pull the tube out a little every day and cut off a piece. If the first trephining does not find pus, trephine at another point. If we are seeking for an abscess due to middle-ear disease and fail to find it in the temporosphenoidal lobe, seek for it in the cerebellum. In cerebellar abscess make a flap with the base up, and trephine or gouge away the bone just below the line of the lateral sinus. Puncture the brain for exploration as for cerebral abscess.

Brain Disease from Suppurative Ear Disease.—Acute otitis media sometimes, and chronic otitis media much more often, cause meningitis (*otitic meningitis*). This may be a circumscribed inflammation of the dura eventuating perhaps in an extradural abscess, a serous leptomeningitis, or a purulent leptomeningitis. There may or may not be involvement of the mastoid (*mastoiditis*). There are always fever and pain and tenderness over the region of meningitis. The pain and tenderness are above the zygoma or back of the mastoid (Dench, in "New York Med. Jour.," August 27, 1910). With these symptoms there may or may not be signs of mastoid involvement. Dench points out that the occurrence of sudden and profound deafness during middle-ear suppuration usually means beginning meningitis (Ibid.). Chronic disease of the middle ear is apt to destroy the bone between the tympanum and the middle fossa of the skull, and thus produce meningitis, thrombosis of the petrosal or lateral sinuses, abscess of the temporosphenoidal lobe or of the cerebellum, or extradural abscess. In chronic otitis media the reflexes of the opposite side of the body are frequently altered (Russell Reynolds, Sir Victor Horsley). In some cases, even without any other evidence of cerebral involvement, there is choking of the disk. Choked disk is apt to be the earliest symptom of abscess, the other symptoms not having developed. Absence of eye symptoms is not proof that abscess is absent, and their presence is not absolute proof of abscess. In many cases the infection is direct, by bone involvement or by the lateral sinus. In many other cases the infection is through the labyrinth. If labyrinthine infection arises, it produces symptoms (disturbances of equilibrium and nystagmus). Chronic otitis media is apt to induce inflammation or suppuration of the mastoid cells (*empyema of the mastoid*). Pus in the mastoid may discharge itself into the middle ear, and from this point into the external auditory canal, through a perforation in the drum-membrane (especially in acute cases). In some cases the pus becomes blocked up within the mastoid process. Pus in the mastoid may after a time break into the cavity of the cranium or into the groove for the lateral sinus, or may find its way externally (*postauricular abscess*) and open into the sheaths of muscles arising from the mastoid. It not unusually opens into the sheath of the digastric muscle (*Bezold's abscess*). These facts teach the surgeon that inflammation of the middle ear should never be neglected, but should if possible, receive the closest attention of the specialist. If no perforation exists in the drum, the

surgeon must make one. In ordinary cases cleanliness and antisepsis are sufficient, the ear being syringed every day with a warm 2 per cent. solution of common salt. If only a small drum-perforation exists, 10 drops of pure alcohol or of corrosive sublimate solution (1 : 5000) are dropped into the ear daily; but if a large drum-perforation exists, boric acid and ioodform (7 to 1) are insufflated. Never inject alum. A strong silver solution is not safe; if it is used, wash the ear out afterward with warm salt water. If granulations or polypi exist, they must be removed. Some cases require the removal of the drum-membrane and the ossicles of the ear. Some cases of mastoid necrosis are due to tuberculosis. If headache, vomiting, and mastoid tenderness exist, open the mastoid (see page 936) in order to prevent abscess of the brain. In acute otitis media it is very rarely necessary to open the mastoid. The middle ear is on a lower level than the antrum of the mastoid, and in most acute cases both the middle ear and mastoid cells drain safely through a drum-perforation. Because a man has chronic otitis media it is by no means always necessary to trephine the mastoid. In many cases removal of the ossicles and drum-membrane effects a cure. In chronic otitis media, even if the mastoid is trephined, the ossicles and membrane ought to be removed in most cases.

Cerebral abscess from ear disease (see page 905) is almost always in the temporosphenoidal lobe, but may arise in the cerebellum. The **symptoms** are a regular, full, slow pulse (except in complicated cases), a transient rise of temperature, followed in many cases by a normal or subnormal temperature; vomiting; mastoid, frontal, and temporal pain. The mind is dull, and stupor arises which passes into coma; the bowels are constipated; choked disk may be present; and convulsions or spasms or paralyses may exist. Trephine and clean out the mastoid, and asepticize (see Operations Upon the Skull and Brain). Also trephine at Barker's point, 1¼ inches behind and the same distance above the middle of the external auditory meatus, open the dura, and seek for pus in the brain. If pus is not found, open the cerebellum.

Extradural Abscess.—The eye-symptoms and pain are the same in this as in cerebral or subdural abscess, but the temperature is different, rising to 103° or 104° F., and never being subnormal. There is often considerable tenderness above and behind the mastoid. In extradural abscess following disease of the middle ear trephine and clear out the mastoid; follow up a bone-sinus to the abscess, rongeur away the bone, being careful to avoid injuring the lateral sinus; curet, irrigate, and drain.

Infective Sinus-thrombosis.—Any sinus may be attacked. The disease may result from scarlet fever, small-pox, diphtheria, influenza, typhoid, or any acute suppuration. In erysipelas of the scalp, subaponeurotic abscess of the scalp, and cranial osteomyelitis septic clots may form in the veins which pass through the bone and reach the longitudinal sinus. Infective thrombosis of the superior longitudinal sinus is thus produced.

In carbuncle of the lip and orbital suppuration the cavernous sinus may become involved.

In caries of the basilar portion of the occipital bone the circular sinus or the cavernous sinus may suffer. The veins of the tympanum join the inferior cerebral veins, and one of the inferior cerebral veins empties into the cavernous sinus. The vein of Trolard, which arises on the parietal convolution and empties into the cavernous sinus, receives blood from the diploic veins which communicate with the veins of the tympanum (C. G. Crane, in "Laryngoscope," 1916, xxvi). The anatomy of the region shows that cavernous sinus thrombosis may be secondary to middle-ear disease, with or without mastoid involvement. In caries of the petrous portion of the temporal bone, and in suppuration of the middle ear and mastoid process, infective thrombosis of the lateral sinus may occur.

In any case the symptoms are those of pyemia. The lateral sinus is the

one most frequently attacked. In infective thrombosis of the lateral sinus there is usually a history of an old discharge from the ear.

Infective thrombosis of the lateral sinus may result from a specific fever, but is usually due to chronic suppuration of the middle ear associated in most cases with carious bone and pus in the mastoid process. Thrombosis of the lateral sinus occasionally follows an operation upon a suppurating mastoid, or develops in an individual who suffers from middle-ear disease, who has been struck upon the head, who has had the ear syringed with force, or who has had injected a corrosive or very irritant fluid. Tuberculous bone disease is an occasional cause.

Symptoms.—In most cases there is a history of chronic ear disease. In children the symptoms are more acute than in adults. In any case the symptoms may rapidly become violent. In some cases there are preliminary symptoms of extradural abscess, pus being lodged in the groove of the sinus. It has been pointed out that pus in the jugular foramen may make pressure upon the pneumogastric, spinal accessory, and glossopharyngeal nerves, producing aphonia, hoarseness, dyspnea, dysphagia, and slow pulse (George F. Cott[1]). Marked headache and often an initial chill usher in sinus-thrombosis. The pain is apt to be localized about the ear and mastoid process, but may become general. There is usually acute tenderness of the mastoid. There is high fever from the start, but when the clot begins to soften and break down, hard rigors develop and the temperature fluctuates violently. The temperature varies greatly each day, fluctuating it may be between subnormal and 106° to 107° F. A chill may occur once or even twice a day, and it lasts from ten to twenty minutes. The pulse is soft and usually rapid. The patient is nauseated, labors under vertigo, is very restless, is sometimes delirious, may become dull and stupid, and the muscles of the neck are stiff. Tenderness and marked edema are detected over the mastoid, and the veins of the neck and mastoid region may be enlarged. When the clot extends into the jugular vein there is pain on moving the head and on swallowing, the cervical glands are swollen, and a cord-like clot may be felt in the neck. Choked disk exists in about half or perhaps two-thirds of all cases. There is often a profuse discharge of pus from the ear, but in some cases a discharge is found to have abated or ceased. Exophthalmos and swelling of the eyelids point to involvement of the cavernous sinus in the process. In early cases there is thrombosis of the lateral sinus alone, or of the lateral sinus and jugular vein. In advanced cases other sinuses become involved (superior petrosal, inferior petrosal, both cavernous, the lateral sinus of the opposite side, the ophthalmic veins, and the torcular Herophili). In sinus-thrombosis there is leukocytosis unless the patient is profoundly septic. A patient with sinus-thrombosis is in great danger of developing pulmonary metastasis and septic meningitis (Jansen). Septic meningitis is accompanied by abscess about the sinus. Infective sinus-thrombosis is a very fatal disease and usually runs its course in from seven to ten days, but occasionally lasts for several weeks. It is a form of pyemia, and death arises from the causes which have been referred to in discussing that disease.

Infective thrombosis of the cavernous sinus occurs when an infected clot comes from another sinus, from disease of the nasal sinuses, from orbital infection, or from a pyogenic process of the face or lids. It causes pain and the general symptoms of pyemia, and also edema of the lids, chemosis, and an extreme degree of exophthalmos. Choked disk exists. Vision may be normal or impaired. The condition almost invariably spreads to the other eye along the circular sinus.

Infective thrombosis of the petrosal sinus produces pyemic symptoms, but no characteristic signs.

The **prognosis** largely depends upon early recognition. The surgeon

[1] "Am. Med.," April 19, 1902.

should, whenever it is possible, open a mastoid before sinus-thrombosis arises, and should evacuate an abscess about the sinus before a clot forms in the venous channel, or at least before that clot becomes septic (Jansen).

Treatment.—In 1880 Zaufal proposed the operation now practised, and Horsely did it in 1886. (See article by Geo. F. Cott, in "American Medicine," April 19, 1902.) Infective thrombosis of the lateral sinus is treated as follows: Open and clear out the mastoid, and expose the sinus by the use of the chisel or rongeur (see Fig. 599). Follow Mr. Ballance's advice and expose the sinus from the bulb to the torcular. The jugular vein should now be exposed at the level of the cricoid cartilage and ligated below any clot which may exist. This is done to prevent propagation of an infected clot and diffusion of sepsis. Even if a clot does not exist in the jugular, the vein should be tied in two places and divided, because the sinus contains infected clot or putrid material even when the vein as yet does not. According to Ballance, the portion of the vein above the point divided should be extirpated. Some surgeons after ligating the jugular do not excise it, but if it contains a septic clot, incise the vein up to the base of the skull and pack the wound. After attacking the vein open the sinus, and if a clot is found to exist, cut away the wall of the sinus. Introduce a small spoon into the lumen and carry it toward the torcular Herophili, and scrape away the clot until blood flows. Arrest hemorrhage by forcing a piece of iodoform gauze into the wound and toward the torcular. Jansen opposes removing the entire clot toward the jugular, and does not tie the jugular, believing that to do so increases the danger of thrombosis of the inferior petrosal and cavernous sinuses. He simply removes the soft clot, but does not disturb the solid clot toward the heart. Most surgeons differ from him. Surgeons are of the opinion that it is futile to do any operation if pulmonary metastasis has taken place. In a case of the author's in the Jefferson Medical College Hospital the patient recovered after operation in spite of the fact that endocarditis had developed.

Until recently it was thought that the lateral sinus was the only sinus which should be attacked surgically, but in one case Knapp, of New York, requested Hartley to remove from the cavernous sinus a clot which was causing blindness and was due to sarcoma. The operation was successfully executed by Hartley, the incision being the same as is employed to reach a Gasserian ganglion in the Hartley operation. This patient lived several months. Dwight operated upon another case by incision of the sinus (E. W. Dwight and H. H. Germain, "Boston Med. and Surg. Jour.," May 1, 1902). Some surgeons advise removal of the eyeball and curettement of the sinus.

Postoperative Insanity.—Various mental disturbances may follow surgical operation (delirium, obsessions, hysterical excitement, morbid fears, illusions, hallucinations, amnesia, confusion, hypochondria, psychasthenia, melancholy, and genuine insanity). Insanity is no more frequent after abdominal operations than after other operations if we exclude operations involving the ovaries. Removal of the testicles and ovaries are peculiarly provocative.

Postoperative insanity is most common in females and in adults. The predisposing elements connected with a surgical operation are: Apprehension, fear, pain, insomnia, and exhaustion before operation. The effects of the anesthetic, shock, and hemorrhage. Postoperative pain, insomnia, worry, and perhaps homesickness. There is always predisposition, hereditary or acquired. The patient may have been on the brink of an outbreak when the operation was performed. The insanity may be apparent as the patient awakes from the anesthetic sleep (Savage), and in these very rare cases the anesthetic is blamed. Most acute insanities come on in from three to five days after operation.

If a man has ever had an attack of insanity operation exposes him to distinct danger of another attack. No special mental condition characterizes postoperative insanity. There may be mania, melancholia, stupor, delusional

insanity, or acute confusion. Acute confusional insanity is the most usual form. In some cases sepsis is present, in others it is not. We must not mistake insanity for febrile delirium, delirium tremens, delirium from opium deprivation, delirium from taking morphin or cocain, delirium of iodoform-poisoning, delirium of the senile, traumatic delirium, hysterical delirium, uremic coma, or bromism.

Many cases of postoperative insanity must be sent to a hospital for the insane. Only cases of brief duration can be properly cared for in a general hospital.

Intracranial Tumors.—An encephalic tumor may originate within the skull. It may have arisen from an external growth invading the cranial cavity, or may be metastatic. A tumor that arises within the cranium may take origin from the periosteum, from one of the membranes of the brain, from the vessels, from the neuroglia, or from the brain substance.

No region of the body is so liable to tumors as the brain. During the course of a number of years the autopsies of the Munich Pathological Institute are stated by Bollinger to have shown 1 tumor of the brain in every 85 autopsies. Hale White's experience is that such tumors are even more common than this, and he estimates them at 1 in every 59 autopsies.

In endeavoring to determine the causes of intracranial tumors we must accredit heredity with considerable influence in tuberculoma, and possibly with some force in sarcoma and carcinoma. Tumors of the brain are decidedly more common in males than in females, probably because of the greater male liability to injury, syphilis, and alcoholism.

The majority of cases of tumor of the brain occur between the ages of twenty-five and fifty. Children are particularly prone to suffer from glioma and from tuberculous growths. In aged persons a tumor of the brain very rarely develops. In 100 cases of brain-tumor collected by Hale White only 2 were aged seventy or over. In 100 cases collected by Mills and Lloyd only 1 was over seventy.

Injury may be responsible for the development of sarcoma, of fibroma, and possibly of other forms; in fact, a syphiloma may arise in a syphilitic person at the seat of an injury.

We use the terms "intracranial" or "encephalic tumor" not only to include true neoplasms, but also to designate growths of parasitic, syphilitic, or tuberculous origin. It is of importance to attempt to make a diagnosis as to the form of tumor that is present, and this may be possible on account of the fact that in many cases the form affects the symptoms. A useful classification of these growths has been made by Knapp, and is as follows: (1) The infective granulomata, including tuberculous growths, gummata, and actinomycotic areas; (2) connective-tissue growths; (3) epithelial growths; (4) aneurysms. The most common of all these tumors is undoubtedly that due to tubercle. In fact, Gowers estimates that, if we exclude syphiloma, tubercle is responsible for one-half of the cases, and glioma and sarcoma together for one-third.

Tuberculous Tumors (*Tuberculous Gummata; Tuberculomata*).—Tuberculous growths may be primary, but are usually secondary to tuberculosis in some other region of the body. Tuberculous tumors are the most common form met with. They are at least four times as common in children as in adults. They may be single, especially in adults, but are often multiple, especially in children; and multiple growths may be very widespread. According to Allan Starr, these growths are most common in the cerebral axis (especially in the basal ganglia), next in the cerebellum, next in the cerebral cortex, and are least common in the centrum ovale. A tuberculous tumor usually arises in the pia mater, particularly in an arterial distribution, but may begin in a ventricle, or even in the brain substance. Some of these growths are distinctly subcortical.

The tubercle bacilli responsible for the condition are carried by the blood. Some of these growths are small aggregations of miliary tubercles in thickened pia. Others are large masses. A large tuberculous tumor is due to the coalescence of many foci. It undergoes caseation in the center, and is surrounded by a zone of softened or sclerotic brain substance. Tuberculous meningitis is present in two-thirds or three-fourths of the cases of tuberculoma.

Gummatous Tumors (*Syphilomata*).—As gumma seldom arises from inherited syphilis, the condition is very rare in children. There may be a single gumma, but, far more often, syphilitic growths are multiple. A gumma may be round or may be irregular in outline; in fact, the outline is frequently blurred and indistinct. Some of these growths are soft, and some, which contain a quantity of connective tissue, are hard. A syphiloma usually arises from the membranes, and, hence, is generally on the surface of the brain; and the membranes in the region of the growth usually show distinct inflammation. Soft gummata are most common at the base; hard gummata, in the cortex of the cerebrum or cerebellum.

Actinomycosis.—This is a very rare condition, in which the mass may remain solid like a tumor, but is far more apt to break down into an actinomycotic abscess.

Sarcomata.—Injury seems to play a considerable part in the production of intracranial sarcoma. Any variety of sarcoma may arise. Giant-cell sarcoma is very rare but has been observed. Sarcomata may arise from blood-vessels, meninges or bone. It may be primary or secondary. As a rule, at least in the beginning, the growth is single; but it may be multiple or may become so. The majority of sarcomata arise from the membranes or from the periosteum, but some cases take origin from beneath the cortex. Early in their progress these growths may be encapsulated, but some of them, from the very start, are infiltrating; and even those that were at first encapsulated later infiltrate. The cortex and the cerebellum are the most common seats for sarcoma. *Endothelioma* is sometimes met with. What is called *angioma of the brain* is, in reality, *angiosarcoma.* A *psammoma* is usually sarcomatous.

Gliomata.—A glioma is a growth of epiblastic origin but it resembles in many particulars connective tissue growths. It grows by infiltration and does not push tissue aside as do tumors which grow by expansion (W. T. Councilman, in "Long Island Med. Jour.," 1914, viii). The growth is often so ill defined and so slightly differentiated in appearance from the brain substance that it may easily be overlooked in an exploratory operation. It arises much more frequently from the white than from the gray matter, and develops from the neuroglia of the cerebrum, of the cerebellum, of the pons, or of the medulla oblongata. The growth remains strictly limited to nervous tissue and may extend on the surface to a great distance from its point of origin (Councilman, Ibid.). A glioma may be soft or may be hard. A soft glioma is sometimes spoken of as gliosarcoma. Hemorrhage is very apt to occur in these growths. They have a tendency to become cystic. They destroy tissue as they grow hence pressure signs are late or absent. Gliomata are the most common of brain tumors.

Fibromata.—Intracranial fibroma is a rare growth. Tumors of the cerebellopontile angle are apt to be of this character. It is of firm consistence, is encapsulated, and may grow to a large size. Such growths can be readily enucleated. Injury seems occasionally to be responsible for their formation.

Osteomata.—Osteophytic growths not uncommonly take origin from the inner surface of the skull, but the osteomata arising in the dura or in the brain substance are rare. Such growths, however, occasionally occur.

Cholesteatomata.—These tumors are fibrous growths covered with endothelium and containing layers of cholesterin. They are particularly apt to arise in the pia mater, but may begin in either of the other membranes or in the brain substance. A cholesteatoma is commonly called a *pearl tumor.*

Enchondromata and *true neuromata* are rare, and *lipomata* are exceedingly uncommon.

Adenomata.—An adenoma occasionally springs from the conarium or the pituitary body.

Carcinomata.—Primary intracerebral carcinoma is rare, but does occur. Secondary carcinoma is more common, and may follow cancer of any part of the body, although it is most apt to follow cancerous growths about the face or neck. A primary growth may begin in the meninges, in the hypophysis cerebri or in the lining of the ventricle. Intracerebral carcinomata may be single or multiple. They are soft and non-encapsulated growths, infiltrating and very vascular.

Cysts.—Mills says that cysts arise about an old hemorrhage, are small retention-cysts of a vascular plexus, or are porencephalic. Dermoid cysts are extremely rare. Hydatid cysts are very rare in the United States. A cyst may result from the degeneration of a glioma or of a sarcoma.

Symptoms.—They are divided into two sets: (1) *General*, due to increase of pressure, and (2) *local*, *localizing*, or *special*, arising because of the part of the brain involved.

In some cases general symptoms are absent, in some special symptoms are absent, in others even tumors of large size produce no recognizable symptoms, either general or special. A large infiltrating growth, a glioma, for instance, may produce no symptoms at all if situated in a silent region, and if it destroys brain substance as it grows, so that intracerebral pressure is not increased.

General Symptoms.—The chief general symptoms are headache, vomiting, and choked disc. All of these may be present, any one of them may be absent, any two of them may be absent, and in some cases all of them are absent. Other general symptoms that may or may not be present are vertigo, general convulsions, insomnia, mental failure, and somnolence or partial stupor.

Headache.—This is the symptom most commonly present. It occurs sooner or later in a very great majority of cases.

At first it may be noted only at certain times of the day and it is usually complained of most on rising in the morning. The headache of brain tumor when once established is intense in most cases, and as a general thing it is practically continuous, with episodes of increased violence. In rare cases it is paroxysmal. In some cases it is trivial, in some few cases it never arises at all. The headache of brain tumor usually interferes with sleep. It may be general, one sided, frontal, or occipital. The situation of the pain is without localizing value unless there is tenderness on percussion or pressure over the seat of pain, which is sometimes noted in growths of the meninges or cortex.

Headache is less common in children. In very young children the explanation of this is found in the open fontanels and the expansile cranium; in older children, in the fact that gliomata are common in children and gliomata may not cause intracerebral pressure.

The dura is sensitive, as Cushing says, to "pull or pressure, not to an incision." The headache of brain tumor is due to stretching of the dura.

Vomiting is present at times in many of the cases. It may happen occasionally or it may never occur.

It is usually cerebral, that is, vomiting with a clean tongue without nausea, and without any relation to the taking of food. In some cases it is projectile, quantities of vomitus being suddenly projected from the mouth. It may, however, be associated with nausea, and in some cases there is nausea without vomiting. It is apt to be most severe on getting up, especially on rising in the morning. It is usually most severe when headache is most intense.

The worst attacks of vomiting occur in cases of cerebellar tumor.

The cause of vomiting is uncertain. Some believe it to be due to stimula-

tion of the vagus center; others, to reflex stimulation of a vomiting center in the medulla. If associated with vertigo it may arise from the auditory centers.

Choked Disk (Optic Neuritis, Papillitis, Descending Neuritis, Papillo-edema).—This is a most important symptom. It is disclosed by the ophthalmoscope. When present it is, as Cushing says, one of the "most reliable" signs of tumor. It is present in 80 per cent. of all cases. It may be noted in a few weeks after a tumor begins to grow, in a few months, or longer. It may come on rapidly or gradually.

It is particularly common and severe in growths beneath the tentorium. It is decidedly less common in tumors of the motor cortex. It is nearly always bilateral, but it is common to find it more marked in one eye than in the other. That it is worse on one side *suggests*, but *only suggests*, that the tumor may be on the side on which the choked disk is worst. Monocular choked disk is very rare. When it exists it indicates that the growth, in all likelihood, is situated near the back of the orbit on the same side as the choking of the disk. Gowers recorded a case of unilateral choked disk due to a tumor compressing the left optic nerve ("Lancet," July 10 ,1909).

Choked disk may exist for some time and attain a high grade without noticeably impairing vision, but ultimately it leads to retinal hemorrhage, white atrophy, and blindness. When atrophy begins, vision wanes. The presence of choked disk does not *prove* the existence of tumor. The cerebral edema of Bright's disease may cause a condition known as albuminuric retinitis, which practically is not to be distinguished from the choked disk caused by tumor. Cushing believes that the processes are identical in tumor and Bright's disease. Choked disk may occur in meningitis, brain abscess, cerebral syphilis, sinus-thrombosis, myelitis, infectious diseases (typhoid, influenza, diphtheria, and other conditions), toxemias from lead, arsenic, and alcohol, anemia, diabetes, or as an hereditary or family disease in the victims of the cranial deformity known as *oxycephaly*. In this condition there is a high and usually narrow head with a prominence over the site of the anterior fontanel (see Wm. Sharpe in "Am. Jour. Medical Sciences," June, 1916). Diabetes or diabetes insipidus associated with primary optic atrophy especially bitemporal hemianopsia is probably due to hypophyseal disease.

The cause of choked disk has been much disputed. Some believe that the condition is a neuritis due to a toxic condition of the cerebrospinal fluid. Others believe that it is not inflammatory, but is a papillo-edema due purely to mechanical pressure, and is an edema or dropsy. The latter theory is largely held by surgeons because they have become convinced by experience that relief of intracranial pressure relieves or cures choked disk. De Schweinitz and Holloway ("Therapeutic Gazette," July 15, 1909) make the following statement in regard to mechanical pressure causing choked disk: "That this is the *only* etiologic factor may with propriety be disputed; indeed, it seems certain that a combination of factors must be active in the production of this condition, but increased intracranial pressure is the one of which we have most certain knowledge."

Cushing, of Harvard, who has done such notable work on this subject, believes that "almost all, if not all, cases of choked disk are primarily of mechanical origin and do not justify the term 'neuritis'" ("Keen's Surgery," vol. iii). Compression forces the cerebrospinal fluid out of its reservoirs. Some of it is forced into the vaginal sheath of the optic nerve. It reaches the head of the nerve and the swollen disk and large, tortuous veins are seen by aid of the ophthalmoscope. If a tumor was, from its start, in contact with the nerves, primary atrophy occurs instead of choked disk. In such a case choked disk cannot arise because the fluid cannot be forced down the blocked nerve sheaths. Primary atrophy occurs in hypophyseal tumors.

Convulsions.—Generalized convulsions may occur, and children are espe-

cially liable to them. Many cases of supposed general convulsions have an unobserved local beginning which is a focal symptom.

Vertigo.—Mills says it is noted in one-third of all cases and is due to dural, ocular, or labyrinthine irritation.

Insomnia is often due to headache and is apt to be associated with restlessness, lack of emotional control, and irritability. It is most pronounced in cases of syphiloma and some forms of malignant disease, and is worse in adults than in children.

In rare cases there is *somnolence* or partial stupor rather than insomnia. In such cases slow speech is often noted.

Mental Failure.—There is often great lack of emotional control, characterized by irritability and outbreaks of anger. Failure of memory is common and change of character is the rule. There may be great slowness of thought and of mental response to stimuli, with defective power of orientation. Progressive mental deterioration may occur. There may be mental depression, apathy, or mental excitement. Tumors in certain regions may cause delusions, illusions, or hallucinations.

Hysteria and neurasthenia sometimes arise.

Pulse and Respiration.—Whereas the pulse is often slow, it is very variable, and I agree with Cushing that "pressure-symptoms which characterize acute lesions (namely, rise in blood-pressure; slow, vagus pulse, and Cheyne-Stokes respiration) are conspicuous by their absence" ("Keen's Surgery," vol. iii).

Anemia is a not uncommon symptom of brain tumor. It is usually a result of secondary hydrocephalus.

Special Focal or Localizing Symptoms.—These symptoms, when present, indicate the situation of the growth. If the tumor is in a silent region there will be no focal symptoms. General symptoms may exist without focal symptoms and focal symptoms may exist without general symptoms.

Among localizing symptoms we should mention various forms of aphasia, hemianopsia, paralysis, Jacksonian epilepsy, sensory disturbances (to touch, pain, or temperature), a sensory aura, disturbances of taste, hearing, and smell, impairment of muscular sense, alteration or impairment of reflexes, nystagmus, and incoördination. Nystagmus is often noted when there is general compression.

Exophthalmos unless due to complicating hyperthyroidism or ventricular tumor, means direct pressure upon the cavernous sinus. A unilateral exophthalmos is nearly always upon the side of the tumor. In bilateral exophthalmos the protrusion is usually worst on the side of the lesion (Weisenberg, in "Jour. Amer. Med. Assoc.," vol. lv).

Diagnosis.—In many cases a diagnosis is made at a period so late that irreparable damage has already been inflicted. Early diagnosis is of the first importance. A careful and painstaking study of the patient and of his history will usually enable us to make a diagnosis before, and often long before, the attainment of a degree of pressure which causes papillo-edema, headache, and vomiting. In doubtful cases an exploratory operation should be performed. Exploration is always called for in advancing cerebral palsy and in focal epilepsy.

In *abscess* the symptoms usually develop much more acutely than in tumor. It is true that some cases of abscess last for months, but in them intervals of complete remission of symptoms occur, which is not the case in tumor. An abscess follows middle-ear disease or some other pyogenic process or perhaps a head injury. There may be fever and leukocytosis. Choked disk is far less common than in tumor.

Chronic meningitis from syphilis exhibits periods of increase and periods of subsidence of the symptoms, and usually palsy of one or more cranial nerves. The symptoms may pass away under the use of mercury and iodid of potassium.

There may be clinical evidences of syphilis. There should be a positive Wassermann reaction.

Chronic tuberculous meningitis causes a headache which is apt to be general and more violent than that of tumor, and there is more commonly cutaneous hyperesthesia and hyperesthesia of the organs of sight and hearing. Optic neuritis may be absent. When present it is of less intensity than that observed in tumor. In some cases the ophthalmoscope discloses tubercles on the choroid. In meningitis there is a continued, irregular fever. The cerebrospinal fluid obtained by lumbar puncture usually exhibits an excess of lymphocytes. It may contain the bacilli. Carbohydrate is absent. It may be sterile. Of course, a tumor might exist with meningitis.

FIG. 588.—Professor Gibbon's case of brain tumor.

In *Bright's disease* symptoms strongly suggestive of tumor may arise (headache, vomiting, and choked disk) with, perhaps, but little change in the urine. The difficulty in diagnosis becomes evident when we recall that in cases of brain tumor the urine may contain casts and albumin. A sudden onset and brief duration of the symptoms suggest uremia.

Ependymitis with ventricular dropsy may cause symptoms resembling tumor with hydrocephalus. Optic neuritis is not so common as in tumor. Bilateral spastic paralysis may arise.

Severe anemia is capable of producing symptoms which suggest tumor. It can even produce choked disk. A blood examination and the rapid improvement under proper treatment makes the diagnosis evident.

In some cases of brain tumor (especially frontal lobe tumors) there are striking evidences of hysteria and neurasthenia. Always think of this when inclined to make a diagnosis of hysteria or neurasthenia.

The *x*-rays may aid us in diagnosis and many brain tumors can be skiagraphed (Fig. 588). Lumbar puncture may aid in the diagnosis, but it must be

used with the greatest care, because in tumor the withdrawal of any considerable quantity of fluid may be followed by sudden death due to the brain stem sinking into the foramen magnum.

Cause, Duration, and Termination.—A brain tumor, unless caused by syphilis, is a certainly fatal lesion if not removed by operation.

Some brain tumors grow for years before they produce symptoms. Some grow with great rapidity. When pressure symptoms appear the patient's life will terminate within a few months unless an operation is performed. It is usually stated that the average duration of life is three years.

Sudden death may occur at any time.

Horsley states that in a very few cases brain tumors have disappeared after mere operative exposure, the tumor not having been removed. Cushing has had the same experience, and regards such an amazing disappearance as due to the cystic degeneration of a glioma.

Localization of a Tumor.—The situation of a tumor is determined not only by localizing symptoms, but also from their mode of onset and manner of combination. In some cases the symptoms are not characteristic, in others they are definite. The more marked the signs of compression, the less the value of localizing symptoms. The nature of the tumor, its depth, and whether it is single, and if other tumors exist is, if possible, determined. Localizing symptoms may be due to irritation or destruction of functionating power. Irritation causes spasm, and destruction induces paralysis. Convulsions which are local or which begin locally are known as *Jacksonian epilepsy*. A local convulsion points to an irritative lesion of, or immediately adjacent to, the center which presides over the muscular movements of the part convulsed. Local paralysis points to a destructive lesion of the center which presides over the movements of the paralyzed part. In some cases a center is damaged and the muscular movements it controls are paralyzed, but the adjacent brain-areas are irritated and the muscles they represent are attacked with spasms. In some cases an apparently paralyzed part becomes convulsed, the center not being completely destroyed and sudden hyperemia serving to awaken spasm. Always note the order of invasion of different regions and observe if spasm is followed by muscular weakness or anesthesia.

The Bárány Tests.—These are tests of the vestibular apparatus. We know that failure in certain normal responses indicates impairment of a certain part of the vestibular apparatus. These failures may enable us to locate a tumor or an abscess. Tumors of the cerebellopontile angle and tumors of the third ventricle can thus be located. The tests must be made and interpreted by an expert. My colleague Prof. S. MacCuen Smith described for me the accepted methods of making the Bárány tests. The description follows.

1. *Rotation Test.*—(*a*) The patient, seated erect in a smoothly revolving chair, with the head at an angle of 30° forward and the eyes closed, is given 10 complete revolutions to the right, occupying about 10 seconds. On the completion of the tenth turn the chair is locked. The patient is directed to gaze into the distance. There will be a left stimulatory—being to the right, and the quick component—cerebral, inhibitory—being to the left. The average duration of the nystagmus is 24 seconds.

(*b*) When rotation is to the right, the left labyrinth is the one receiving the greater stimulus, because on the left side the endolymph in the external semicircular canal is made to flow toward the ampulla, while in the right external semicircular canal the endolymph movement is away from the ampulla.

The Pastpointing Reaction (after Stimulation).—(*c*) The patient is rotated to the right, as in the manner just described, with the exception that the eyes remain closed throughout the test. At the completion of the tenth revolution the patient's extended right index-finger is placed directly on the examiner's index-finger, held stationary. This is done to give him the location of the

examiner's finger. The patient is then directed to raise his horizontally extended arm to a vertically extended position and then to return to the examiner's finger. The same is repeated with the left arm. A normal individual will bring his finger down several inches to the right of the examiner's finger, for the reason that when the revolutions cease he experiences vertigo, the subjective sensation being that of rotation in the opposite direction, namely, to the left. This reaction depends upon the pathway of the stimulus over the fibers of the eighth nerve being unobstructed from the external canals to the cerebral cortex. If there is a lesion along the pathways, or if the labyrinth is dead, there will be no pastpointing.

(*d*) All the rotation tests are the same, with the exception that the head is placed at an angle backward of 60° in order to bring the vertical canals in the plane of rotation. Reactions are normally as follows: After rotation to the right, there will occur left rotatory nystagmus, the slow movement being to the right and the quick component being to the left. Pastpointing will be to the right. If there is a lesion along this pathway, or if the labyrinth is dead, there will be no nystagmus or pastpointing.

2. *Caloric Tests.*—(*a*) The caloric test is made by irrigating the right external auditory canal with water at 67° F. under the following conditions: The patient is seated erect, with the head at an angle of 30° forward. The water is permitted to flow through a tube in a continuous stream, without undue pressure, from a glass reservoir into the canal until nystagmus is noted, usually within 40 seconds, or until the examiner is satisfied that it will not occur. In a normal individual, with this chilling of the labyrinth wall there is a flow downward of the endolymph in the vertical canals toward the ampulla, producing left rotatory nystagmus; the slow movement to the right, the quick component to the left and causing pastpointing to the right.

(*b*) One of the advantages of the caloric test is that only one set of canals and their pathways is stimulated at one time. The reactions depend upon the pathways from the vertical canals on the right side to the cerebral cortex being unobstructed. Should there be a lesion along the pathway, nystagmus and pastpointing, one or both, may not occur. If the labyrinth is entirely dead, neither will occur.

(*c*) To stimulate the external canal, it is only necessary to place the patient's head at an angle backward of 60°, because the endolymph is already chilled from the irrigation just performed. The flow of the endolymph is now away from the ampulla, and in a normal individual a left horizontal nystagmus will occur; the slow movement will be to the right, the quick component to the left. Pastpointing will be to the right. The pathway of the stimulus is now that from the external canal to the cerebral cortex and the reactions depend upon its being intact.

(*d*) When the irrigations are performed with hot water at 112° F., the flow of the endolymph is reversed and the reactions are reversed.

Summary.—(*a*) Rotation to the right, horizontal nystagmus to the left for an average of 24 seconds, pastpointing to the right with both arms, and continuing so long as the vertigo is experienced; when the rotation is to the left, the same reactions will occur, only in the opposite direction, as when rotated to the right. When the head is extended back during rotation, there will result a rotatory nystagmus; the duration of the nystagmus and pastpointing will be the same in the first stimulation.

(*b*) In rotation to the right, two-thirds stimulation is obtained from the left and one-third from the right labyrinth. The stimulation passes over the vestibular fibers of the eighth nerve, from the semicircular canals to the cerebral cortex.

(*c*) The caloric test with water at 67° F. will stimulate one set of semicircular canals at a time; head erect, the vertical canals are stimulated and will produce

rotatory nystagmus to the opposite side, with pastpointing to the same side; with the head thrown back 60° there will be horizontal nystagmus to the opposite side, with pastpointing to the same side. The stimulation passes over the vestibular fibers of the eighth nerve from the semicircular canals to the cerebral cortex. Pathological lesions will interrupt the stimulus and in this way its location may be studied.

Aphasia.—The localizing value of aphasia is a subject of dispute.

It is generally held that, in right-handed persons, word blindness results from cortical destruction in the neighborhood of the angular gyrus of the left side, that word deafness results from injury or disease of the left first temporal convolution, and that motor aphasia is due to damage to the convolutions around the fissure of Sylvius, except the foot of the third frontal and the base of the ascending parietal (Broca's center). All agree that complete aphasia means destruction or inhibition of all the language centers.

Marie does not believe that motor aphasia is due to lesion of the left third frontal convolution. He maintains that motor aphasia is due to lesion of the lenticular nucleus and island of Reil (Frauent, in "Lyon. méd.," 1914, cxxii).

Lesions in the Cortical Motor Area.—A slow-growing tumor which irritates the cortex will cause tonic or clonic convulsions on the opposite side of the body. These convulsions have a local beginning (Jacksonian epilepsy). After a time paralysis may develop (monoplegias and perhaps, ultimately, hemiplegia). An irritative lesion of the lower third of this area causes spasm of the opposite side of the face, angle of mouth, or tongue; and this condition is often associated with tingling. The spasm may remain limited or may extend widely, and may even become general. An irritative lesion of the middle third of the cortical area causes spasm, which is limited to or begins in the fingers, thumb, wrist, or shoulder. An irritative lesion of the upper third of the cortical motor area causes spasm, which is limited to or begins in the toes, ankle, leg, or thigh. If such lesions exist, an aura is occasionally felt in the affected region before the spasm begins, and there is often numbness after the spasm. Destructive lesions of the motor area cause local paralysis, which may be preceded by local spasm of the same parts, and is often associated with local spasm of other parts. If paralysis comes on unpreceded by convulsions the lesion is *subcortical* rather than cortical, that is, it is in the white matter between the motor area and the internal capsule.

Tumors of the anterosuperior portion of the prefrontal region give no definite localizing symptoms, but produce general symptoms. Mental disorders may arise in tumors of any area of the brain, but in tumors of the prefrontal region they are most apt to occur. The intelligence is nearly always impaired, and there is apt to be mental apathy, loss of memory, hysteria, irascibility, and pronounced change of character. As the tumor grows it may subsequently involve the motor region, which in all probability lies entirely in front of the fissure of Rolando.

In tumors of the prefrontal region there may be focal convulsions or local palsy on the opposite side, due either to a spread of irritation from a superficial tumor to the motor cortex or to involvement by a deep tumor of the commissural fibers which join the frontal lobe and the motor cortex.

Tumors of the Antero-inferior Portion of the Prefrontal Region.—In a right-handed man tumor of the second left frontal convolution causes *agraphia*, and of the third left frontal convolution, *motor aphasia*. In a left-handed person these localizations are on the right side of the brain.

Inferior Frontal Areas.—Foster Kennedy ("Jour. Am. Med. Assoc.," Nov. 14, 1916) describes the following syndrome: On the side of the lesion there is true retrobulbar neuritis with central scotoma and primary atrophy. If pressure is considerable there will be choked disk of the other eye and "ipsolateral anosmia."

Malcolm Gunn pointed out years ago the pupillary reaction characteristic of retrobulbar neuritis. When light is poured upon the pupil quick contraction occurs but the contraction is slight and very temporary. The pupil quickly dilates to its former diameter in spite of light continuing to pour upon it.

Tumors of the parietal lobe may occupy a silent region of this lobe. The centers of general sensibility and for the muscular sense are back of the fissure of Rolando in the parietal lobes. Hence a tumor in this region may cause disturbance of muscular sense and general sensibility in the limbs without spasm or palsy (Durante). There may be word-blindness when the left angular gyrus is affected.

The extension forward of a parietal tumor will involve the motor zone and produce spasm or palsy. Extension backward will involve the occipital lobe and produce hemianopsia.

Tumors of the occipital lobe are apt to produce *lateral homonymous hemianopsia* (blindness of the nasal half of one retina and the temporal half of the other retina. If the right side of the brain contains the lesion the right side of each retina is blind, and vice versâ). Wernicke's pupillary sign is absent. By this sign we mean loss of pupillary light reflex when light is cast upon the blind part of the retina. This sign only occurs in a lesion in or in front of the centers for pupillary reflex. Lesions of the cuneus and of the calcarine fissure are especially apt to produce hemianopsia. A lesion of the occipital cortex may produce it. Tumors of both occipital lobes cause blindness. In tumor of an occipital lobe color vision only may be affected (Cushing). Tumor of the optic radiation may produce hemianopsia (that is, growths of the chiasm, optic nerve, or pulvinar may, but it is not certain that a growth of the quadrigeminal bodies or of the external geniculate body can).

In a tumor of the occipital lobe (the left lobe in right-handed persons and vice versâ) there may be *mind-blindness*, that is, an inability to know what is seen. The patient may fail to understand written or printed words (*word-blindness*), the nature of things (*apraxia*), or signs (*asemia*).

Tumors of the temporosphenoidal lobe frequently produce no symptoms. In the temporal lobes the cortical centers for hearing are placed, and each center is connected with both auditory nerves, but the crossed auditory bundle is larger and more active than the direct (Francesco Durante, "Brit. Med. Jour.," Dec. 13, 1902). Tumors in the left lobe are particularly apt to cause deafness and may cause *word-deafness*. Tumors at the apex of the lobe may cause perversion or impairment of taste and smell. Tumors of the temporosphenoidal lobe may make pressure on the motor tract and cause paralysis of the opposite side.

Tumors of the Corpus Callosum.—These growths affect mentality as do tumors of the frontal lobes and frequently cause hemiplegia of each side.

Tumors of the Crus.—These tumors cause hemiplegia of the opposite side and paralysis of the third nerve on the side of the lesion. If the optic tract is pressed upon there will be hemianopsia. If the tegmentum is involved there will be hemianesthesia.

Tumors In or About the Optic Thalamus.—On the side of the lesion there are nystagmus and impairment in the movements of the eyeball. There are muscular weakness and impairment of sensation in the limbs of the opposite side. There may be sudden and uncontrollable movements, astereognosis, mental dulness, emotional outbreaks, and impairment of emotional control of the facial muscles. A lesion of the posterior part of the thalamus causes hemianopsia and the pupillary reaction of Wernicke.

Tumors of any size in or about the **corpus striatum** cause hemiplegia of the opposite side by pressure upon the internal capsule. Pressure upon the *optic thalamus* produces homonymous hemianopsia and hemianesthesia. Growths near the basal ganglia produce intense choking of the disk and early pressure because of distention of the ventricles.

Tumors of the Corpora Quadrigemina.—These tumors produce cerebellar ataxia, palsy of the eye muscles, and sometimes, perhaps, hemianopsia. Hearing may be impaired in the ear opposite to the lesion. Tumors of the corpora quadrigemina are apt to involve the crura, and later the third nerve. Ocular symptoms are always present (loss of pupillary reflex and nystagmus). If the third nerve is involved there are paralysis of the motor oculi area on the side of the lesion (external strabismus, dilated pupil, and drop-lid) and hemiplegia of the opposite side of the body from pressure upon the crus. This condition is a form of *crossed paralysis*.

Tumors of the Third Ventricle.—Symptoms are due in part to pressure on nearby structures and in part to secondary hydrocephalus. Weisenburg on the strength of 30 reported cases, each case with an autopsy, pointed out a syndrome, viz., exophthalmos, dilated pupils, impaired pupillary reactions, cerebellar ataxia and paralysis of upward associated eye movements ("Brain," 1910, xxxiii). Bassol ("Jour. Am. Med. Assoc.," Nov. 11, 1916) reports a case of soft glioma filling the third ventricle. There was secondary hydrocephalus. The symptoms were headache, mental dulness, drowsiness, papillitis and blindness, ataxia, and limitation of ocular movements. The patient was fourteen years of age and there was precocious development of hair and also of the genitals.

Tumors of the Fourth Ventricle.—The symptoms result from internal hydrocephalus and pressure upon the cerebellum, pons and medulla. So far diagnosis from cerebellar tumors has not been possible.

Tumors of the Pons.—Pontine lesions produce symptoms by pressure upon the particular nerves which come from this region, with or without the evidences of pressure upon the motor path. Forms of crossed paralysis may exist. Lesions in the lower half of the pons may affect the fifth, sixth, and seventh nerves on the side of the lesion and the limbs on the opposite side. The auditory nerve may be involved in the lesion. In crossed paralysis the face on the side of the limb paralyzed is usually not affected, but in extensive tumors it may be paralyzed. *Conjugate deviation* of the eyes may occur *away* from the *facial paralysis*. In tumors of the upper part of the pons the pupils may be first contracted because of irritation of the third nerve nuclei, and later dilated by destruction of these nuclei. Anesthesia as a result of pontine tumors is not nearly so common as motor paralysis, and convulsions are rare. There may be hemiplegia with crossed hemianesthesia. A tumor on the side of the pons which involves the peduncles causes ataxia and sudden, uncontrollable movements. Knee-jerk may be absent in a case of pontine tumor.

Tumors of the Medulla.—An extensive lesion inevitably causes death. Cranial nerves only may be involved, but crossed paralysis may take place. There may be hemiplegia with crossed paralysis of the hypoglossal nerve. Vomiting is common, retraction of the head is not unusual; respiratory and circulatory disturbances and dysphagia are usually noted; sometimes there is numbness and occasionally there are convulsions; usually there is incoördination because of pressure upon the cerebellum.

Tumors of the Cerebellum.—The main function of the cerebellum is to synergize body movements and the symptoms of cerebellar disease are due to impairment of this power.

As a rule tumors are gliomatous, they grow slowly and affect particularly the middle regions of the cerebellum. Tumors often cause internal hydrocephalus. In general it may be said that tumors of the cerebellum cause headache, vomiting, vertigo, choked disk, and early blindness. *Tumors of the middle peduncle* cause sudden uncontrollable movements of the trunk, either toward the side of the tumor or away from it. Vertigo and nystagmus are common. Symptoms are frequently complicated by evidences of pontine disease proper.

Tumors of the middle lobe of the cerebellum cause a sense of lost equilibrium

and obvious unsteadiness in attempting to walk or even to stand. The knee-jerks vary. The Babinski reflex is absent in an uncomplicated case. The patient has a tendency to fall backward; there are giddiness and vomiting, early and violent choked disk and occipital headache, nystagmus, inability to stand steady when the feet are together and the eyes shut, and perhaps temporary palsies of the eye muscles. Nystagmus which is brought into being by voluntary movement is probably due to a lesion outside of the cerebellum which lesion affects vestibular fibers. Cranial nerve symptoms usually mean extracerebellar lesions. The same may be said of dizziness with ear symptoms. Motor involvement points to a pontine lesion (Weisenburg, "Jour. Am. Med. "Assoc.," 1915, lxv).

Cerebellar symptoms are common in cases of internal hydrocephalus.

Tumors of the cerebellar hemisphere produce no localizing symptoms. The usual unsteadiness of gait is due to pressure upon the middle lobe (Nothnagel).

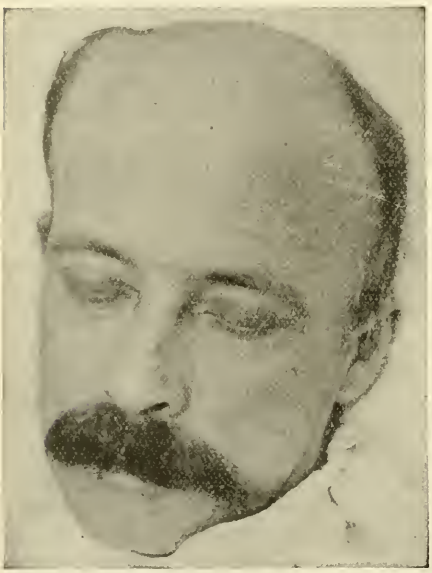

Fig. 589.—Case of cerebellar tumor. Bulging of flap after osteoplastic exploratory operation.

Tumors of the Cerebellopontile Angle.—Tumors of this region are usually attached to the acoustic nerve, sometimes to the seventh, sixth or fifth nerve. They are usually fibromatous and are occasionally cystic. They produce general pressure-symptoms and may cause cerebellar or pontine symptoms by making direct pressure on those parts. In these cases localizing symptoms may be late in appearing. The Bárány tests are valuable. If the tumor arises from the cerebellum the first symptoms will be cerebellar. If the tumor springs from a cranial nerve the first symptoms will point to that nerve. If the tumor involves the acoustic nerve there will be tinnitus, objective vertigo (sometimes with, sometimes without forced movements), a liability to sudden attacks of falling to the ground, failure of hearing or actual deafness, perhaps sudden blindness or sudden unconsciousness, and sometimes tonic extensor spasms. If the tumor involves the trigeminal nerve there will be violent neuralgia in the course of the nerve and anesthesia of the face on the same side as the tumor, the anesthesia involving the cornea. If the seventh nerve is involved there will be peripheral facial palsy of the same side. If the sixth nerve is involved internal strabismus will arise because of palsy of the external rectus muscle.

Tumors of the Hypophysis Cerebri.—The hypophysis cerebri is a ductless gland of immense importance to the economy. It is present in all vertebrates. If the anterior lobe is removed death follows. If the anterior lobe is damaged or partially removed developmental disturbances occur. The pars intermedia of the posterior lobe furnishes a very active substance which is called pituitrin which acts upon the kidney, uterus, urinary bladder, intestine, the secretory cells of the mammary gland, the heart and the blood-vessels. Overaction of the anterior lobe, however induced, is the cause of acromegaly. Underaction produces *Fröhlich's syndrome.* This syndrome is composed of adiposity, retarded development of the genital organs and generally delayed development. The posterior lobe can be removed without dangerous results. Diabetes

insipidus is probably due to underaction of the posterior lobe. In this disease subcutaneous injection of extract of the posterior lobe will diminish the amount of urine one-half or more (J. L. Miller, "Jour. Am. Med. Assoc.," 1916, clii).

Pituitrin arrests hemorrhage by its power in causing coagulation. It is used in intestinal stasis and peritonitis following operation to cause peristalsis. It stimulates uterine and vesical contractions, raises blood-pressure, and lessens the rapidity of the heart.

In pituitary tumor the *x*-rays show enlargement of the pituitary fossa.

A. D. Dunn ("Am. Jour. Med. Sciences," 1914, cxlvii) has drawn up the following useful schedule of classification of disorders of the function of the pituitary body. I quote it in the words of the abstract in "Surgery, Gynecology and Obstetrics," Dec., 1914.

"1. Affections of the pars anterior:

a. Hyperfunction—acromegaly, gigantism.

b. Hypofunction—true or pituitary dwarfism—not chondrodystrophic, rachitic, or cretinic dwarfs.

2. Affections of the pars posterior:

a. Hyperfunction—diabetes insipidus.

b. Hypofunction—hypophysial obesity—dystrophia adiposogenitalis.

3. Mixed affections:

a. Hyperfunction of the pars anterior with hypofunction of the pars posterior—acromegaly with hypophysial obesity.

b. Hypofunction of both lobes—dwarfism with hypophysial obesity.

4. Hypophysial disturbance, in conjunction with perverted activity of other glands.

a. Ovarian or testicular hypofunction with:

1. Hyperfunction of the pars anterior—acromegaly with sexual impotence—eunuchoid giants.

2. Hypofunction of the pars anterior—pituitary dwarfism with sexual impotence.

3. Hypofunction of the pars posterior—dystrophia adiposogenitalis.

b. Associated with disturbances of the functions of other ductless glands; i. e., adrenals, pancreas, thyroid, pineal gland, thymus (status thymolymphaticus), etc.

The size of the pituitary fossa is determined by the *x*-rays.

When the gland is imperfectly developed and hypopituitarism exists the fossa is small.

The fossa may be deformed by tumors enlarging from within or by tumors pressing down from above. Enlarged sella may be due to adenoma of the anterior lobe, to malignant growth of the fossa, perhaps to repeated physiological enlargement, sometimes to general or local hydrocephalus, to local meningitis or to distant brain tumors (V. Z. Cope, in "Lancet," 1916, cxc).

Cope says that if the dorsum sellæ, or anterior or posterior clinoid processes are obliterated or definitely absorbed there is decided intracranial extension of the tumor (Ibid.). The pituitary body may be subjected to pressure from, or become involved in, tumors of the region about it or tumors or cysts may spring from it directly. Tumors of or tumors making pressure upon the hypophysis may in some cases cause acromegaly, and in others impotence, genital infantilism, a tendency to fat deposit and stunted stature, and amenorrhea in women. There is intense headache, amblyopia due to primary atrophy (no preceding choked disk), appearing often as a bitemporal hemianopsia (Cushing, "Jour. Amer. Med. Assoc.," July 24, 1909). In some cases extreme drowsiness has been noted, and in some cases there has been binasal hemianopsia. When there is stimulation of the pituitary (hyperpituitarism) acromegaly develops; when there is lessened secretion (hypopituitarism) there are obesity and genital

atrophy. In hyperpituitarism, dextrose may be found in the urine. In hypopituitarism there may be polyuria and polydipsia and immense increase in carbohydrate tolerance.

Any brain tumor which causes internal hydrocephalus may thus cause pressure on the hypophysis and lead to the development of hypophyseal symptoms. (For full information regarding the hypophysis see the classic monograph by Harvey Cushing, called "The Pituitary Body and Its Disorders").[1]

Treatment.—If any doubt exists as to the existence of brain syphilis, and if the Wassermann reaction is positive, give the patient a dose of salvarsan (intravenously) and a course of iodid of potassium. Give the iodid at first in small amounts, but rapidly increase it until heroic doses are taken (100 or more grains a day). Mercury should also be given hypodermatically or by inunction. If salvarsan, iodid of potassium, and mercury really relieve the symptoms, and if the improvement is not merely temporary, operation is unnecessary, although it may be demanded later in order to remove an irritant scar. If antisyphilitic treatment fails, the question of operation must be considered. The test of success is improvement in the choked disk. If this improves, the treatment is succeeding; if it does not, the treatment is a failure. It should not be persisted in over six weeks if there is no improvement in the eye-grounds. To delay operation further may mean blindness. We must always bear in mind that in certain cases of glioma the symptoms *temporarily* improve under antisyphilitic treatment. The term *operable case* does not of necessity mean a tumor which can be entirely removed by operation. Some tumors which can be only partially removed should be operated upon. An operable case is one in which an attempt may be made to remove the tumor and in which the tumor can be entirely removed or in which a part can be removed, the removal of this part promising relief. We are justified in being radical, because without operation a brain tumor is a certainly fatal malady. In many cases of undoubted tumor excision for cure is not attempted because of the absence of localizing symptoms or because of the inaccessible situation of the growth. In all cases operation is, first of all, exploratory. Tumors of the dura which have not infiltrated the brain, many cortical and some subcortical growths, are operable. Cerebral and cerebellar cysts may be opened and drained in hope that benefit will result. Tumors of the lateral lobe of the cerebellum and tumors of the cerebellopontile angle have been removed. Byron Bramwell maintains that tumors at the base, tumors of the pons and medulla, of the corpus callosum, of the basal ganglia, and of the deeper parts of the centrum ovale are irremovable. Surgeons now regard some tumors of the cerebellopontile angle as operable, but agree with Bramwell's views as to growths in the other situations he mentions. Frazier has concluded that "if the tumor is found to be very vascular and of the infiltrating type, it is very questionable . . . as to whether any attempt whatsoever should be made to extirpate" ("University of Penna. Med. Bull.," April–May, 1906), and with this opinion I certainly agree. In tumors which are very extensive complete removal is usually out of the question. There is no use in removing secondary malignant tumors. It often happens that the brain itself (as in syphilis) is so extensively diseased, or that other organs (as in tuberculosis) are so involved, as to render attempts at removal of the tumor futile or actual removal useless. Mills thinks that 50 per cent. of cerebellar tumors can be attacked surgically ("New York and Phila. Med. Jour.," Feb. 11–18, 1905). He classifies operable tumors of the cerebellum as follows: 1. Tumors situated entirely or chiefly in the lateral lobe. 2. Tumors upon or even invading a part of the vermis or middle lobe. 3. Tumors of the cerebello-oblongatopontile angle. The most favorable

[1] For full consideration of localizing symptoms see particularly the writings of Gowers, Mills, Allan Starr, Potts, Lloyd, Burr, Dana, Dercum, Osler, and Cushing, which have been freely used in the above section.

tumors for removal are fibromata and encapsuled sarcomata. Gliomata and gliosarcomata have been removed, but are very apt to return. A syphiloma requires removal as truly as a real tumor. The cases are commonly unfavorable, as there is often widespread brain disease. The same is true of tuberculoma. Among inoperable tumors are most gliomata and all infiltrating sarcomata, metastatic tumors, and multiple tumors. Bramwell[1] tells us that he has studied 82 cases of intracranial tumor, and he considers that in only 5 of them could the tumor have been entirely removed. In 157 reported cases the tumor was either not found or not removed; in 104 reported cases the tumor was found, and in some of them it was removed (Ransohoff, in "Jour. Amer. Med. Assoc.," Oct. 11, 1902). The conclusion is that though some tumors of the brain may be successfully removed, extirpation is feasible in only a small minority of cases and is to be decided on only after careful study of all the indications and contra-indications offered by the case. When about to operate, apply an apparatus to the arm and take the blood-pressure just before the operation and at frequent intervals during it. Thus by noting a great fall in blood-pressure the surgeon gets early warning of dangerous shock, learns when to hasten, and whether or not the operation should be temporarily abandoned and be completed at another time (**two-stage operation**). We may be driven to abandon operation after cutting the bone and dural flaps, and if we are forced to stop, we restore the bone and dura to position, and complete the operation after a day or two. I agree with Frazier that the lessening of hemorrhage by temporarily clamping the common carotids in the neck is not free from danger, and it is not proper to do more than apply Crile's clamp to the vessel on the side operated upon. In a brain tumor when the dura is first opened there is usually at once marked bulging of the brain, which is called *initial bulging;* after working for a time on a brain, even when there is no tumor, bulging occurs from traumatic edema, which is called *consecutive bulging*. That consecutive bulging may occur is a sound reason for operating rapidly (Frazier). The mortality from tumor operations is large, death being due to shock and hemorrhage. Haas collected 122 cases in which the tumor was removed; the mortality was 60 per cent. Operations completed at one séance give a larger mortality than two-stage operations. During the operation an erect posture causes the brain to recede and permits of extensive exploration under the dura (Ransohoff-Cushing). The same thing is accomplished by lumbar puncture (Cushing). The fibromata constitute the best cases for operation. In operating on a cerebral tumor make a large osteoplastic flap. If on opening the dura the tumor is not visible, and if the localizing symptoms have been reasonably positive, the surgeon is justified in making an exploratory incision through the cortex to see if there is a subcortical growth. Operations for cerebellar tumors are peculiarly difficult because of the large blood sinuses, because of the limited space through which one must work, because of the great bulging after the dura has been opened, because of the impossibility of reaching the anterior, mesial, or upper surfaces through the incision, because of the liability to injure the pons and medulla, and because of the difficulty of retracting the parts (Frazier, "New York and Philadelphia Med. Jour.," Feb. 11–18, 1905). In approaching tumors which are not within a cerebellar hemisphere by a one-sided exposure of the cerebellum, it may be best to remove a considerable portion of the hemisphere in order to obtain free access to the growth. I prefer Cushing's "cross-bow" incision and bilateral exposure (see Fig. 601). This enables the surgeon to dislocate the sound lobe outward and so obtain room to work upon the lobe containing the tumor. The diagnosis of cerebellar tumor is usually doubtful, hence practically all operations are at first exploratory and are then made palliative or radical as the case demands. Operation must be early because cerebellar growths quickly cause blindness. If we operate for cerebellar tumor and find nothing, puncture the callosum and

[1] "Edinburgh Med. Jour.," June, 1894.

then explore the fourth ventricle (Bassol, "Arch. f. Psychiat.," 1911, xlviii). Cerebellar operations are very dangerous particularly because of the sudden relief of pressure.

In tumor of the cerebellopontile angle, the usual method is to retract a lobe of the cerebellum to gain access to the growth. Some hold that the mortality of the operation is 70 per cent. or over. This high mortality is due to the sudden relief of pressure, to hemorrhage, to contusion of the brain and disturbances of circulation caused by retraction of the lobe. In tumors involving the acoustic nerve, not involving the cerebellopontile angle Zange reaches the growth by a translabyrinthine operation ("Berlin. klin. Wochen.," 1915, lii). It would seem possible to remove a tumor of the fourth ventricle if it arises from the roof and many do arise from the roof. Sir Victor Horsley, McArthur, Hochenegg, von Eiselsberg, Cushing, Frazier, and others have operated for tumor of the hypophysis. Removal of a healthy pituitary body from dogs is sure to be fatal, as the gland is necessary to the life of the dog. Removal of a healthy pituitary in man would in all probability prove fatal. The entire anterior lobe should not be removed. If the tumor is associated with acromegaly, removal of the tumor may arrest the acromegaly. One route of approach to the hypophysis is from the side, just as we reach the Gasserian ganglion (Carton, Paul, Horsley). Another route is by way of osteoplastic frontal resection, the longitudinal sinus being ligated and the frontal lobes lifted (Krause, Hartley, Borchardt). Another method involves osteoplasic resection of the anterior wall of the frontal sinus and nose. This is called the transphenoidal route. The transphenoidal route has been variously modified. Cushing's plan of approach through a sublabial incision is described on page 940. Though thorough extirpation of a brain tumor is feasible in only a minority of cases, operation should often be performed for palliative purposes when the tumor cannot be located, when it is in a region from which it cannot be removed, or when its nature forbids removal. Grainger Stewart, Annandale, Horsley, Macewen, Cushing, and Keen have advocated *palliative trephining* in certain cases. Simple trephining is of little value. In order to really relieve pressure the dura must be opened and left unsutured, so that hernia cerebri may follow. Cushing has had some cases of extraordinary improvement in cases of cerebral tumor after trephining in the right temporal region and removing a piece of the dura. The operation is called by Cushing a *decompression operation*. The brain bulges through the dural opening, but the dense temporal fascia stitched together over it prevents fungation. It is the temporosphenoidal lobe that bulges, and the right side is selected because word-deafness might ensue if the operation were done on the left side. I have seen several of Cushing's cases. One of them, a colored man, had been almost blind for some time, and was unconscious and had rapidly failing respiration when the operation was performed. He was so much benefited that he returned to work and has useful vision and no pain. I have had several very gratifying results in my own practice. A decompression may, in rare cases, cause a glioma to degenerate and pass away. Horsley saw such a case. In cases of cerebral tumor subtemporal decompression, and in cases of cerebellar tumor suboccipital decompression, may be performed. Sir Victor Horsley believes that the opening for decompression should be near the tumor and not always in the subtemporal region. He believes an opening near the tumor possesses the advantage of aiding us later if the tumor should become operable. He maintains that subtemporal decompression may later confuse the localizing symptoms should such symptoms develop.

Decompression may relieve choked disk and thus retard or prevent optic atrophy and blindness. Cushing demonstrates that intracerebral pressure is the chief element in choked disk.

This procedure is of value in diminishing excessive intracranial pressure,

and thus relieving headache and choked disk, and decreasing the tendency to sudden death from inhibition of the heart or from respiratory failure. The usual method of decompression will not relieve the headache caused by tumor of the hypophysis. This headache is due to distention of the dural box in which the gland is placed, and can be relieved only by incision into the dural box (Harvey Cushing, "Jour. Amer. Med. Assoc.," July 24, 1909).

We conclude that in most cases of brain tumor operation should be performed for exploration; in some cases extirpation may be performed; in most cases extirpation is impossible, and the surgeon must be content with the palliative influence of Cushing's decompression operation. A tumor of the brain if not cured by antisyphilitic treatment is of necessity fatal if unoperated upon, and exploratory operation is not very dangerous.

Thorburn ("Med. Chronicle," 1914, lix) tabulated 490 cases of operation for brain tumor. In nearly 40 per cent. of the cases the operation was useless and in some of them it hastened death. In nearly 24 per cent. of cases it cured the patient or at least prolonged life greatly. In over 38 per cent. the value of the operation was uncertain. Thorburn takes the ground that most brain tumors are malignant and that the surgeon seldom aims at cure but in most cases simply seeks to prolong life, prevent blindness and abolish headache. Operations which expose the surface have little danger. Operations involving brain substance are very dangerous. Heuer and Dandy ("Bull. Johns Hopkins Hospital," 1916, xxvii) report upon 62 cases of brain tumor operated upon in Prof. Halsted's clinic. On these 62 cases 71 operations were performed. Six deaths occurred within twenty-four hours to five days of the operation, an operative mortality of 8.6 per cent. Two cases died later. Including these the total operative mortality was 11 per cent. No patient died upon the table.

In a case of brain tumor if operation is refused, if extirpation is impossible, or if decompression fails, it may be necessary to use the bromids for convulsions and morphin for headache. The headache is often benefited by purgatives, courses of potassium iodid, and the ice-bag to the head.

Operative Treatment of Epilepsy.—The shock of an accident or a cerebral concussion may establish epilepsy, especially in those predisposed by heredity or other causes. Traumatic epilepsy, Le Dentu[1] tells us, may be due to: (1) Bone-fragments from skull fracture; (2) outgrowths of bone due to tumor; (3) cicatrices of meninges resulting from laceration of membranes by bone-fragments; (4) chronic meningitis which ends in sclerosis of membranes; (5) cysts resulting from intracranial hemorrhage at the point of fracture; (6) arteriovenous aneurysm. We would add: (7) tumors of the brain; (8) sclerosis of the cortex. We refer here, in speaking of traumatic epilepsy, purely to the condition when it follows a head injury, and this is the common meaning of the term. Remember that epilepsy, as shown by Sachs, may follow a long-forgotten injury. Before undertaking a brain operation for epilepsy it is a sound rule to remove all sources of definite peripheral irritation. I have seen apparent cure follow the removal of a tender cicatrix and follow circumcision of a patient with phimosis. Briggs reported a case of epilepsy in which there was a distinct depression of a portion of the skull. There was also necrosis of the tibia, and after the cure of the necrosis the convulsions ceased. The removal of supposed peripheral irritation, however, is only occasionally beneficial. Are operations upon the skull and brain curative? Surgeons are much less enthusiastic than they were a few years ago. I believe operation can cure less than 5 per cent. of cases, but it is important to remember that in some cases in which operation seems to have failed medical treatment becomes much more efficient than it was before the operation. The high rate of cure (70 per cent.) once claimed for operations was due to failing to follow the patient sufficiently long. A patient should

[1] "La Presse médicale," June 9, 1894.

not be reported as cured until at least three years or, better, five years have passed without any evidence of the disease. Another source of error was a failure to understand that any traumatism may improve epilepsy *for a time.* "The administering of an anesthetic, the shock of an injury, the traumatism of an operation, just like a febrile seizure, may interrupt an epileptic habit and cause a patient to go for weeks or months without an attack" (the author, in "Medicine," Feb., 1904).

Operation must never be indiscriminately applied. In some cases it gives hope of relief, in others it is obvious that it would be utterly futile. In order to determine if a case is or is not suitable for operation it must be studied with great care. The history must be carefully obtained, particularly as to hereditary predisposition, the first convulsion, and its *supposed* cause. The question of injury, recent or old, should be thoroughly investigated, and it is a sound rule to have the head shaved and then examine for a scar and for a depression. Convulsive seizures must be studied by an expert, hence the patient should be in a hospital, constantly watched by a trained nurse, until one or two fits have occurred. The nurse watches the convulsion and describes it in writing, noting particularly if it had a local beginning. The general health must be investigated. An *x*-ray should be taken.

I am accustomed, for surgical purposes, to make the following classification of epilepsy. It is a modification of Sir Victor Horsley's classification (the author, in "Medicine," Feb., 1904):

1. Reflex epilepsy, the surgical treatment of which I shall not discuss in detail.
2. The common non-traumatic, idiopathic, or essential epilepsy, in which the attacks are general and are without a local onset.
3. Idiopathic epilepsy with a local onset of attacks (focal or Jacksonian epilepsy).
4. Traumatic epilepsy. This may be subdivided into two forms: (*a*) attacks without a local onset, and (*b*) attacks with a local onset (focal or Jacksonian epilepsy).
5. Jacksonian epilepsy due to gross brain disease (tumor, aneurysm, etc.).
6. Epilepsy following infantile cerebral palsy.
7. The posthemiplegic epilepsy of adults.

1. **Reflex Epilepsy.**—Remove the supposed cause of irritation. When epilepsy follows traumatism and a scar is found on the scalp, excise the scar. This is an imperative duty if the scar is tender or the seat of an aura.

2. **Essential or Idiopathic Epilepsy.**—Operation upon the brain is useless. If persistent headache exists, it may be proper to trephine and open the dura for exploration. Such an operation is done to relieve headache. Some claim remarkable results from bilateral excision of the cervical ganglia of the sympathetic (see page 854). The operation is a theoretical one and of doubtful utility. It was founded upon a misconception as to the cause of epilepsy, and favorable reports are no more favorable than have been set forth regarding various other now abandoned procedures.

3. **Idiopathic Epilepsy with Local Onset of Attacks** (*Focal or Jacksonian Epilepsy*).—Many of these cases begin in young children who have had infantile palsy, the traces of the palsy having disappeared. In such cases the convulsions may begin on one side, and, in fact, may be nearly limited to one side. If, from the very beginning, the attacks began in one group of muscles or in one extremity, whether or not they spread to the rest of the body, and if the case is seen within two years of the first attack, the surgeon is justified in exposing the brain and excising the irritated portion of cortex. This operation, it is true, cures very few cases, but it benefits many for a considerable time and seems to make them more amenable to medical treatment. In the vast majority of cases fits recur, but rarely as severely as before. After fits have

been going on for two years operation offers no prospect of cure, as the association fibers have surely degenerated. But, even in very old cases, if the attacks are frequently repeated and thus threaten life, the excited center should be removed to save life.

In cortical excision more of the cortex than the excited center is of necessity removed, because, in order to get the entire center, we must go wide of it. Paralysis of the parts controlled by the extirpated cortical area follows. The paralysis is seldom permanent except to the finer movements. The operation gives the best prognosis in young persons, and when done early in the case. The return of fits after apparent cure is thought to be due, at least in some cases, to the formation of *adhesions* between the brain and its membranes. Various unsatisfactory attempts have been made to prevent adhesion by the insertion of silver-foil, gold-foil, rubber tissue, egg-shell membrane, and Cargile membrane. In operating for cortical epilepsy a large osteoplastic flap is required. In the previous remarks we dealt with partial epilepsy and with generalized epilepsy in which, from the first, the attacks had a local beginning. If cases of apparent idiopathic epilepsy develop Jacksonian attacks (attacks with a local beginning), it is useless to excise the cortex. The entire cortex is diseased, though one region is particularly unstable.

4. **Traumatic Epilepsy.**—Always remember the origin of epilepsy subsequent to a traumatism may be a coincidence; the condition may be essential epilepsy and the traumatism may have had nothing to do with it. Epilepsy ensuing upon traumatism may not begin until months or even several years after the injury. In the earliest attacks consciousness may or may not be lost. The causative injury may have been slight or severe. "An injury may cause a hemorrhage or a depressed fracture; may be followed by a scar upon the membranes; may occasionally lead to the development of an innocent or malignant tumor or a cyst, or may merely induce some trivial change in the subtle chemistry of the nerve-cells" (the author, in "Medicine," Feb., 1904). Injury may produce general epilepsy or Jacksonian epilepsy. If an identified traumatism exists, the surgeon should operate even after years. When the traumatism has not left definite evidence, the surgeon is justified in making an exploration any time up to the termination of the third year after the accident. The earlier the operation, the better the prognosis. The best prognosis of any form of epilepsy is given by Jacksonian epilepsy of traumatic origin.

"In focal epilepsy with evidences of skull injury or depression, trephining is imperative and somewhat promising. The dura should invariably be opened, even if it seems in good condition. A dural scar should be extirpated. The brain should be examined by sight and by touch, and should be explored with the little finger and with the dural separator to well beyond the limits of the opening in the dura. If a tumor is found, it should be removed; if a scar upon the brain exists, it should be extirpated; if a cyst is discovered, it should be drained; and if there is any obviously damaged area in the brain tissue, it should be unhesitatingly cleared away. If nothing obvious is found on exploration, and if the attacks have been distinctly local in origin, it is justifiable to extirpate the motor center from which the discharge seems to originate.

"When Jacksonian epilepsy has followed an injury in the motor region, the chances of effecting a cure are much better than they are when the epilepsy has followed an injury in the sensory region. When it has followed an injury in the frontal region, operation affords very little hope of cure.

"When the condition is not focal but essential epilepsy, the surgeon will remove a scalp scar; and if there is any evidence of bone injury, he will trephine the bone, open the dura, and explore the brain. It is needless to say, however, that in such a case he will not extirpate any of the cortex.

"In cases of focal epilepsy I use the osteoplastic method of operating. In cases of generalized epilepsy I use the simple trephine and leave the button

of bone out, as a means of effecting a prolonged modification in the intracerebral pressure" (the author, in "Medicine," Feb., 1904).

Bramwell maintains that when traumatism is followed by epilepsy and the epileptic discharge starts from a cortical center which is not beneath the scar, the surgeon should trephine first at the seat of injury, and if this fails, he should trephine over the excited center.

5. **Jacksonian Epilepsy Due to Gross Brain Disease.**—The treatment of this condition is the treatment of the brain disease.

6. **Epilepsy Following Infantile Cerebral Palsy.**—In this group of cases the palsy is manifest. It is justifiable to operate upon a child, but not later in life. The prospect of benefit is poor even in a child.

7. **The Posthemiplegic Epilepsy of Adults.**—Operation is useless.

Our conclusions are that these operations sometimes seem to cure epilepsy, but so, occasionally, does any operation. White[1] records 90 trephinings in which, though no cause was found for the epilepsy, great relief followed, and 2 cases were apparently cured; he mentions benefit or apparent cure following tracheotomy, ligation of the carotid artery, incision of the scalp, etc. The same effect may be obtained by a great shock, high fever, the administration of an anesthetic, or an accident. The fact seems to be that any operation, by means of nervous shock, may interrupt the epileptic habit; but in ordinary operations the fits tend after a time to recur and soon reach their old standard of frequency. In the special brain operations with removal of obvious lesions or extirpation of discharging centers the fits usually recur, but they will rarely reach the old standard of frequency, and will be more amenable to medical treatment.

In non-traumatic chronic epilepsy without localizing symptoms trephining is not justifiable unless persistent headache calls for it as a means of relief from intracranial pressure. Annandale advised us to consider experimental operation in such cases when the drug-treatment has failed and when the patient's condition seems hopeless. He says there is no chance of improvement without operation, and operation may possibly disclose a removable lesion.[2] After trephining for epilepsy five years should elapse without a convulsion before cure is reasonably assured; and if convulsions arise, they must at once be met by medical treatment. A man having once had a convulsion may at any time have others; hence he should always be watched. It is not unusual for a few convulsions to occur soon after an operation for epilepsy, and then to cease for a considerable time. These early fits result from habit (*habit fits*). Among the operative procedures suggested for the treatment of epilepsy may be mentioned circumcision, clitoridectomy, ocular tenotomy, ligation of the vertebral arteries, removal of the cervical ganglia of the sympathetic (see page 854) (Alexander, Jonnesco, Jaboulay), the actual cautery to the head (Féré), puncture of the corpus callosum, drainage of a lateral ventricle, and appendicostomy. Dr. Charles L. Reed is convinced that epilepsy is a chronic convulsive toxemia and bears a constant relation to constipation due to mechanical causes and associated with acidosis. In severe cases or cases of long standing he finds conservative treatment of little avail and operates. "The local conditions may require parietal implantation of the colon with or without either appendicostomy or cecostomy; an ileosigmoidostomy supplemented by either an anatomical or a physiological colectomy; or a resection may be required" ("Medical Herald," Feb., 1917).

Operative Treatment of Insanity.—(See the author, in "Journal of Nervous and Mental Diseases," June, 1904.)

1. **Epileptic Insanity.**—The conditions which call for operation on a non-insane epileptic (see page 926) call for it on an insane epileptic. It is sometimes

[1] "The Supposed Curative Effects of Operations *per se*." "Annals of Surgery," Aug. and Sept., 1891.

[2] "Edinburgh Med. Jour.," April, 1894.

justifiable to operate if there has been a head injury, and operation may lessen the number and diminish the violence of the attacks. If focal seizures exist, we may proceed as for focal seizures in the sane. In status epilepticus we may operate to relieve pressure. It will be observed that operation is for the convulsions and not for the insanity.

2. **Paresis.**—I do not advocate operation in paresis. If we believe in traumatic paresis, we may be inclined to advise operation. Personally I do not believe that genuine paresis is ever cured; the lesions of the disease are widely disseminated; the pons, medulla, and even the cord may be diseased and the lesions cannot be removed.

3. **Non-traumatic Insanity and Paranoia.**—Operation cannot cure the insanity and is not to be advised.

4. **Hypochondriacal Delusions.**—Operation is useless. Some practice it with the idea of getting rid of a delusion by removing a part to which the attention is directed. Such attempts always fail, because it is the insanity which causes the delusion, not the delusion which causes the insanity.

5. **Operations for Traumatic Insanity.**—A psychosis constructed on the basis of a traumatic neurosis never calls for operation. The only cases in which operation is ever justifiable are those in which traumatism is the direct cause. Insanity may begin at once or soon after an injury, but is often unrecognized for weeks or even months. Nearly all of these cases are predisposed to insanity and the injury has been only an exciting cause. Traumatism is the direct cause in about 2 per cent. of cases of insanity.

"An antecedent injury may have directly induced the alienation; it may have had no bearing at all upon the latter; or it may have produced an insanity by fear and shock, and not by creating a direct brain lesion. Again, the head injury, by increasing the individual's susceptibility to alcohol and to the effects of the sun, may, if this person drinks alcohol or exposes himself to the rays of the sun, be indirectly resonsible for lunacy.

"In insanity following an injury to the head there may be various supposed causative lesions: A fracture of the skull, with or without depression; the development of an exostosis; sclerosis or softening of the cortex; edema of the membranes or of the brain itself; cerebral hyperemia or congestion; thickening of the membranes; adhesion of the membranes to the skull, to each other, or to the brain; new growth; inflammation of the membranes; or minute, slowly developing, widespread nutritive changes. The injury may be assumed to be the cause of the insanity if the insane condition becomes manifest almost at once or soon after the accident; but if the symptoms do not appear until long after the accident the traumatism may be considered to be the directly exciting cause in some cases, and not in others. It may be blamed if, between the time of the accident and the appearance of the insanity, there has been a marked change in the patient's disposition, temperament, or character; if he has developed headache, insomnia, irritability, passionate outbreaks of temper, moodiness, or lapses of memory; if he has plunged into immorality or excesses in alcohol; if he has displayed a tendency to neglect business or family obligations, and if he has shown increased susceptibility to alcohol and to the sun. Sometimes epilepsy may develop during this period (Richardson, 'American Journal of Insanity,' July, 1903. The author's 'Address on Surgery,' delivered before the meeting of the Medical Society of the State of Pennsylvania, May 18, 1897). If there was none of these intermediate changes in the normal mode of thinking and way of acting, one cannot count the traumatism as causative. Many persons that have received severe head injuries have shown these changes, but have never gone insane. I have been studying this point for a number of years, and have decided that quite a few patients that have been trephined for fracture or for meningeal hemorrhage have subsequently shown pronounced and per-

manent changes in character and disposition. Of the number that show such changes, many never go insane, but some do. Such an insanity is distinctly traumatic in origin" (the author, in "Journal of Nervous and Mental Diseases," June, 1904). The prognosis is very unfavorable; some recover sanity after operation, many do not. Some recover sanity without operation. Sometimes operation cures by removing a lesion; sometimes by shock, etc. Some cures following operation did not result from the operation.

On what cases should we operate?

We should operate on cases "in which insanity has soon followed a head injury. If the site of the trauma is indicated by a scar, a depression of bone, local tenderness, fixed headache, or some localizing symptom—motor or sensory—operation should positively be undertaken. In a case in which the insanity has developed later, in which the intermediate period between the injury and the development of the insanity has shown the change from the normal mode of thinking and way of acting previously alluded to, and in which the site of trauma is indicated by any of the evidences mentioned above—operation should positively be performed. One should not operate upon a case simply because there is a dubious record of an antecedent fall or blow, which merely suggests the possibility of a traumatic origin for the insanity. In any case in which there are positive signs of increased pressure it may be considered proper to trephine as a palliative measure" (the author, Ibid.).

Abdominal, Gynecological, and Genito-urinary Operations.—If an insane person has a disease which is dangerous to life or which is productive of pain, discomfort, or ill health, he or she is entitled to be cured, if possible, by a surgical operation. The removal of pain and other depressing influences may result in great improvement in the general health and in notable mental improvement. The operation may thus indirectly exercise a beneficial influence on the insanity, but the influence is not direct and it is never justifiable to do such an operation as oöphorectomy upon an insane woman unless the condition of the ovaries would call for it in one not insane.

Operations on the Skull and Brain.—As a preliminary it is well to note that urotropin (hexamethylenamin) given by the mouth quickly appears in the cerebrospinal fluid, and that the fluid contains the maximum amount in from one-half hour to an hour after ingestion. The presence of this drug decidely inhibits the growth of bacteria in the fluid. This is Crowe's discovery. We believe it wise to give this drug in all cases in which meningitis is threatened or exists (S. J. Crowe, in "Johns Hopkins Hospital Bulletin," April, 1909). It should be given for twenty-four hours preceding and for several days after an operation upon the brain or spinal cord. From 40 to 60 gr. a day are given by mouth. Cushing has subjected this drug to the severest test in his operations to reach the pituitary body. He gave 60 gr. a day of this drug "on the day preceding and for some days after the operation" ("The Pituitary Body and Its Disorders," by Harvey Cushing). After 33 transsphenoidal operations there were 2 cases of meningitis. One of these cases (which was inaugurated by violent sneezing) was fatal. Cushing now does much work upon the skull and brain with the aid of local anesthesia. He believes that any watery solution damages brain tissue and in cases requiring the direct application of an antiseptic employs dichloramin-T.

Trephining for a Fracture of the Skull.—The patient should be anesthetized unless he is unconscious, and should be placed upon the back with the shoulders a little raised. A sand-pillow is placed under the neck, and his head is turned away from the side to be operated upon. The position of the surgeon is such that the patient's head is a little to his left. A large semilunar incision is made with the base down, which incision goes through the periosteum, and the flap is lifted. The bleeding vessels of the flap are caught by forceps. The fracture is sought for and found. The pin of the tre-

phine is projected beyond the crown and is set upon sound bone, the crown overhanging the line or edge of the fracture. The surgeon tries to avoid the region of a sinus or large artery. A gutter is cut in the bone, the pin of the instrument is withdrawn, and the trephining is completed. In going through the diploë bleeding is copious. In a young child the diploë may be absent. The inner table feels very dense. Stop from time to time, clean out the gutter in the bone with gauze, and try the bone with an elevator to see if it is loose. In an old person the skull may be much thinned by absorption. Bear in mind Holden's valuable admonition: "Think that you are operating on the thinnest skull ever seen, and thinner in one portion of the circle than the other." When the fragment is loose enough, pry it out. If the surgeon desires to replace the button, hand it to an assistant, who places it at once in a bowl of warm normal salt solution, kept warm by standing in a basin of water at 105° F., or in warm carbolized towels. The edges of the opening should be rounded by a rongeur, and the bone, if depressed, must be elevated. Sometimes it may be necessary to remove splinters and fragments of bone. After removing the fragments the edges of the opening should be smoothed by the use of the rongeur forceps. The dura should be examined to see if injury exists, and hemorrhage must be stopped. Bleeding from the dura is arrested by passing a ligature of silk or catgut threaded in a small curved needle under the vessel on each side of the wound, and tying the ligatures (*suture-ligatures*). Bleeding from the pia is arrested by direct ligation, by suture ligature, or by gauze packing. Bleeding from the diploë is arrested by

Fig. 590.—Galt's conical trephine.

Fig. 591.

Fig. 592.

Fig. 593.

Figs. 591–593.—Hudson's burrs.

the use of Horsley's wax. The wound is cleansed, the edges of the dura are sutured by catgut or fine silk; in some cases the button of bone is reintroduced; in other cases some chips are cut from the bone and scattered upon the dura, but in most cases no attempt is made to fill up the gap in the bone. The scalp is sutured by silkworm-gut, and horse-hair or gauze drainage is employed for a day or two. Sterilized gauze dressings are put on, and a gauze bandage is applied. In a young person the opening may close partly or entirely by thin bone. In most youths and in practically all older persons the closure will be by fibrous tissue or fibrocartilage and a soft area remains on the cranial vault. In many cases a raised ring of bone forms around the opening. In some cases the bone thins and the

opening is slightly lessened in size by a ring of new bone. A soft spot is of course vulnerable to traumatism and to that extent a danger. The older surgeons were accustomed to protect the region by wearing a plate of silver upon the scalp. This custom gave rise to the popular belief that the opening in the bone was closed by the insertion of a silver plate. If the bone defect is very large it may be closed by bone transplantation. In some cases the transplant becomes absorded. In others the operation is successful. Some surgeons have used

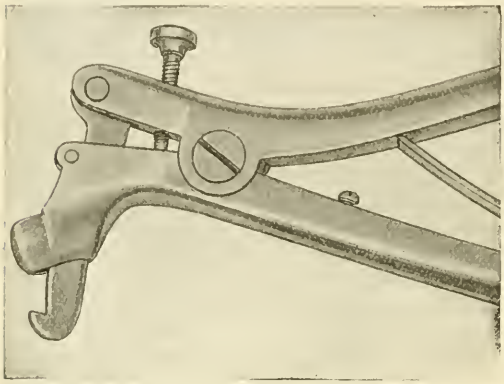

Fig. 594.—Hudson's modified DeVilbiss forceps.

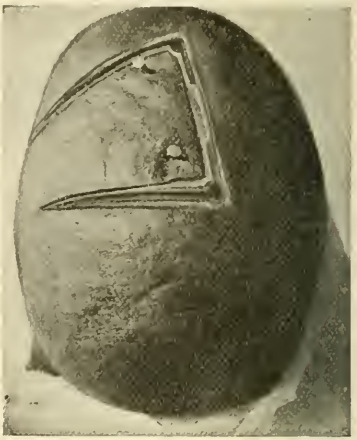

Fig. 595.—Combined osteoplastic operation. First step. Incision through superficial tissues and bone. Flap held in place on the bone by tacks.

plates of horn, cut to the required shape and sterilized by keeping for three days in alcohol. Estor has closed defects in a number of cases by gold plates, inserted about two months after trephining. He slips the edges of the plate between the two tables of the skull. The operation is indicated when coughing or straining causes the brain to bulge at the opening. Gold undergoes no change ("Bull. et mèm. Soc. de Chir. de Paris," 1915, xli).

Fig. 596.—Combined osteoplastic operation. Second step. Bone flap turned down.

Fig. 597.—Combined osteoplastic operation. Third step. Showing exposure of brain by removal of dural flap.

Instead of the trephine some surgeons use the chisel or gouge and hammer to remove a portion of the bone. Other operators, believing that this procedure may cause concussion, employ the surgical engine.

I now seldom use the old trephine, preferring instead the instruments of Hudson (Figs. 591–594).

Osteoplastic Resection of the Skull.—Wolff suggested this operation, and in 1889 Wagner performed it. It is employed for the removal of tumors and the Gasserian ganglion, for focal epilepsy, and for exploration. It is the operation of choice when a large opening is needed, as when the operation is, first of all, for diagnosis. The incision shown in Fig. 595 is made through the scalp and periosteum, and the flap is tacked to the bone, ordinary long tacks being used. Otherwise our manipulations may separate the flap from the bone (Fig. 595). A groove corresponding to this incision may be cut in the bone by special gouges or chisels. I do not use chisels. I am convinced that the blows of the mallet add to shock, may cause hemorrhage or add to existing hemorrhage, may extend a line of fracture or cause a fracture, may diffuse a purulent collection, or produce concussion of the brain. Some surgeons use the surgical engine. It is difficult to keep it sterile, it runs at too high a speed to be readily controlled, and it is troublesome to cut a bevel with it. The instrument is dangerous except when in very skilful and highly trained hands. Some surgeons make trephine openings and then cut from within outward by the Gigli wire saw (Obalinski). Cushing, of Harvard, does what is called the *combined* method. I prefer this to any other plan. It is rapid and free from all danger of wounding the dura. I make two or several openings with Hudson's burr. This excellent instrument divides bone with great rapidity, but does not divide the dura. In fact, one cannot divide the dura with it, for the burr binds as soon as it is through the bone. Figs. 591 to 593 show Hudson's burrs. The sides of this bone-flap are rapidly cut by Hudson's improvement of the DeVilbiss forceps (Fig. 594). The upper margin is cut on a bevel with the Gigli saw. Because of this bevel when the flap is restored to place the upper edge of the flap rests on a shelf of bone and does not press on the brain. By whatever method performed, three sides of the bone-flap are cut through, but the bone is left attached to the scalp. It is a good plan to save the scalp from detachment by temporarily nailing it in place (Fig. 595). The bone is then broken outward, the fracture taking place at the base of the bone-flap, the dura is opened a little distance from the edge (sufficient space being retained for sutures), and the exploration is made and the operation is performed (Figs. 596 and 597). When we are ready to suture the dura we note if the brain bulges greatly. If it does, manipulation will surely injure it, and we should cause the brain to recede before suturing by placing the patient nearly erect or by performing lumbar puncture. After suturing the dura the bone which is still adherent to the pericranium and scalp is restored to its proper place, and the scalp is sutured. In cases of injury or tumor in which a considerable portion of dura requires removal the defect is filled by a flap of aponeurosis or a piece of transplanted fascia which is sutured in place.

Besides restoring a flap of bone into position, or replacing a button of bone, or strewing the dura with bone-fragments, other methods of closing the opening have been practised—for instance, heteroplasty with a decalcified bone-plate, with a celluloid plate, or other foreign material.[1]

Trephining the Frontal Sinus.—This operation may be employed for inflammation of the lining membrane of the sinus or for empyema. Make a vertical incision in the middle of the forehead, starting 1½ inches above the nasion and terminating at the root of the nose. The button of bone is removed and the opening is enlarged if necessary. The mucous membrane is incised, the opening into the nose is found and is dilated, and a drainage-tube is passed into the nose from the sinus, the upper end being left in the sinus. In some severe cases Jacobson advises us to curet the sinus, to disinfect it by the use of silver nitrate or chlorid of zinc, and to insufflate an "aseptic powder." In some cases resect the mucous membrane. I prefer an osteoplastic resection to trephining the frontal sinus.

[1] See Bretano, in "Deutsche med. Woch.," May 17, 1894.

Trephining the Mastoid.—(See Operation for Mastoid Suppuration, page 936.)

Technic of Brain Operations.—In focal epilepsy a faradic battery is required. Always shave the scalp and always antisepticize it. In localizations, mark out the fissure upon the scalp with an anilin pencil, with iodin, or with silver nitrate. Have the patient semirecumbent. Mark three points upon the bone with the center-pin of the trephine before incising the scalp (both ends of the Rolandic fissure and the point at which the trephine is to be applied). Make a semilunar flap 3 inches in diameter, with the base below. Control bleeding in the flap by forceps pressure. If the operation is by trephining the 1½-inch trephine should be employed, but if a smaller trephine or the Hudson burr is used the opening must be enlarged with a rongeur. Before enlarging the opening separate the dura from the bone by a dural separator. In most cases an osteoplastic flap is preferable to trephining. It is always employed in explorations for tumor. As a rule, open the dura and examine the brain. The dura is lifted by a mouse-toothed forceps and is opened by scissors along a line ¼ inch from the bone edge, a broad pedicle of dura being left uncut. Hemorrhage is arrested by pressure and hot water or by passing suture-ligatures of silk or catgut around any bleeding vessel by means of a curved needle. In some cases packing must be retained or forceps must be kept on. In packing,

Fig. 598.—Showing terminal and connection of Cushing's electrode (¾ natural size). Instrument should be 16 inches or more in length.

endeavor to use but one piece of gauze, so as to avoid leaving in a forgotten piece. Upon opening the dura cerebrospinal fluid flows out, the stream being increased at each expiration. Absence of pulsation of the brain points to abscess or tumor, and a livid color indicates subcortical growth. An old laceration is brownish. If the brain bulges through the opening, it means increased pressure (tumor, abscess, effusion into the ventricles, etc.). After opening the dura employ no antiseptics, especially when the surgeon intends using electricity to locate a center. Irrigate by warm salt solution only. In operating for tumor the dura is opened and in some cases the brain is incised. The tumor is turned out by the finger or, if this is impossible, by the dry dissector, the scissors, the dull knife, or the sharp spoon. If the entire tumor cannot be removed, it is sometimes proper to take away as much as possible. The removal of a portion may retard the growth of the remainder, and the trephining, by lessening cerebral pressure, may relieve the symptoms and prolong life. After removing a tumor arrest distinct points of bleeding by ligatures or by suture-ligatures. Pack the tumor cavity with gauze and bring the end of the strand out of the wound. Stitch the dura with silk and suture the scalp with silkworm-gut. In electrifying the brain faradism is employed of a strength about sufficient to move the fibers of the exposed temporal muscle. The best electrode is that of Cushing (Fig. 598). It is a "glass unipolar electrode carrying a fine platinum wire core, coiled into a spiral at the end" (Cushing, in "Keen's Surgery," vol. iii). The other pole is attached to an extremity, "preferably on the homolateral side." During the electrical test the patient must not be deeply anesthetized. A careful observer watches the muscular movements. If, for instance, the surgeon wishes to remove the thumb center, he moves the electrode from point to point until he obtains thumb movements. The region is sliced away bit by bit until the center which is responsible for the

convulsive movements is removed. It will be found impossible to remove only the thumb center. Adjacent centers are sure to be more or less damaged, and a certain amount of paralysis follows the operation. If we wish to *tap the ventricles*, Keen directs the trephine opening to be 1¼ inches behind the external auditory meatus and the same distance above the base-line of Reid (Fig. 599, *a*). A grooved director or metal tube is passed into the brain in the direction of a point "2½ to 3 inches above the opposite meatus." The normal ventricle will be entered at a depth of 2 to 2¼ inches, but the dilated ventricle will be entered sooner. The moment of entry is marked by lessened resistance and a flow of cerebrospinal fluid. Drainage can be maintained by introducing a rubber tube. This operation has been employed in hydrocephalus. Kocher punctures the ventricle 2½ cm. from the midline and 3 cm. in front of the

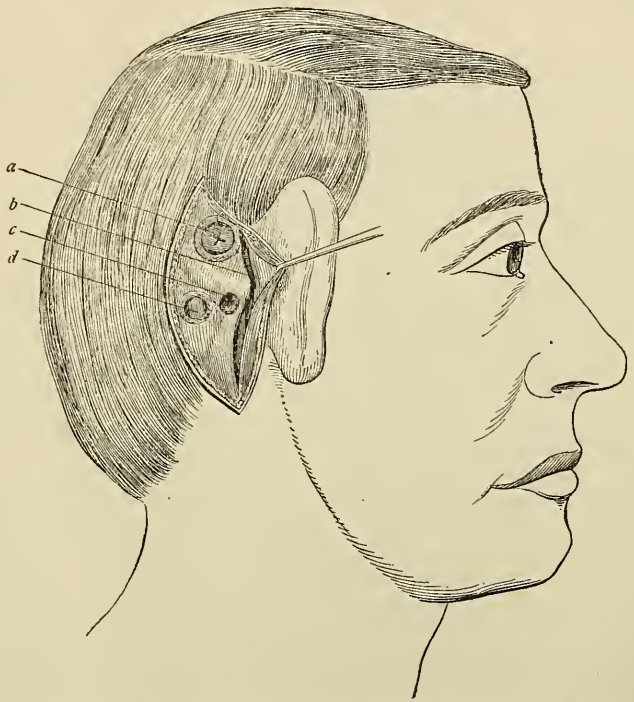

FIG. 599.—Opening the mastoid antrum and the lateral sinus; exposure of the temporosphenoidal lobe and puncture of the descending horn of the lateral ventricle: *a*, Temporosphenoidal lobe (descending cornu of lateral ventricle is 1 cm. deeper); *b*, inner surface of periosteum; *c*, mastoid antrum; *d*, lateral sinus (Kocher).

fissure of Rolando. After an aseptic cerebral operation, as a rule, do not drain unless hemorrhage has been considerable. In many cases after trephining replace the bone, but not when the bone is diseased, is infected, is very compact, or if we desire to alter pressure.

Control of Hemorrhage in Brain Operations.—Elevation of the patient's head decidedly lessens hemorrhage. A table should be used which permits elevation. If the blood-pressure falls rapidly the head must be lowered. A rubber band around the head usually controls scalp bleeding; but will actually increase it if there is a large cortical growth with greatly enlarged vessels joining intracranial and extracranial veins (Landon, in "Surgery, Gynecology, and Obstetrics," 1914, xviii). I seldom use the band and depend upon clamp forceps for the temporary arrest of scalp hemorrhage and upon the sutures which close the wound for permanent arrest. Bleeding from diploë is controlled

by Horsley's wax or by bits of muscle. Bleeding on the dura can usually be arrested by hot-water and pressure or by the application of a bit of muscle. If this fails a suture ligature is used. Bleeding from a pial vessel is arrested by suture-ligatures if a bit of muscle fails. When the patient comes out of ether he should be placed erect in bed.

Operation for Mastoid Suppuration.—Place a sand-bag under the neck. An incision is made ¼ inch posterior to the auricle and down to the bone, and in the direction of the long axis of the mastoid. The bone is bared and examined, especially at a point in the line of the incision, which is on a level with the roof of the meatus (Fig. 599, *c*). The bone will usually be found softened. Gouge it away and thus open the mastoid antrum. The bone-opening is within the limits of *Macewen's suprameatal triangle*, a space bounded by the posterior root of the zygoma, the posterior bony wall of the meatus, and an imaginary line joining the two. If the mastoid is opened in this triangle the antrum is entered directly and there is no chance of wounding the lateral sinus. If, in the adult, pus is not found on opening the mastoid antrum, gouge downward and backward, but with great care, so as to avoid the lateral sinus. If there be any possibility of the existence of pus in the groove of the sinus, the sinus should be unhesitatingly exposed. After evacuating the pus from the mastoid, gouge away bony septa, enlarge the opening between the mastoid and the middle ear with the gouge and remove the superior half of the posterior bony wall of the meatus (avoid the facial nerve on the floor of the meatus), turn the head toward the side operated upon, and irrigate the mastoid with salt solution, dust with iodoform, pack with iodoform gauze for a few days, and then introduce a silver drainage-tube. Treat the causative ear disease. Sheild and Macewen operate on inveterate cases of mastoid disease as follows: A thick flap is raised behind the auricle, the flap including the orifice of any sinus and being "left attached by its stalk." The auricle is "detached forward and the soft parts over the mastoid are turned backward by horizontal incision." The "lining membrane of the canal is separated from the bone." The mastoid is opened and dead bone and caseous matter are removed, overhanging edges are chiseled down, and the posterior bony wall of the external auditory meatus is gouged away. The skin-flap is pushed into the cavity and is held in place by pads of gauze. The margins of the flap may be sutured, but this is not necessary. Macewen calls this procedure "papering" the cavity with skin.[1]

If mastoid suppuration has established *abscess in the temporosphenoidal lobe*, trephine, 1¼ inches behind and 1¼ inches above the middle of the external meatus (Barker's point), and search for pus as directed on page 904. If *abscess of the cerebellum* exists, trephine below the line of the lateral sinus. "The position of the lateral sinus is indicated by a line running horizontally outward from the occipital protuberance to within about 1 inch of the external auditory meatus, and thence downward to the mastoid process" (Owen's "Manual of Anatomy"). If *infective sinus-thrombosis* exists, break into the lateral sinus (Fig. 599, *d*) from the mastoid opening and proceed as directed on page 908.

Linear Craniotomy.—Make a large flap. Trephine the skull a finger's breadth from the sagittal suture, and the same distance back of the coronal suture. Rongeur the bone away in a line parallel with the sagittal suture and a safe distance from the longitudinal sinus, up to a point in front of the lambdoidal suture. Remove the pericranium which covered the bone excised. Insert the dural separator or pass it along the margins. In some cases an additional portion of the bone is removed over the fissure of Rolando. Various suggestions have been made as to the direction and situation of bone-sections. Bleeding is arrested and the flap is closed without drainage.

Removal of Gasserian Ganglion.—(See page 859.)

Operation for Infective Sinus-thrombosis.—(See page 908.)

[1] "Lancet," Feb. 8, 1896.

The Decompression Operation (*Decompressive Trephining*).—This operation is employed particularly in cases of inoperable brain tumor. It differs from palliative trephining in the fact that the dura is incised and an opening left to permit of bulging of the brain. The bulging relieves pressure. By Cushing's method we get a hernia of the brain, but not a fungus cerebri. I have followed Cushing's recommendation in tumors, and have used it on both sides in fractures of the base of the skull, and I believe it often saves vision and life.

Cushing and Bordley have performed it in cases or uremia and improvement has followed ("Amer. Jour. Med. Sciences," Oct., 1908). They suggest that the operation be used in certain cases of renal disease when medical treatment and lumbar puncture have failed to abate uremic symptoms, or when blindness is impending. It has been used in apoplexy and in pneumonia with cerebral symptoms.

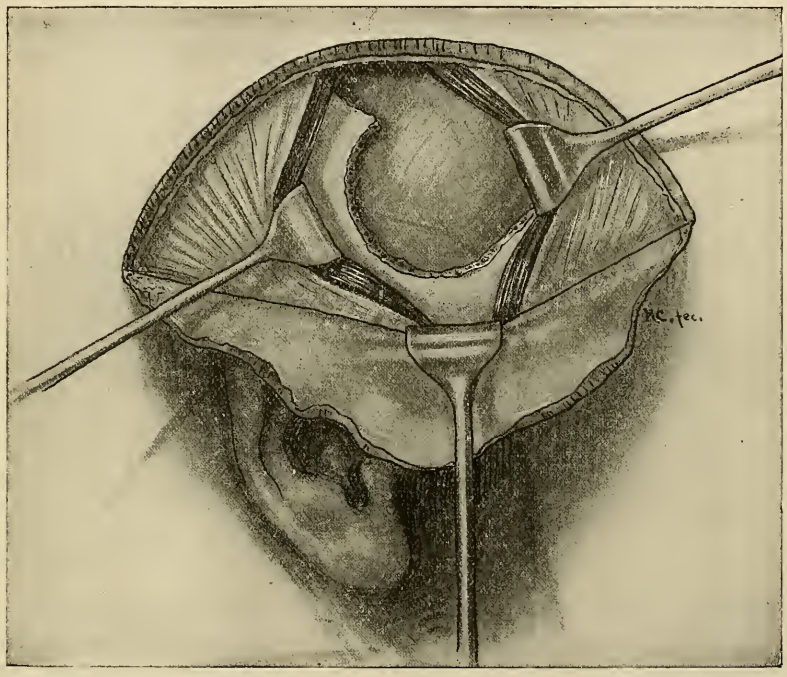

Fig. 600.—Sketch of the intermusculotemporal field of operation, showing exposure with subtemporal bone defect partly made (Cushing, in "Keen's Surgery").

The effect of the operation in cases of brain tumor is sometimes extraordinarily beneficial. In other cases it does no good at all. I believe at least half the cases are improved. I have seen paralysis practically disappear after a few months. It does little good when a tumor has caused coma unless the operation is associated with tapping the ventricles. Its most prominent benefit is in abolishing choked disk. It must not be done over a tumor, because the bulging tumor might become the seat of hemorrhage. It may, however, be done near the tumor (see page 924).

It is, of course, useless in relieving blindness, for blindness means atrophy, but it is often very valuable in *preventing* blindness. Blindness of even a day's duration is not recovered from by relieving pressure. Choked disk should be regarded as a late symptom of brain tumor. When choked disk exists

operation should be done early even if there be good vision. If in advanced cases any sight remains, it should be performed. Now and then there is an unfavorable result, for instance, the development of retinal hemorrhages or even the loss of vision, which may have been good previous to operation. (See deSchweinitz and Holloway on "Operative Treatment of Papillo-edema Dependent Upon Increased Intracranial Tension," "Therapeutic Gazette," July 15, 1909.) Decompression will probably be fatal if there is a tumor of the third or of the fourth ventricle. The patient may die upon the table or a few hours later. Elsberg ("Surgery, Gynecology and Obstetrics," August, 1916) points out that if a subtemporal decompression is made for subtentorial tumor and the ventricle is dilated, the ventricle may be dragged upon and nerve tracts damaged. He further says that in a (1) left or right midbrain tumor a subtemporal decompression on the right side usually aggravates motor symptoms. So it does in a tumor to the (2) inner side of the internal capsule. In these two classes of cases, (1) and (2), bilateral decompression is advisable, the right side being done first and the ventricle punctured, so as to avoid too great a prolapse of the left temporal lobe and a resulting aphasia. The duration of the relief to the choked disk is variable. It is not always permanent. The operation may be done for an unlocated tumor and later the tumor may perhaps be located and removed. It may be done for an inoperable tumor and later, the decompression having made the danger less, operation may perhaps be performed.

Cushing's subtemporal decompression is done upon the right side, as a rule, but in some cases on the left side. An objection to doing it on the left side is that the bulging of the left temporosphenoidal lobe may cause word-deafness. A curved incision is made through the skin and subcutaneous tissue, the flap is turned down, the temporal fascia is incised in the direction of the muscle-fibers beneath it, the temporal muscle is split and not cut, the periosteum is separated from the bone, the soft parts are retracted, the bone is opened as the surgeon prefers, and the opening is enlarged by a rongeur (Fig. 600). The dura is opened and radiating incisions are made through it toward the edges of the bone gap. The wound is closed by four layers of fine silk sutures.

Figure 601 exhibits the exposure for suboccipital depression as done for subtentorial tumors. The same exposure is obtained in order to remove a cerebellar tumor. "In subtentorial decompressions a puncture of the corpus callosum or at least a ventricular puncture should always precede the opening of the dura" (Elsberg, Ibid.).

Drainage of the Cisterna Magna (*Haynes's Operation*).—This operation was suggested by Cunningham and the technic was developed by Haynes (see Deuch, in "Laryngoscope," 1913, xxiii). An incision is made in the middle line from the occipital protuberance to the posterior arch of the atlas. The periosteum is stripped from a portion of the occipital bone at and above the foramen magnum. The bone is trephined and is cut away into the foramen magnum. The occipital sinus may not be present. If present as a double sinus, incise the dura between the two sinuses. If there is one sinus, divide the dura between two ligatures. Open the dura and arachnoid by a very small incision. As soon as excess of fluid has escaped enlarge the incision. By lifting and separating the cerebellar lobes the surgeon can determine if the foramen of Magendie is patent. Gutta-percha tissue is used as a drain. The muscles are sutured together by catgut. The skin is closed below the drain by silkworm-gut (abbreviated from Haynes's description in "The Laryngoscope," June, 1912). So far the results of this operation in meningitis have not been encouraging. It is said to have succeeded in hydrocephalus. I had one gratifying case.

Methods of Reaching the Pituitary Body.—The subtemporal route was sug-

gested by Carton and Paul. Horsley has operated in this way. The bone is removed from the subtemporal region, the dura is opened, the brain is lifted and the dural box of the hypophysis is incised. It may be necessary to remove bone from each subtemporal region and raise the brain from both sides. Borchardt performed osteoplastic frontal resection, ligated the superior longitudinal sinus, and lifted the brain.

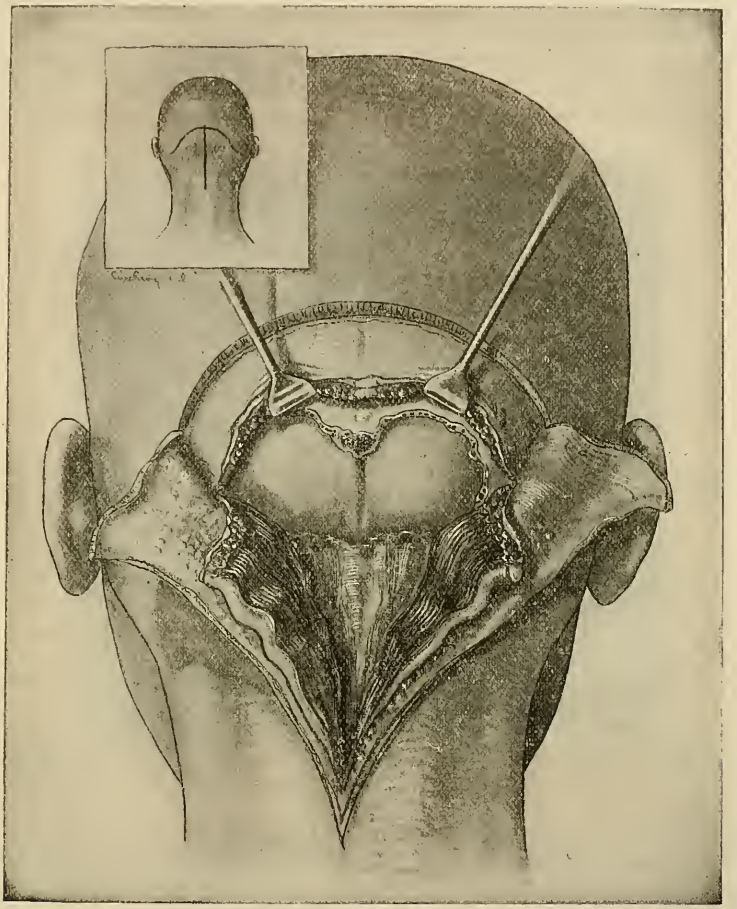

FIG. 601.—The suboccipital exposure, showing opening partly made and Cushing's "cross-bow" incision (Cushing, in "Keen's Surgery").

Giordano suggested a transsphenoidal operation, and Schloffer improved his method. Schloffer freed the nose so as to turn it toward the right side and then excised the turbinates, orbital wall, maxillary sinus, the middle septum, the left nasal process of the superior maxillary, and the ethmoid cells (Cushing, "The Pituitary Body and Its Disorders"). In the inferior route of Kanavel most of these structures are preserved and the incision is within the mouth.

McArthur ("Jour. Amer. Med. Assoc.," June 29, 1912) trephines the frontal eminence of one side 4 cm. above the supra-orbital notch and preserves the button in warm salt solution. By means of the DeVilbiss forceps and the chisel he cuts away a bone-fragment, which brings with it a considerable part of the roof of the orbit. This fragment, too, is placed in warm salt solution. The rest of the orbital roof is cut away by a rongeur. The dura covering the

inferior surface of the frontal lobe is separated from the bone, while the lobe is raised and the orbital contents are held out of the way. Between the clinoid processes the dura is divided by Krause's hook-shaped knife. An enlarged hypophysis will now be accessible. At the conclusion of the operation on the hypophysis the bone-fragments are replaced. Frazier has modified McArthur's operation ("Annals of Surgery," Feb., 1913). I have performed the operation once for a cyst of the hypophysis. Cushing has had wonderful success with his nasal method which involves resection of the septum (1 death in 32 cases). To perform this one must be highly skilful in working in a very small area. To most surgeons the fronto-orbital method will be easier. The operation can be done aseptically and by aid of sight and the brain must be retracted

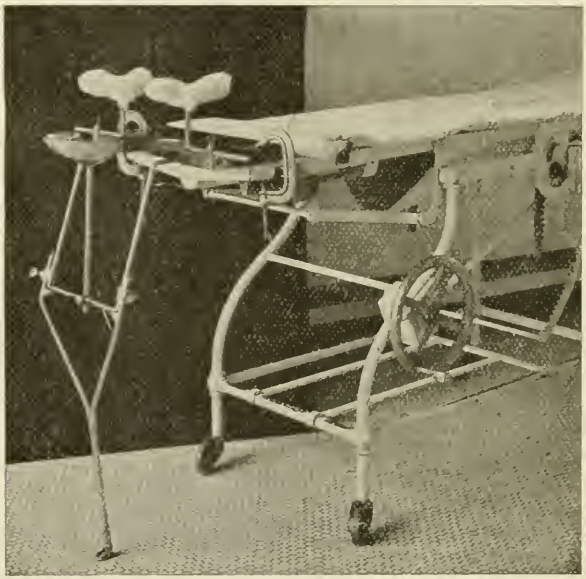

FIG. 602.—Horner B. Smith's head-rest for operations upon the cerebellum (modified by William J. Taylor).

far less than in the temporal approach. A solid tumor can be removed more satisfactorily than by the nasal route. After the operation there may be edema of the eye and the eyeball may not be quite on a level with the other eyeball.

The Combined Method of Harvey Cushing (From Cushing's "The Pituitary Body and Its Disorders").—This surgeon, whose experience is very large, operates as follows: Intratracheal anesthesia. Place the patient with the shoulders slightly raised so that the head drops back. Pack the posterior nares with a sea-sponge. Insert cotton wet with adrenalin in each nostril. Lift the upper lip. Make a transverse incision across the frenum, and carry it down to the anterior nasal spine. By blunt dissection raise the soft parts on each side from the inferior margin of the osseous nasal opening until the cartilaginous septum is exposed. From now on the operation is submucous. Separate the membrane on each side from the bony and cartilaginous septum. Introduce a retractor on each side between the separated mucous membrane and the septum. Separate the blades of the instrument. Remove "most of the vomer, the lower edge of the median plate of the ethmoid, and a small strip of cartilage." It may be necessary to remove by means of a rongeur the anterior maxillary spine. With the retractors retained, a series of dilating plugs are introduced.

These "flatten the turbinates." The largest dilator has a diameter of 1.8 cm. The retractors are removed and a bivalve speculum is inserted. An electric head-light must now be used. It may now be found necessary to remove "the prow of the vomer."

The body of the sphenoid is identified and the "anterior and lower walls of the sinuses are chipped away with long-handled nasal rongeurs." The lining of mucous membrane is removed, when the protrusion of the sella can be identified. The floor of the pituitary fossa is then clipped away. The dural case of the gland (or tumor) is divided by a hook-shaped knife.

Removal of the entire anterior lobe must never be done, as this lobe is necessary to life.

XXV. SURGERY OF THE SPINE

Congenital Deformities. **Myelocele or Rachischisis.**—This condition is due to deficiency in the formation of the vertebral arches, the cord being rudimentary, the medullary plates having failed to coalesce, the central canal not having formed, and the endothelium which should line it being exposed. If the entire cord is involved, the condition is called *amyelia* or *total rachischisis*. If a part of the cord is involved, the condition is called *partial rachischisis*. In partial rachischisis a portion of skin is absent in the midline. At this area is a circular, dark red focus surrounded by a very thin and glistening membrane which becomes continuous with the skin. A dimple at the upper part and a dimple at the lower part of the dark area indicates the situation of the central canal above and below. Victims of rachischisis are usually stillborn or, at most, live but a few days.

Spina Bifida.—This is a deformity similar to the one just discussed, but in it the cord is much more developed. The first accurate description of it was given by Tulpius in 1685. It is a congenital sac of fluid due to vertebral deficiency, permitting protrusion of the contents of the spinal canal in the median line. In this condition the cutaneous epiblast is adherent to the spinal exiblast, because structures from the mesoblast have failed to grow between. The laminæ or spines of one vertebra or of several vertebræ or of many vertebræ may be deficient, most frequently in the lumbosacral region. In very rare cases there is division of the vertebral bodies and the projection is forward and to the side. A case in which there are ununited laminæ but no protrusion is called *spina bifida occulta*. Sometimes there are two protrusions in one person. In spina bifida the dura does not cover the sac because it is cleft as well as the laminæ. There are three distinct varieties of spina bifida: 1. *Meningocele.* In this condition the dura is cleft (Hildebrand), there is a protrusion of the arachnoid, fluid gathers in the arachnoid meshes and "distends this so as to form one continuous cavity which is traversed by nerve-roots" (Henle, in "A System of Practical Surgery," by von Bergmann, Bruns, and von Mikulicz. Translated and edited by Wm. T. Bull and Carlton P. Flint). The cord is not in the sac. 2. *Meningomyelocele* (the commonest form) is a protrusion of arachnoid and cord substance, the sac containing cerebrospinal fluid, nerves, and cord-substance. The cord may spread upon the sac wall or it may pass through the sac and re-enter the canal. A cutaneous dimple or furrow indicates that the cord is attached and hence is within the sac. 3. *Syringomyelocele* a protrusion of cord. There is great distention of the central canal, the sac wall being formed of the thinned cord and the spinal membranes. A spina bifida varies in size from that of a walnut to that of an infant's head; it grows rapidly during the early weeks of life; it is usually sessile, but may present, where it joins the body, a definite constriction or even a pedicle, the base of the sac is covered by healthy skin, and the fundus is covered by thin epidermis only

or by the spinal membranes themselves. Pressure upon the tumor may diminish its size and increase the tension of the anterior fontanel, and possibly cause convulsions or stupor. The cyst in meningocele is translucent and the margins of the bony aperture are distinct. Meningomyelocele and syringomyelocele are not translucent but usually pulsate. Crying, coughing, or pressure upon the anterior fontanel makes a spina bifida more tense. Spina bifida is apt to be associated with club-foot, with hydrocephalus, and with rectal or vesical paralysis. Spina bifida usually causes death (90 per cent. of cases die during the first year of life). A few meningoceles and a very few meningomyeloceles undergo spontaneous cure by growth of the vertebral arches constricting the neck of the sac. The sac may remain distended with fluid or may shrink. Syringomyelocele is invariably fatal. The cause of death may be rupture of the sac or marasmus. The *x*-rays show the bony gap. *Spina bifida occulta* is a cleft in the vertebral column without any protrusion of the cord or of the membranes. In this condition there is usually a profuse growth of hair in the skin over the bony gap and the hairy condition may be much more widespread. In some cases the hair is present at birth; in others it appears at puberty. Trophic changes and deformities may exist in the lower extremities.

Treatment.—Very small protrusions which grow slowly and are covered with sound skin may be treated by the use of a compress and bandage, by an elastic bandage, or by applications of contractile collodion. It was formerly regarded as proper to tap and drain the sac. Injection was used by many. The skin having been cleansed, the child was placed on its side and a little chloroform was given. A fine trocar was plunged obliquely in at the side of the sac through sound skin, little or no fluid being drawn off, and 1 dram of Morton's fluid injected (iodin, 10 gr.; iodid of potassium, 30 gr.; glycerin, 1 oz.). The trocar was withdrawn and the puncture was sealed with a bit of gauze and iodoform collodion. The child was put to bed. If injection proved successful, the sac was found to shrink; if the injection failed, it was the custom to repeat it at intervals of from seven to ten days (Jacobson, White). Surgeons now prefer excision of the sac (see page 968). Whenever possible the incision should be through healthy skin. If the sac contains nerves they should be placed within the canal. Bayer treats it as he would a hernia. Robson in some cases excises the entire sac. Operations upon children much under the age of five have an enormous mortality. Operations are comparatively safe when the child reaches the age of five. Operations for spina bifida have been done successfully immediately after birth (Lovett, in "Amer. Jour. Orthop. Surg.," Oct., 1907). We should not operate if there is hydrocephalus or extensive paralysis, if the mass is very large and growing rapidly, or if there are other marked deformities. A ruptured sac or a sac about to rupture should be operated on at once; otherwise death is practically certain.

Tumors of the Vertebræ.—Secondary tumors (sarcoma, carcinoma) of the vertebral bodies are not very uncommon.

Primary tumors, except osteomata, are very seldom found. Only 9 or 10 cases are on record as having been operated upon. Enchondroma is the most common growth. Sarcoma (spindle-cell or giant-cell) may arise. Chondrosarcoma and myxosarcoma have been met with.

Sacrococcygeal Tumors.—Dermoids dorsal to the sacrum are occasionally seen in this region. In the lower sacral or coccygeal region the cutaneous structures sometimes fail of complete coalescence and a *postanal dimple* or *sinus* is the result. Such a sinus is lined with skin and its wall contains numerous glands and often hairs. It may inflame or suppurate. If it blocks up at the outlet, a form of dermoid develops. Lipomata and hydatid cysts may be found in front of the sacrum. The term sacrococcygeal tumor should mean a tumor ventral to the sacrum and arising from misplaced anlages. Early in embryonic development the neurenteric canal joins the central canal of the spinal

cord with the primitive alimentary canal. The neurenteric canal later undergoes obliteration. At a certain point the ectoderm and entoderm grow together, pushing aside the mesoderm and forming the canal plate. The plate becomes depressed forming the canal pit or proctoderm. The proctoderm invaginates more and more in front of a portion of the gut and reaches the gut above the neurenteric canal. There is a section of gut behind the anus known as the *postanal gut* which is obliterated during development. This is a region of tissue vestiges, remains and misplacement; in it developmental defects are not unusual and new growths may arise. Tissue misplacement may give rise to dermoid formation. Teratomata and curious mixed tumors may arise which are apt to show growth from all three embryonic layers (Law, in "Surgery, Gynecology, and Obstetrics, 1913, xvii). Mammary tissue, testicular tissue, an eye, a limb may be found. In fact, some observers regard such a tumor as in reality a suppressed fetus.

Law (Ibid.) says sacrococcygeal tumors vary so much and show such diverse tissue elements that they have been called "histological potpourri."

As a rule they originate in the connective tissue of the pelvis and are encapsuled. They are on the verge of malignancy.

Treatment.—Dermoids require extirpation. If a postanal dimple causes no trouble, it is let alone; otherwise it should be dissected out. It may or may not be possible to remove teratomata. Lipomata and hydatid cysts are extirpated.

Tumors of the Spine and of the Spinal Cord.—Tumors may arise from the cellular tissue, fatty tissue, the nerve-roots, the membranes of the cord, or from the vertebra (*extramedullary tumors*). They may arise within the cord (cord tumors proper or *intramedullary tumors*).

Extramedullary Tumors.—Syphilomata, hydatid cysts, tuberculomata, and inflammatory masses or adhesions may compress the cord and produce symptoms indistinguishable from genuine tumor. Among extramedullary tumors are secondary carcinoma, sarcoma (primary or secondary), fibroma, myxoma, lipoma, chondroma, and neuroma. Dermoid sacral cysts may exist. Lipoma, fibroma, and certain cysts may be congenital. Injury of the back sometimes seems to bear a causal relation to extramedullary tumors.

The *symptoms* are due to pressure upon nerve-roots and the cord. The most prominent symptoms are pain in the back and evidences of nerve-root irritation.

The early or irritative symptoms are pain and stiffness of the back, usually very severe and interfering with sleep, shooting pains in the area of the implicated nerve-roots, and sensory abnormalities in the same area. There may be hyperesthesia of a limited area. The area of distribution from one or two roots is involved in pain, sensory disturbance, and slight motor impairment. In some cases the nerve-roots of one side only exhibit irritation and the symptoms are strictly unilateral. In other cases the symptoms are bilateral, but are most marked on one side. In some cases the symptoms are symmetrically bilateral and indicate pressure upon the cord rather than upon nerve-roots. Muscular spasms may occur. There may be lateral curvature of the back, the concavity of the curve being on the side of the tumor. Sooner or later paralytic symptoms come on (motor and sensory paralysis). They may be due to pressure upon and destruction of nerve-roots or to compression of the cord. When anesthesia exists there may be a zone of hyperesthesia above its upper limit. As motor palsy develops from root compression the pain usually abates. The muscles undergo atrophy.

A tumor may, by cord pressure, produce the symptoms of compression-myelitis, locomotor ataxia, or myelitis. Contractures or paraplegia may arise from tumor. The location of the growth can be inferred by a study of the territory of paralysis and the zone of sensory disturbance. The tumor is always situated somewhat above the upper limit of anesthesia. In many cases the

diagnosis is impossible. Gradually increasing painful paraplegia, with pain in the back and with hyperesthesia or anesthesia appearing after a time and ascending from the feet toward the trunk, points to tumor as a cause. The paralysis is usually spastic, but may be flaccid, or it may be spastic at first and become flaccid. In spastic paraplegia the reflexes are increased. In flaccid paraplegia they are decreased. In spastic paraplegia there are ankle clonus, the Babinski sign (extension of the great toe or all the toes when the sole of the foot is irritated), Gordon's paradoxical reflex (extension of the great toe or all the toes when pressure is made upon the deep calf muscles), and Oppenheim's reflex (extension of the great toe or all the toes when the handle of the percussion hammer is drawn along the inner edge of the tibia so as to make pressure from above downward). Trophic lesions are apt to arise in the trajectory of nerve involvement. The sphincters are usually involved. Growths outside the membranes produce particularly pain and spasm; growths within the membranes produce especially motor paralysis and anesthesia. Symptoms that are unilateral, were at first unilateral, or which are most marked on one side, are very significant.

Intramedullary Tumors.—These tumors develop in the substance of the cord. They are far less common than extramedullary growths and are more often benign. These growths are, as a rule, primary and solitary and do not produce symptoms of pressure until they attain the size of a hazelnut. The most common tumors are glioma, sarcoma, and tuberculoma. Syphiloma occasionally arises. Most tumors in cord-substance are small, but the glioma may involve practically the entire cord. A tumor is often for a time limited to one side of the cord, but later it presses upon and finally involves the opposite side. When the cord is pressed upon, degeneration occurs. In some cases a wrench or bruise of the back is supposed to be causal. Glioma may be congenital.

Symptoms.—They are at first, in most cases, very uncertain. In some cases, however, paralysis develops early.

There is often pain in the back, but it is not nearly so severe as in extramedullary tumor. The most prominent symptom is a slow-developing motor palsy. In some cases the palsy is at first unilateral, but later becomes bilateral. Irritative root symptoms are absent (spasm and darting pain). Anesthesia or hyperesthesia develop. The sphincters are involved and trophic disturbances arise. There may be spastic paraplegia or flaccid paraplegia. If the tumor is in or presses upon the anterior cornu there will be limited muscular atrophy. Tuberculoma produces the symptoms of transverse myelitis.

In glioma there are paresis and muscular atrophy. Although sensibility to pain, heat, and cold are lost, sensibility to touch is preserved (sensory dissociation).

Treatment of Tumors of the Cord.—If syphilis is suspected, give the patient a course of heroic doses of iodid of potassium, and administer mercury hypodermatically or by inunction. Intravenous injection of salvarsan is advisable. In a focal lesion not due to dissemination of a known malignant growth, perform the operation of laminectomy to permit of exploration and possibly of removal. The laminæ of at least three vertebræ should be removed and the tumor looked for distinctly above the upper level of the zone of anesthesia. It is not necessary for the patient to wear a spinal support after the performance of laminectomy. Extramedullary tumors are usually removable. Localized intramedullary tumors should be removed if they can be located and if removal can be accomplished without serious injury to the cord. After exposing the cord and discovering an intramedullary tumor, follow the advice of Elsberg and Beer ("Amer. Jour. Med. Sciences," Nov., 1911) and make a short incision in the posterior median column a little external to the posterior median fissure. The cut reaches the tumor, which bulges through it. Do not attempt removal now.

Suture the skin and muscles and wait one week. On opening the wound the tumor will be found almost completely extruded from the cord. In order to remove it it is only necessary to divide a few strands of tissue. Extrusion by this method probably inflicts little injury upon nerve-fibers. This method is called *delivery by extrusion.* I had one very promising case after this plan. The patient improved greatly and was apparently on the high road to recovery when he developed empyema from pneumonia and died. McCosh truly said that operation for spinal-cord tumor was decidedly more hopeful than for brain tumor, because localization was much more accurate and removal could be effected with less permanent damage. The mortality from laminectomy is certainly not over 10 per cent. and is probably less. Lloyd collected 51 operations: 10 per cent. died and 31 per cent. were actually cured or improved. Joseph Collins ("Med. Record," Dec. 6, 1902) collected 70 cases of spinal tumor, 30 of which were operated upon. In 12 the operation was a success, that is, the pain disappeared and motor power returned; in 8 the operation was partly successful, that is, the pain disappeared and the motor power improved; in 10 the operation failed and death occurred within a few weeks. Complete recoveries have been obtained. Elsberg cites a number of cases "Internat. Abstract of Surgery," June, 1914). If the tumor is found to be irremovable, McCosh suggests division of several nerve-roots to relieve the pain.

Acute osteomyelitis of the vertebræ is a rare disease; it may be associated with osteomyelitis of other bones, may be secondary to some distant suppurative focus, or may occur alone. It may begin in the periosteum or in the marrow. Infection of the viscera not unusually accompany it. In many cases there is a history of trauma. Any part of the spine and any part of a vertebra may suffer from it. The vertebral arch is most apt to be attacked whereas in tuberculosis the body is usually diseased. This condition may follow cold, overexertion, distant suppuration, any focal infection or traumatism, and is more common in the first two decades of life than in elderly people. The process may be superficial or it may involve the bone deeply and widely. Suppuration always occurs; sequestra generally form, and phlebitis is a dangerous complication. Any region of the spine may be attacked, but the lumbar region is particularly liable to invasion, next the dorsal, next the cervical. The sacral region is least often affected. The situation of the abscess varies with the situation of the disease. If the vertebral bodies are diseased the pus passes forward (retropharyngeal, mediastinal, psoas, or pelvic abscess). If the vertebral arches suffer the pus passes backward (cervical lumbar or dorsal abscess). Rupture into the spinal canal may occur. The membranes of the cord, the cord itself, the nerves, and the vertebral articulations are frequently involved in the process. Motor palsy and anesthesia may arise. Paraplegia is not uncommon from pressure or myelitis. Staphylococci, streptococci, or other pyogenic bacteria may be cultivated from the pus.

Symptoms.—The general symptoms are those of osteomyelitis. The local symptoms depend on the seat of disease. If the posterior portion of the column is diseased there is a hard swelling which, in the neck, is in the middle line; in the dorsal and lumbar regions, in the middle or to the side; and in the sacral region, invariably to one side.

Rigidity o the spine always exists. If the vertebral bodies are affected, rigidity is noted, the spine is tender, and special symptoms appear, their nature dependent on the region affected (retropharyngeal abscess, etc.). Occasionally symptoms of meningomyelitis are noted. The constitutional symptoms of sepsis are marked. The condition is sudden in onset, the general symptoms are violent, and purulent collections diffuse widely and rapidly. Mentality is frequently markedly dulled. These points enable the surgeon to make a diagnosis between osteomyelitis and Pott's disease. In osteomyelitis angular deformity rarely arises, because the patient is obliged to be recumbent and

because hyperostosis is taking place. The mortality is from 40 to 60 per cent. Metastatic abscesses are apt to arise. Death may be due to pachymeningitis, pneumonia, empyema, retropharyngeal abscess, invasion of the cord, or amyloid disease (H. S. Warren, "Boston Med. and Surg. Jour.," May 7, 1903).

Treatment.—The patient is kept recumbent. His constitutional treatment is such as will combat sepsis (food, stimulants, etc.). The treatment is early operation. A purulent area must be incised and disinfected. If bone denuded of periosteum is found, it is touched with a solution of chlorid of zinc or with the actual cautery. If a sequestrum exists, it is removed. A drainage-tube is inserted and dressings are applied (Müller, Makins, Abbot, Tscherniak, Hahn, Volkmann, and Chipault).

Typhoid Spine.—It was pointed out by Gibney in 1889 that typhoid fever may leave as a legacy a painful, stiff, and weak back; 74 cases of the condition have been reported (F. W. White, in "Jour. Amer. Med. Assoc.," Feb. 13, 1908). The muscles of the back are found to be rigid and there is tenderness of one or more vertebræ. The pain may only be appreciated on motion, but in some cases there is aching even when the patient is at rest. The pain may be localized, may run into one or both thighs, or may be felt in the abdomen. The symptoms arise at an uncertain period after the fever, develop rapidly, and are occasionally associated with transient episodes of elevated temperature. Kyphosis or lateral curvature may develop. (See L. W. Ely, "Medical Record," Dec. 20, 1902.) Many of the patients are hysterical. The condition is due to osteitis and periosteitis, or chronic osteomyelitis. The prognosis is excellent.

Treatment.—The use of a plaster or leather jacket; counterirritation by the hot iron; later, massage and electricity.

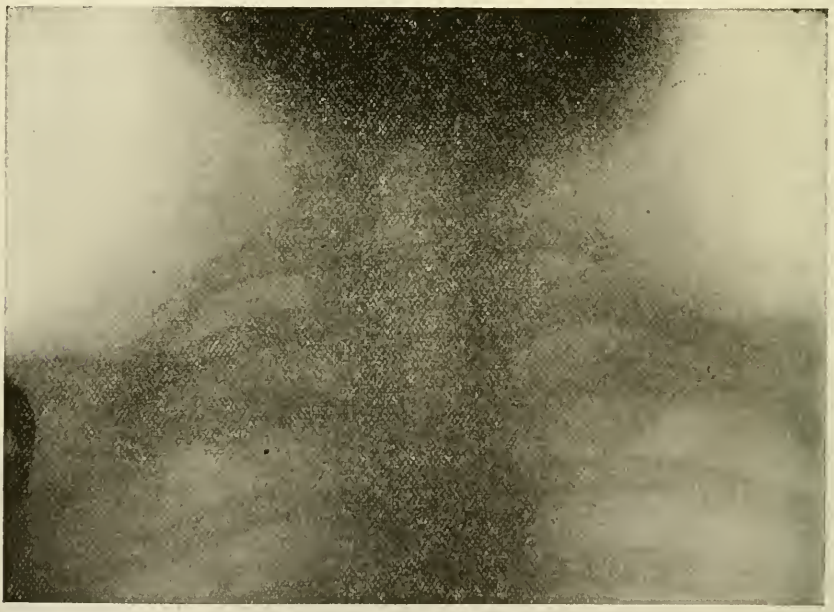

Fig. 603.—Cervical ribs.

Cervical Rib.—This condition was first described by Hunauld in 1743. A cervical rib is most commonly seen arising from the fifth cervical vertebra but on every rib there is a nodule upon the transverse process from which development may occur. It may arise from the sixth cervical, from the fifth, etc. The anterior limb of the transverse process of the seventh cervical vertebra,

which has an independent center of ossification, may develop into a separate bone of large size, known as a cervical rib. Such a rib may form on one side but is apt to form on both. It may scarcely reach beyond the transverse process, it may project well beyond the transverse process and have a free end, or it may constitute a complete rib which fuses anteriorly with the sternum, the cartilage of the first rib, or with a cervical rib of the opposite side.

Most instances described were found in the dead body, although Tillmanns collected 26 cases among the living (Carl Beck, in "Jour. Amer. Med. Assoc.," June 17, 1905). It is three times as common in women as in men. Of late *x*-ray findings indicate that the condition is much more common than was formerly supposed. I have seen 6 cases and have operated successfully on one case. It may never produce any uneasiness, and hence may escape detection and seldom does produce trouble in youth. It raises up the brachial plexus and subclavian vessels, if the rib is large. It may lead to damage of the subclavian artery (Keen's case developed aneurysm), or gangrene of the hand may result from bending or blocking of the vessel, or neuritis of the brachial plexus may arise from pressure. Pain is common. Anesthesia, palsy or both may develop. When sufficiently large to produce venous or vascular trouble, a cervical rib can be felt and the pulsating artery over it is very distinct and higher than natural in the neck. Sooner or later the artery dilates distal to the rib. The *x*-rays confirm the diagnosis. The treatment, when the rib is causing trouble, is excision of the rib with its periosteum. In a case of cervical rib the operation is by no means easy. (See Kammerer, in "Annals of Surgery," Nov., 1901, on "The Diagnostic Difficulties.") The operation should be done by the plan of A. A. Law (Abstract in "Surgery, Gynecology, and Obstetrics," 1914). He makes a vertical incision parallel to the border of the scalenus medius muscle, divides the scalenus anticus across (being careful to avoid the phrenic nerve), frees the subclavian artery and plexus by dissection, separates the pleura from the inner surface of the rib and divides the rib by means of cutting forceps.

Variations in the Lateral Process of the Fifth Lumbar Vertebra.—If this process is sufficiently long it impinges on the anterior portion of the iliac brim when the patient is in an upright position. The pain may develop suddenly after a twist or contusion. It may develop gradually. It may only be felt when the patient is in certain positions, or it may be more or less constant, being aggravated by certain postures. Over-extension is particularly prone to develop it. Pain may radiate on the fifth lumbar nerve which emerges between the sacrum and fifth lumbar vertebra. The sciatic nerve may be affected. Radiating pain and paralysis may develop in one or both lower extremities. In making the *x*-ray diagnosis a picture must be taken from several directions. The treatment usually suggested is operative removal of the process. The operation fails more often than it succeeds because it is almost impossible to avoid doing damage to the fifth lumbar nerve. Paralysis may follow operation. H. A. Wilson maintains that in less than 30 per cent. of reported operations was the result perfectly satisfactory (Paper, delivered before the "West Virginia Medical Association," Oct., 1917). It has been suggested that instead of excising the lateral process the portion of the ilium against which it impinges should be removed. In the latter operation the nerve escapes.

Spinal Curvature.—There are four chief forms of spinal curvature: (1) Lateral curvature (the scoliosis of the older surgeons); (2) posterior curvature (the excurvation, gibbosity, or kyphosis of the older surgeons); (3) anterior curvature (the lordosis of the older surgeons), and (4) angular curvature (from spinal caries). The normal spine has four curves: the *cervical* curve, the convexity of which is forward; the *dorsal* curve, the convexity of which is backward; the *lumbar* curve, which is convex anteriorly, and the *pelvic* curve, which is concave anteriorly. The dorsal and the pelvic curves,

which are primary, are due to the formation of the cavities of the chest and pelvis, and depend upon the shape of the bones (Treves). The cervical and lumbar curves, which are compensatory, depend upon the shape of the intervertebral disks, and only appear after birth when the erect position is assumed.

CONDENSED DIFFERENTIAL DIAGNOSIS TABLE OF SPINAL DISEASES AND CONDITIONS WITH WHICH THEY MAY BE CONFOUNDED

(After Professor H. Augustus Wilson)

	Scoliosis	Rachitic spine	Pott's disease	Hyperesthetic spine	Arthritis deformans	Torticollis, congenital	Hip disease
Age.	8 to 16.	4 to 6.	4 to 6.	16 to 20.	After 30.	Any age.	4 to 6.

General symptoms.	Constant.	Constant.	Intermittent.	Constant.	Constant.	Constant.	Intermittent.

Scoliosis is a non-pathological distortion of the spine characterized by rotation and lateral bending, hence the name, rotary lateral curvature (Plate 9). It is either functional or organic.

Functional scoliosis is caused by any prolonged alteration in the relationship normally existing between the axis of the shoulders and the axis of the hips. The etiological factors depend upon the maintenance of faulty postures in occupations, especially during the period of growth. School-life is especially influential in producing the condition because school furniture is adapted to the average requirements of a given class, and therefore a very small proportion of pupils are able to find desks and benches that are suitable. Properly furnished modern schools are supplied with desks and seats that are adjustable to each occupant. Gould ("The Ocular Factors in the Etiology of Spinal Curvature," H. Augustus Wilson, "New York Medical Journal," July 12, 1906) has directed attention to the errors of refraction that produce head tilting and thereby induce scoliosis. In adults, scoliosis is observable in blacksmiths, fencing masters, and waiters, in whom excessive use of the right arm produces an asymmetrical posture of the body. If a child has chronic appendicitis it holds the trunk bent toward the right side. A spinal convexity to the left forms in the lumbar region and to the right in the dorsal region.

When functional scoliosis is not corrected or occurs in rachitic or indolent children, it results in organic or permanent changes in the contour of the bones composing the spinal column. Organic scoliosis may be congenital, caused by prenatal deficiencies or augmentations of the spinal column.

Postmortem examinations reveal a confirmation of Wolfe's law that prolonged alteration of the normal functions always results in changes of anatomical structures. In extreme cases the bones of the spinal column become extensively altered in shape, the ribs are altered in contour, and the thoracic and abdominal viscera are forced into unnatural positions and assume abnormal shapes, their functions often being materially altered.

Rotary lateral curvature of the spine.

Diagnosis.—The patient is usually taken to the physician because of apparent elevation of one shoulder, or because one hip is thought to be larger than its mate, or one mamma higher than the other. Dressmakers and corset makers are generally the first ones to direct attention to the faulty posture (as scoliosis occurs in 8 girls to 1 boy). A patient suspected of having scoliosis should be nude at the time of inspection, as clothing hampers the normal action and tends to conceal the movements of the body. The accompanying diagnostic table (see page 948) is a condensed comparative statement of the important features in diseases and conditions that may resemble scoliosis in some respects. It is only by carefully studying the symptom-complex that a definite decision can be reached. It is frequently observed that patients with mild types of functional scoliosis can sit or stand erect for a few minutes and thereby deceive even a critical observer. The habitual posture, and also the rapidity with which the patient returns to the distorted position after temporary voluntary correction, demand careful attention. Young children, when chided by parents or teachers, often temporarily assume an approach to a normal posture without actual correction. The ease with which their surrounding joints yield in compensatory action is often overlooked. A patient with contracture of the pectoral muscles will elevate the shoulders into an apparent correction of stoop or round shoulders instead of throwing the shoulders well back, a posture that is to them impossible.

Goldthwait has directed attention to forward curves of the scapula that are often present in patients who are stoop-shouldered and has devised an operation for correction.

In the same way, a patient who has preternatural contracture of the ham-string tendons, either unilateral or bilateral, will often conceal that condition by bending the knee or knees enough to permit the pelvis and trunk to bend forward.

Fig. 604.

Lateral dorsal curvature to the right, and compensatory lumbar curve to the left.

Treatment consists especially in removing the cause. If the eyes produce head-tilting, proper refraction will be necessary. Adenoids should be removed. The clothing should be regulated to avoid constriction and the shoulder straps should fit close to the neck and not be allowed to slip on to the shoulder-joint.

Contractures of the pectoral muscles should be stretched by corrective manipulations. Hamstring contracture should be removed by corrective manipulation. Hoke ("A Study of a Case of Lateral Curvature of the Spine: A Report On an Operation for the Deformity," "Amer. Jour. Orthop. Surg.," vol. i, November, 1903, p. 169) has devised an operation of rib resection for cosmetic purposes. Every effort should be made to prevent the *occurrence* of scoliosis. The successful treatment of scoliosis depends on preventing its progress. Each individual patient requires careful study to determine the special characteristics that may be present.

Remedial measures should be employed that meet the peculiar individual requirements of each case.

School gymnastics are generally more harmful than beneficial in cases of scoliosis. No one but a physician should prescribe the gymnastic work. The soft bones may be still further distorted by injudicious exercises.

The first requirement in the application of applied physical culture is to secure the hearty coöperation of the patient. Without such coöperation progress cannot be expected.

No gymnastic apparatus of any kind is required when the patient can be instructed in the proper methods of autoresistance. There are over four thousand movements of the body that may be employed in remedial physical

culture. From this vast assortment those may be selected that are suitable to the peculiar conditions of the patient. At first the least tiresome forms are to be employed, and gradually and progressively others are resorted to until the patient presents a strong robust development. Usually about a year is required for the purpose, as the progress must be essentially educational. Training in developing muscle action goes hand in hand with instruction in walking, in sitting, and in all the postures assumed by the human body in the various occupations of the patient.

In organic scoliosis, in which the distortion is more or less of a permanent character, much can be accomplished in preventing the progess of the condition as well as in aiding correction by removing any rigidity that may be present. By increasing the flexibility we facilitate muscular development in much the same manner as in functional scoliosis.

When rigidity is present it must be considered in the same light as rigidity of any other joints. Its presence prevents muscular development. Manipulative measures are similar in effect to those employed in fibrous ankylosis of any joint, and are peculiar to the parts involved. In the majority of cases the force for manipulative correction must be applied through the interposition of the ribs, and the great danger of producing fractures of these structures should be realized.

If, however, there is any tendency to increase of the deformity, a suitable brace or removable jacket of plaster or celluloid should be applied to maintain correction until the musculature has been strengthened and trained to perform its full functions.

Organic or structural scoliosis has been shown by Abbott, of Portland, to be capable of correction by several types of fixed jackets (E. G. Abbott, "New York Med. Jour.," 1912, and A. M. Forbes, Ibid., July 6, 1912). The keynote of the treatment in each method is flexion of the spine, as in that position the vertebræ are unlocked. Partial correction is secured by means of bandages pulling in various directions and, after proper padding, a plaster jacket is applied. Further progress to overcorrection is continued by means of pads of felt slipped under the jacket to increase the pressure in certain directions. After overcorrection has been obtained, a celluloid jacket is worn to maintain this and exercises are assiduously employed to restore muscle function. These methods of treatment constitute the greatest advances in this work in many years, but to secure the best results they must be followed out most carefully by a skilled physician. Special forms of apparatus are essential in the application of these jackets. The combination of the gymnastic and mechanical treatment in severe functional and in organic scoliosis proves the most satisfactory in that it not only restores muscle balance, but also corrects deformity, and secures as great correction of the deformity as possible before ankylosis occurs. Any appliance used in these cases should be made to order to fit the peculiarities of the patient and should never be one of the shop-kinds that are so extensively advertised. Much valuable time is often lost while unmechanical and unsuitable apparatus is being used, during which time the bony changes may become permanent and beyond repair.

Anteroposterior curvature (not from spinal caries or from hip-joint disease) is an increase of the normal anteroposterior curves. Increase of the dorsal curve is *posterior curvature, kyphosis,* or *excurvation* (Fig. 605, A); increase of the lumbar curve is *anterior curvature, lordosis,* or *saddle-back* (Fig. 605, B). Both lordosis and kyphosis are apt to be present. Scoliosis has nearly always some anteroposterior curvature associated with it. Lordosis is apt to be compensatory, to prevent the center of gravity going too far forward. Lordosis is found in pregnant women and in very fat men. In an old man kyphosis arises because of flattening out of the vertebral disks from pressure. Rheumatic gout may cause anteroposterior curvature. Anteroposterior curvature

is often due to paralysis of the erector spinæ mass (from infantile paralysis). Pseudohypertrophic paralysis causes lordosis.

Symptoms and Treatment.—The *symptoms* of anteroposterior curvature are as follows: the thorax is flattened or pigeon breasted; the shoulder-blades are widely separated and the scapular angles project; the abdomen is protuberant; the patient complains of backache and soon tires. A recent kyphosis disappears when the patient lies upon his stomach. The facts that the erector spinæ muscles are soft and that pain is absent on concussion transmitted to the back separate kyphosis from caries. Lordosis is unmistakable. When the spine is movable, employ the same plan of *treatment* as in lateral curvature, suiting the gymnastics to the deformity. In painful kyphosis with partial ankylosis endeavor to make the ankylosis complete in order to prevent pain, obtaining this result by applying a plaster jacket which laces up and letting the patient wear it for several years.

Fig. 605.—Kyphosis (A) and lordosis (B).

Angular curvature (*spinal caries; spondylitis; Pott's disease*) is usually due to tuberculous caries of the vertebral bodies, and occurs particularly in children who are the victims of tuberculosis, but it may arise at any age. Any portion of the spinal column may be attacked. The dorsolumbar region is most prone to suffer. The chief *cause* is tuberculosis, but syphilis and secondary cancer of the vertebræ are occasional causes, and acute osteomyelitis is a very rare cause (see page 945). Blows or sprains appear to have a causal influence in some cases (see Trauma in Tuberculosis, page 247). Angular curvature may develop after an exanthematous fever.

The cancellous tissue of the anterior portion of the vertebral body becomes primarily carious, or the inflammation begins in an intervertebral disk. The changes of tuberculous osteitis have previously been set forth (see pages 275, 565, and 566). The body of the vertebra and the vertebral disk are destroyed, and the process extends to adjacent vertebræ. The weight which rests upon the spinal column causes softened bone to crumble, compresses the diseased vertebræ and disks, and produces angular deformity (the anterior part of the column formed by the vertebral bodies is shortened, the posterior part is not, and hence the spines project). In some cases the disease is spontaneously arrested by organization of inflammatory products, and ankylosis (fibrous or bony) in deformity is Nature's cure. In most cases, however, the disease spreads and caseous pus is formed, which, according to the point of formation and the route it takes, causes lumbar abscess, dorsal abscess, psoas abscess, or postpharyngeal abscess (see pages 266 and 267). In some cases the spinal cord is compressed, but in most cases it is not, and even when it is compressed paraplegia is rare and is usually temporary. Compression of the cord may be caused by the displaced vertebræ, by inflammatory material or caseous matter between the bone and dura mater, but is most often due to pachymeningitis. Caries of the cervical region constitutes a more dangerous disease than caries of either the dorsal or the lumbar region (*dangerous* pressure may occur here). Death may be caused by exhaustion, sepsis, hemorrhage, amyloid disease, pneumonia, peritonitis, pleuritis, tuberculous dissemination, pressure upon the cord, or inflammation of the cord or its membranes.

Symptoms.—The sufferer from Pott's disease, if a child, grows tired easily. The disposition alters. The victim becomes weak, sickly, moody and irritable, and complains of vague pains in many places, and is disposed to lean, rest, or lie down, suffers on movement but is easy when at rest. The child walks with the back rigid, which produces a peculiar gait. Examination may disclose evidences of pulmonary or glandular tuberculosis. A painful spot may be found by pressing upon the spines. Faradism to the back causes pain.

Spasm of the erector spinæ mass is detected (Hilton, Golding-Bird). It is not proper to seek to develop pain by jarring the back or by pressing the head downward. The posture of the child and the muscular rigidity prove the existence of inflammation, and to seek to develop pain by the methods referred to may do harm, and at best can only call attention to what is already known. Pain in the back, which is increased by motion, by pressure, and by vertebral jars, may be absent until late in the case. Distinct pain and tenderness in the back often mean abscess formation. Neuralgic pains pass into distant parts (sciatica, intercostal neuralgia) and are often linked with muscular spasm. A chronic bilateral pain in the trunk or extremities is suggestive of Pott's disease. "Chronic bilateral bellyaches in children are almost diagnostic" (Jordan Lloyd). The pain of dorsal caries can be relieved by lifting the shoulders; the pain of cervical caries, by traction on the head. Cramp in the legs occurs in dorsal and in lumbar caries. The presence of the knuckle due to bending the spine at an acute angle is a very important sign of the disease. In many cases angular deformity appears late; in some cases it does not appear at all. An angular deformity is detected sooner in those regions where the normal curves are posterior than where the normal curves are anterior. The deformity appears early in the dorsal region, but late in the cervical and lumbar regions. In many cases lateral deformity occurs. Rigidity is an early sign of great importance. It is always present. Rigidity is manifest very early in cervical caries, tolerably early in lumbar caries, late in dorsal caries. Lloyd gives the following practical rules to enable us to detect rigidity.[1] In the cervical region: seat the patient in a chair and tell him to nod the head affirmatively. Stiffness in nodding points to occipito-atloid disease. Tell him to look far to the right and then far to the left. Stiffness of these motions suggests atlo-axoid disease. Tell him to place his shoulders against the back of the chair and carry his eyes back along the ceiling. Stiffness in this movement indicates disease below the second cervical vertebra. It is practically useless to examine the dorsal region of an adult for rigidity, but such an examination can be made in a child. Place the patient prone on an adult's lap, mark the tip of each spinous process with an anilin pencil, then make the child stand up straight on the floor, and observe if any of the pencil marks fail to come nearer together. If it is seen that two or more marks do not approach each other, there is rigidity which prevents approximation. To test for rigidity in the lumbar region lay the naked patient prone upon a couch. Grasp the patient's ankles and raise the pelvis from the couch. If the lumbar spine is flexible, the pelvis can be lifted without raising the chest from the bed, and the maneuver deepens the hollow of the loin. If the lumbar spine is stiff, the maneuver lifts the trunk and produces no alteration in the vertical outline of the lumbar spines. If a child with Pott's disease is asked to pick up something from the ground, because of rigidity or pain on movement he will not bend the back, but will bend the knees or get upon the knees. Paralysis may exist, and it is due to pachymeningitis more often than to pressure from bone. Cervical caries causes dyspnea and torticollis, the head requiring support with the hands. Dysphagia indicates abscess. In adults the first signs of Pott's disease to attract attention are headache, backache, neuralgia, girdle pain, cramp, or even paralysis. In abscess due to caries of the dorsolumbar vertebræ the pus usually enters the psoas muscle and passes out of the pelvis below the junction of the middle and outer thirds of Poupart's ligament. It may point here or may pass to the inner aspect of the thigh and point a little below the spot where a femoral hernia is met with if it exists. In a psoas abscess a mass is always felt in the iliac fossa above Poupart's ligament; in a hernia no such mass exists (J. T. Rugh). In sacral caries there is no deformity and frequently no pain.

[1] "Birmingham Med. Review," April, 1897.

The diagnosis becomes apparent when bilateral abscess is detected in the buttocks or groins (Jordan Lloyd). If an abscess due to spinal caries opens spontaneously, sinuses form and persist, there will be free discharge of tuberculous pus containing tubercle bacilli and healing will not occur. The *x*-rays will usually show some large sequestra. If mixed infection takes place death may follow.

Treatment of Caries of the Spine.—When recent caries of the spine is active and affects a child; when it is accompanied by pain and fever; and when paralysis threatens, insist upon perfect rest. Place the child supine on a hard mattress, and, if possible, take it, while in a portable bed, out of doors daily. Leeches, blisters, or the hot iron over the area of pain may do good. When the activity of the process abates, apply a fixation apparatus. In diseases at or near the vertebro-occipital articulation, as long as dyspnea persists, keep the patient supine with a small hard pillow under the nape of the neck (Hilton) and a sand-bag on each side of the head and neck. After several months mechanical support can be given by Furneaux Jordan's method. Jordan applies his support as follows: The patient lies on a flat, hard table,

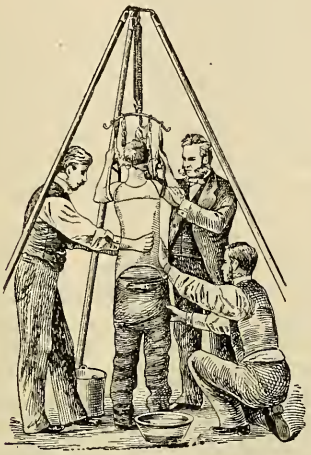

Fig. 606.—Plaster-of-Paris jacket (Sayre).

Fig. 607.—Plaster-of-Paris jacket and jury-mast applied (Sayre).

his arms are raised above his head, and traction is made upon the head by means of a pulley and a weight. Cotton pads are placed over the ears, the back of the neck and the clavicles, and are held in place by a broad flannel bandage applied as a figure-of-8 on the head, neck, and chest. The flannel bandage is overlaid with plaster-of-Paris bandages.[1] In disease of the cervical region below the axis, or of the dorsal region above the seventh vertebra, use Sayre's jury-mast (Fig. 607), or some other form of head support. Instead of the jury-mast a steel upright may be used to hold the head rigid. Sayre's appliance relieves the spine from the weight of the head and acts admirably. In most cases of dorsal and lumbar caries a steel, leather, or plaster jacket as a fixation apparatus must be employed. The best of all fixation apparatus is Sayre's plaster-of-Paris jacket applied while the patient is suspended (Fig. 606) or, better, while the column is in hyperextension. The Sayre apparatus applied in this manner is used for the treatment of caries of the lumbar region and the lower half of the dorsal region, or a plaster jacket may be applied while the patient is lying prone in a hammock or stretched between two tables. Greater corrective pressure over the deformity is secured by this method than by suspension. When all subjective signs cease, substitute for the plaster-of-

[1] See "Children's Deformities," by Walter Pye.

Paris jacket a felt or sole-leather jacket which laces down the front. Caries of the upper half of the dorsal region is often treated by a Sayre's jury-mast (Fig. 607); but if the jury-mast fails, it may be necessary to place the patient horizontally in "an open cuirass, fitted to the back from occiput to sacrum, and combined with pulley extension to the head and pelvis."[1]

During the course of caries of the spine have the patient eat fat-forming and nutritious food, insist on a plentiful supply of fresh air day and night, and administer tonics. Full antituberculous treatment is imperative (see page 255). Sea-air is very beneficial. When all active disease ceases and only angular curvature remains, use an apparatus to combine extension with mechanical support, the plaster jacket being generally employed.

Albee's Bone Transplantation Method of Treatment.—The ordinary ambulatory treatment of Pott's disease is seldom satisfactory. It is particularly unsatisfactory in the upper dorsal region. Ridlon and Jones emphasize this fact and declare that when the disease is situated in that region only prolonged recumbency prevents increase of the deformity. Albee reached the conclusion that the treatment should be one which secures bony union and hence perfect immobility. Perfect bony fixation means cure.

Albee was accustomed to see perfect cure in hip tuberculosis after ankylosing the joint, and in knee tuberculosis after erasion. He has secured a like result in vertebral caries by grafting into the spinous processes a large piece of bone cut from the patient's tibia. This graft usually becomes fixed to the spinous processes. It at least unites with the surrounding ligamentous structures and gives unyielding support which produces cure (see page 968). It is a highly useful method (Albee, in "New York Med. Jour.," March 9, 1912; in "Post-Graduate," Nov., 1912).

Beyond question this is a very valuable method. The mortality is extremely low. The fixation is secured within a year (other methods require several or a number of years). The diseased area undergoes cure. An abscess usually disappears without being opened and in most cases all manipulations are carried out on healthy tissue (J. T. Rugh, in "Am. Jour. Orth. Surg.," 1916, xiv).

Spinal abscesses are treated as indicated on pages 270 and 271.

Paralysis in Pott's Disease.—Partial or complete motor and sensory paralysis may develop in the course of vertebral caries. It may be due to the pressure of tuberculous material or to pachymeningitis with thickening of the membrane. In only 2 per cent. of cases of paralysis is the paralysis due to the pressure of angled bone (Willard). The paralysis may come on gradually. There are weakness in walking or actual inability to walk, exaggerated reflexes, muscular rigidity, and impaired sensation in the legs, and loss of control of the bladder and rectum. Caries in the high dorsal region is more apt to result in paralysis than in any other region because of the small size of the canal. Pressure in the cervical region is highly dangerous.

Treatment.—We must remember that angulation is the rare cause, tuberculous masses the common cause. Treatment for paralysis due to tuberculous masses is the full open-air treatment of tuberculosis, with rest, fixation, and progressive straightening of the spine. The patient is kept in bed (see Treatment of Tuberculosis, page 255) on a Bradford frame and with his head over-extended. If after one year the condition is not notably improved, do laminectomy and clear away tuberculous masses. If angulation is the cause of the paralysis, consider gradual correction, laminectomy, and Albee's bone transplantation. In several of the cases reported by Albee recovery from paralysis occurred soon after bone-grafting.

Gradual Correction of Angular Deformity.—Pressure is made upon the hump with the hand, and while the hand is thus held the weight of the body is allowed to bear upon it above and below. Something is perhaps gained and

[1] Jordan Lloyd, in "Birmingham Med. Review," April, 1897.

then plaster of Paris is applied, somewhat later a little more gain is obtained, and so on. This method is safer and more satisfactory than forcible correction.

Forcible correction of angular deformity was advocated by Chipault and Calot in cases of Pott's disease without abscess. It was only used in angular deformity of the middle and lower part of the dorsal region and was not advised in the cervical, upper dorsal, or lumbar regions. The operation is not safe, and a number of deaths have been reported. Gabaert[1] pointed out certain disasters which might follow forcible correction; they are: death during anesthesia; rupture of an abscess; subsequent paralysis of the legs and bladder; disseminated tuberculosis, and shock, with convulsions and death. I do not believe in forcible correction and I do believe that the alleged dangers are real dangers, that the operation is unsafe, and that it should never be done.

Laminectomy is warmly advocated by some surgeons for paraplegia from spinal caries. This operation is rarely necessary, but in some few cases it is imperatively demanded. Many cases recover from paraplegia without operation. Operation for paraplegia has a very heavy mortality (25 per cent.), and many are not benefited at all by it. If degeneration of tracts in the cord has occurred, operation cannot help the paralysis. Nevertheless, in some cases laminectomy has certainly cured palsy and saved life. Menne has collected 132 cases of laminectomy. Of these 56 per cent. were cured or permanently improved and 18 per cent. were temporarily improved.

Laminectomy should not be undertaken until treatment by rest, fixation, and extension has been applied for at least one year. Laminectomy may become necessary in cervical caries to prevent asphyxia. The operation enables the surgeon to remove masses of inflammatory material which make pressure on the cord, and also to free the cord from pressure due to angulation. The dura should not be opened unless there is evidently trouble beneath it, in which case it is incised and any tuberculous area removed, the dura being subsequently sutured. Ménard removes the transverse process of the diseased vertebræ and the heads and necks of the associated ribs in order to give the surgeon access to diseased vertebral bodies.

Spondylitis Deformans (*Bechterew's Disease*).—This is the name usually applied to osteo-arthritis of the spine (see page 729). In this disease osteophytic formation takes place at the vertebral borders, and the vertebræ become ankylosed. The vertebral bodies, as a rule, are most affected by the disease, but any portion of a vertebra may be attacked, and often the heads of the ribs are anchored to the spine by bone.

The disease may begin in infancy, childhood, youth, adult life, or old age.

Symptoms.—There are decided and persistent pain and tenderness of the spine, and occasionally evidence of pressure on the nerve-roots. Early in the case deformity is apt to occur, because at this peroid there is inflammatory softening.[2] The deformity is not angular, but is usually a total kyphosis, the column being bent forward from above and made into a single curve. Lateral curvature may occur. In many advanced cases and in some compara, tively recent cases the spine becomes rigid and ankylosed, and when it does there may be evidences of irritation of the posterior nerve-roots. In this condition there is rigidity of part or of the entire spine, other joints escaping. If the entire spine is involved, there is rigid cervicodorsal kyphosis, a condition which causes the neck to stick forward and the head to appear as if forcibly driven down between the shoulders. If the entire spine is involved, the lumbar spine is rigid and the normal lumbar curve disappears. As a consequence the patient stands in an unnatural attitude, the hips and knees being partly flexed, and the legs and feet being in a condition of external rotation. In Bechterew's disease there are compression of the posterior nerve-roots, severe

[1] "Ann. de la Soc. Belge," July 15, 1898.
[2] J. Jackson Clarke's book on "Orthopedic Surgery."

pain, muscular atrophy, and ascending degeneration of the cord. What Marie calls *spondylitis rhizomelique* is said by Osler to be a form of arthritis deformans. There is rigidity of the spine, shoulders, and hips, but no nervous lesions, as in Bechterew's disease.

Treatment.—Cure is impossible, but amelioration can be obtained.

The local and constitutional treatment is as for osteo-arthritis in any region (see page 729). If spinal curvature begins, a mechanical support must be applied or Albee's bone-grafting operation performed. Rugh operated on such a case with gratifying results ("Internat. Clinics," Vol. I, Twenty-third Series). So did Finkelstein ("Annals of Surgery," 1916, lxiv).

Injuries of spinal ligaments and muscles, which may complicate more serious injuries or may exist alone, are caused by wrenches, twists, and violent muscular efforts (as in lifting). Railway accidents may be responsible for these sprains and strains. The injury is called *railway spine* when it is caused by a railway accident.

Symptoms.—Injuries of the back, even without cord injury, are frequently linked with very deceptive nervous symptoms. Symptoms are often severe, but are usually temporary. In some few cases the symptoms are persistent. Secondary disease of the cord is extremely rare. Any region may be affected, but the lumbar is most usually injured, and the entire spine may suffer. The three marked symptoms are pain, tenderness, and stiffness of the back. At the time of injury and for a while after there is often marked shock, and hysterical excitement is occasionally observed. The cardinal symptoms may arise very soon, but may not become severe for a day or two. The pain is not acute when at rest, but becomes acute on movement.[1] The pain is felt in the back and sometimes darts into the extremities. The muscles of the back are rigid, the spasm being due to pain. The patient is very careful not to twist or bend the spine, because to do so increases pain. In a one-sided injury the rigidity is unilateral, and this symptom cannot be simulated. Often, but by no means always, the region of the back is swollen and the skin is discolored. The tenderness is not of the skin, but of the muscles. Firm pressure on a spot of real tenderness causes rapid pulse (*Mannkopf's sign*). The vertebral spines are regular and are not mobile. There is no distant paralysis or hyperesthesia unless the cord is damaged (though in some rare cases the bladder and the rectum are paralyzed when no cord lesion can be detected, and hyperesthesia may exist over the spines). Moullin tells us that the extremities feel weak because they are deprived of proper support on account of the immobility of the muscles of the back. For the same reason the action of the abdominal muscles is interfered with, and the power of micturition and of defecation is impaired (there are constipation and difficulty in emptying the bladder).

The **treatment** of recent injuries comprises rest, the application of an ice-bag, and leeching over the painful area. After a day or two hot fomentations, tincture of iodin, compression by adhesive strips, and inunctions of ichthyol and lanolin are used; and, later still, massage, douches, and frictions with a stimulating liniment are employed. Phenacetin helps to relieve pain, though in some cases opium is temporarily necessary.

Traumatic neurasthenia is apt to arise after the *immediate* effects of the accident subside. In this condition the patient grows tired easily and complains of pains and aches in the back and loins, interfering with or preventing work; paresthesia and numbness exist in the extremities; in many cases sexual intercourse is impossible because of premature ejaculation or of incapacity for erection. There are dyspepsia, eye-strain, tremor, insomnia, loss of memory, headache, rapid and irregular pulse, elevated blood-pressure, cardiac palpitation, and mental depression or confusion. The reflexes are usually exaggerated,

[1] Moullin on "Sprains."

but they can be exhausted more easily than can the exaggerated reflexes of organic cord disease (because of irritable weakness). Some rigidity and tenderness exist in the back, and the skin over this region is often hyperesthetic. Attacks of retention of urine may occur. Hypochondriasis is not unusual. Neurasthenia is not unusual as a result of war wounds. Arteriosclerosis predisposes to neurasthenia and neurasthenia aggravates sclerosis. It is probable that the ductless glands play a part in neurasthenic states. The prognosis is much better in the young than in the elderly, as the former are free from arteriosclerosis (Doré, in "N. Y. Med. Jour.," Sept. 9, 1916).

Treatment of Traumatic Neurasthenia.—Employ rest, tonics, massage, douches, and frictions to the back. Secure sleep, and endeavor to bring about a gain in weight. If sexual incapacity or seminal emissions worry the patient, dilate the urethra with steel sounds.

Traumatic hysteria develops only in those predisposed by a neuropathic hereditary tendency; traumatic neurasthenia may arise in any one. In the first named disease the accident is only the *exciting* cause; in the second disorder it is the cause. Many cases of so-called "railway spine" are really examples of traumatic hysteria. Traumatic hysteria and neurasthenia may be associated. Neurasthenia is a condition of exhaustion associated with a number of chronic disorders; it forms a foundation on which hysteria is apt to build its structure. The structure of hysteria is made up of morbid impressionability, hyperesthesia of centers, lowered self-control, and sensitiveness of the peripheral nervous system. The accident plays a double part in producing traumatic hysteria—first, by its effect on the mind (psychical traumatism); second, by its effect on the body, which anchors the attention to one point. An area of pain or stiffness often serves as an autosuggestion which undergoes morbid magnification when viewed through the distorting medium of hysteria. Erichsen taught that the symptoms of what he named "railway spine" arose from inflammation of the cord and its membranes, a view now abandoned. A blow given to a hysterical person causes a feeling of numbness, and thus negative sensation from local shock may establish the idea of paralysis, or traumatism, acting as a suggestion, may inhibit motor representations and destroy the normal ideas of motion and feeling (Charcot and Pitre). Terror always causes a feeling of loss of power in the legs, and the terror of the accident may thus develop the idea of paraplegia. The site of a traumatism may localize symptoms; for instance, a blow upon the eye may cause amaurosis or blepharospasm. It is important to remember Charcot's saying that a hysteria long latent and unrecognized may be awakened into obvious activity by a blow or an accident. Pitre shows the same to be true of epilepsy. A not unusual lesion is hysterical traumatic monoplegia, not coming on at once after the accident, but usually some days afterward, and presenting flaccid muscles, the electrical reactions and reflexes remaining normal, but the muscular sense being lost (Pitre). The muscles usually waste. The skin of the paralyzed limb is anesthetic or analgesic. There may be anesthesia limited to a limb, hemianesthesia, or general anesthesia.[1] Hysterical paralysis is usually associated with the permanent *stigmata of hysteria*—concentric contraction of the visual field, pharyngeal anesthesia, convulsive seizures, and hysterogenic zones (Clarke and Pitre). The permanent stigmata may be latent. Hysterical phenomena lack regularity of evolution, and they may be produced, altered, or abolished by mental influences or by physical forces which produce no effect on organic disease. In most hysterical conditions the general health is not profoundly impaired.[2] In making a diagnosis of hysteria we must be most careful to exclude both malignant disease and imposture, because hysteria is a sort of diagnostic waste-basket into which we

[1] J. Mitchell Clark, in "Brain."

[2] Read the works of Thorburn and Pitre.

cast most things which we fail to understand. Babinski proposes that we should call phenomena hysterical only when they can be produced or can be cured by suggestion ("Brit. Med. Jour.," Jan. 23, 1909, p. 234). Brain tumor may cause hysterical symptoms.

The constant strain, the exhaustion, the expectancy, the homesickness, the privations, the exposures of war are responsible for many cases of hysteria. Many arise in those who have been wounded. In others who have not been wounded and may have served long and gallantly, the overtense strings of the nervous system may seem to relax suddenly or snap asunder. Many cases have been reported in men who were near a shell explosion but yet received no obvious physical injury, although it is always necessary to bear in mind that even if no organic injury presents symptoms which permit detection there may be multiple hemorrhages of the brain or of the brain and cord. Hysteria arising in men on the fighting front is called war hysteria or *war shock*. Many writers have called it *shell shock*, a very incorrect term because it implies that all cases are due to shell explosions. We know that many cases result from the numerous strains and depressions of war. If phenomena so induced are purely hysterical they are recovered from entirely. If they have an organic basis, as they may have when induced by the detonation of a high explosive shell, the patient does not recover completely. We are not justified in regarding bleeding from the ears after a shell explosion as in any sense proof of basal fracture. An explosion may rupture the ear drums and thus cause bleeding. In war shock strange, temporary conditions arise; among them are: deafness, dumbness, blindness, convulsions, monoplegia, hemiplegia, paraplegia, states resembling cerebral concussion, symptoms of neuritis, zones of anesthesia, muscular contractures, delirium, mania, tremor, and anterior spinal curvature (Rosanoff-Saloff, in "Nouvelle Iconographie de la Salpétrière," No. I, 1916–17).

Treatment is by moral means chiefly. Gain the confidence of the patient. Suggestion is of great value. So is discipline. In many cases separation from family and friends is necessary and isolation is desirable. The Weir Mitchell rest-cure is often the best plan of treatment, and all its details should be carried out faithfully. It is said by some that cases of war shock are best treated near the front, in an environment of discipline. When so treated they get well. If discharged from the service they may spend their days on endless pilgrimages from clinic to clinic.

Malingering.—Persons often pretend to suffer from maladies of the spinal cord or column as a result of accident when no diseases of those parts exist. Some get well upon the rendering of a favorable verdict by a jury (**litigation backs**). In any case always examine carefully, so as to be able to exclude malingering. Note the patient's behavior and motions when his attention is diverted from his disease. *Meningomyelitis* can be excluded if there be no spasm, paralysis, hyperesthesia, paresthesia, or anesthesia at a distance (A. Pearce Gould). If pain has lasted for months; if pressure downward upon the head or shoulders does not increase pain; if the vertebræ are movable and there is no angular displacement, exclude *caries*. Gould states that when there are wasted muscles, when moderate spine movement is painless, but effort in bringing the body erect causes pain in the erector spinæ region, the trouble is a *strain of the erector spinæ muscle*. If the muscle is not wasted and the pain is in bending forward rather than in straightening up, the *vertebral ligaments* are the seat of trouble. Unilateral spasm cannot be simulated. The administration of ether may dispose of a pretended paralysis, the patient moving the suspected extremity while drunk from the anesthetic. Naturally cases of simulation are encountered by army and naval surgeons. Marie ("Brit. Med. Jour.," Aug. 14, 1915) divides supposed hysterical patients into two classes: 1. Unconscious simulators. This class includes neuropaths and victims of hysteria and traumatic hysteria. 2. Exaggerators who have really

been wounded but who multiply and magnify their troubles and in so doing commit "physiological solecisms."

Anosacral Cysts.—These cysts develop between the sacrum and rectum and originate from remnants of the postanal gut and neurenteric canal. Such cysts may be multilocular or unilocular. They can be detected by a finger in the rectum.

Treatment.—Some of these growths are removed after osteoplastic resection of a portion of the sacrum; others are removed by incising the rectal wall.

Concussion of the Spinal Cord.—This term has no definite pathological meaning. It is probable that there is such a condition, but it is usually associated with laceration of capillaries and of cord substance.

The **symptoms** are shock, intense pallor, nausea, often vomiting, and sometimes syncope. With this condition special symptoms may be linked—as temporary paralysis, a girdle sensation, numbness and loss of power in the limbs, hiccup, torticollis, coarse tremors, pains in the back and limbs, areas of anesthesia and analgesia—depending on the portion of cord lacerated.

The **treatment** in concussion of the spinal cord is the same as that for sprains. Traumatic neurasthenia and hysteria or organic cord disease may follow this injury.

Contusion of the spinal cord may arise from a blow or a sprain, but it is usually due to extreme flexion of the spine. It causes hemorrhage into the gray matter of the cord (*hematomyelia*). The symptoms are motor and sensory palsy and diminished reflexes. Some cases recover, but others end in myelitis.

Wounds of the spinal cord are rare and are very dangerous. A knife is sometimes thrust in between the occiput and atlas. Wounds above the origin of the phrenic nerves cause almost instant death. Gunshot-wounds are the most usual form, the cord being damaged by the bullet and by bone-fragments.

In the American Civil War gunshot injuries of the cord were very rare (¼ of 1 per cent. of all wounds), but at the present day in war they represent a considerably greater per cent. of all wounds, the increase in frequency being due to the increased penetrating power of the modern military bullet. The mortality is about 60 per cent.

A revolver bullet or a small-caliber bullet fired at long range may produce vertebral fracture without cord injury, and any bullet may fracture a process of a vertebra without cord injury. If the laminæ are fractured the cord is almost sure to be injured. The cord may be concussed, lacerated, or cut across by bone or bullet, or compressed by bone or blood. The bullet may lodge or may perforate.

Treatment.—In a suspected gunshot-wound of the cord excise the wound in the soft part, perform exploratory laminectomy, arrest hemorrhage, and relieve pressure if bone is depressed. If a bullet or a bone fragment lodged, remove it. I operated upon a young man who was shot accidentally twenty years before and who had had complete flaccid paraplegia and paralysis of the bladder and rectum all that time. He sought help because of violent pain in the abdomen and back. The *x*-rays showed a bullet within the canal and in front of the cord. He was operated upon in the Jefferson Hospital. The bullet was found outside of the theca and was removed. It had passed forward between the bone and the theca. In a few weeks spastic paraplegia replaced flaccid paralysis. He lived several years, gaining power slowly all the time and regaining control of the bowels and bladder. He died of an intercurrent malady.

Injuries of the Spinal Cord in War.—Injuries of the cord as seen in civil practice are usually due to a wide application of violent force (crushes, caving of embankments or roofs of coal mines, falls of masonry, railroad accidents, etc.). The resulting lesion of the cord is extensive, and in most cases

operation is of no avail. "In gunshot-wounds, on the other hand, a larger proportion of incomplete injuries is seen, and these are due to small missiles which though they hit the spine, do not often make a direct hit upon the theca" (D. M. Hughes, in "Brit. Med. Jour.," March 9, 1918).

If the theca should be struck directly by the missile or by a fragment of bone a complete lesion will almost certainly be produced or ensue.

There will be flaccid palsy, absent reflexes and loss of sphincter control. When the cord is exposed by the surgeon the laceration is usually evident, though damage which is not visible exists far wide of the lesion. Occasionally a cord appears uninjured when it has been damaged beyond hope of recovery. Hughes (Ibid.) points out that in incomplete injuries the theca has not been penetrated by bone or bullet and that the resulting paraplegia may be "transitory and flaccid, but apparently complete"—may be for a time flaccid and become spastic—may not appear until after an interval.

The condition may be due to concussion or contusion of the cord, to hemorrhage, to pressure of bone or bullet and later to pus. If a bullet is lodged within the spinal canal it is apt to cause dreadful girdle pains. In cases in which there is persistent palsy, or violent girdle pains, or spastic palsy, operation is necessary. Lodged missiles must be removed. Sepsis requires appropriate treatment. When an operation is performed excise the wound.

In but few cases is there recovery of function. Urinary and pulmonary complications are prone to develop. Gray (N. Y. Med. Jour., 1918, cvii) points out that local concussion may cause extensive palsy but it will begin to clear up in a few days.

Compression of the spinal cord may be due to blood or to inflammatory exudate, as well as to displaced bone (see page 951). *Compression from blood* may be due to *extramedullary* hemorrhage or to *intramedullary* hemorrhage. *Extramedullary* hemorrhage causes sudden pain in the back, the pain radiating from compressed nerve-roots; hyperesthesia and paresthesia in the area of the radiated pain; spasm of muscles supplied by the compressed nerves, sometimes of muscles whose nervous supply is below the lesion; tremors; convulsions; retention of urine; paralytic symptoms following the signs of irritation, but no absolute paralysis (Mills). A girdle sensation is usual. *Intramedullary* hemorrhage causes pain, a girdle sensation, abolition of reflexes, and paralysis. Spasms, rigidity, and paralysis come on early. Bedsores may form, and retention of urine and incontinence of feces may be observed. Paralysis from hemorrhage is rapidly progressive from below upward (*crawling paralysis*). Compression from extramedullary hemorrhage may be recovered from without operation, and in some cases recovery is rapid.

Treatment.—If paralysis from spinal bleeding extends rapidly and life is endangered through the probable involvement of a vital center, perform a laminectomy, remove the clot, and arrest hemorrhage. It is wise always to open the dura and inspect the cord. Extramedullary hemorrhage may be arrested by sutures or by packing. Intramedullary hemorrhage may be arrested by suture-ligatures or by packing. If an extramedullary clot is extensive it is proper to make a second laminectomy near the lower end of the spinal column in order to permit the surgeon to wash it out thoroughly. The dura must be sutured and drainage is to be employed. If there is paraplegia, complete anesthesia of the paralyzed parts, and entire abolition of the deep reflexes, operation is probably useless, but it is justifiable to try it because of a possibility that the cord has not been completely divided. In some cases with persistent paraplegia the operation should be undertaken. If operation is not undertaken, have the patient lie upon his side, apply an ice-bag to the spine, and give morphin hypodermatically. If hemorrhage continues in the cord and if the patient be plethoric, perform venesection. To promote absorption of the clot and exudate give a combination of carbonate and acetate

of ammonium, order pilocarpin, and employ spinal galvanism and hot douches. Iodid of potassium may be given.

Fractures and dislocations of the spine are very rare. The spinal regions most liable to injury are the atlo-axial, the cervicodorsal, and the dorsolumbar (Treves). A vertebra may be fractured alone, but dislocation without fracture, except in the upper cervical region, very rarely occurs. These two lesions, dislocation and fracture, are so often associated that the term *fracture-dislocation* is used by many surgeons to include them both. The causes of fracture and dislocation are direct force (seldom) and indirect violence (commonly). In fracture by direct force the laminæ and spinous processes are most apt to suffer. In most cases the fragments are not greatly displaced. A fracture by indirect force may result from a fall on the shoulders, from a weight falling on the shoulders, or from a fall on the buttocks. Forced

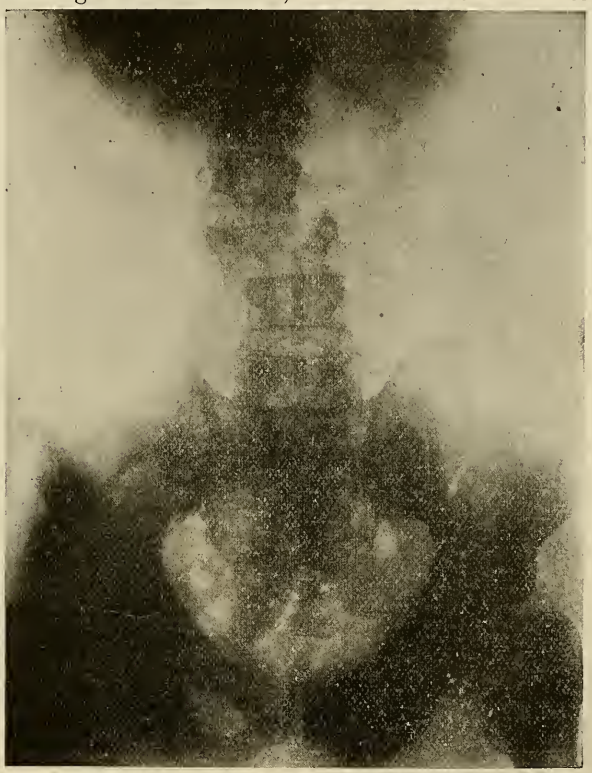

Fig. 608.—Fracture of third lumbar vertebra.

flexion or overextension is the commonest cause. In fractures from indirect force the cord generally suffers. In some cases the displacement of the vertebræ lacerates the cord, the vertebræ return into place, and no deformity is detectable. Fracture-dislocation from direct force may occur at any part of the column, and in this accident the posterior vertebral segments are driven together, and the cord, as a rule, escapes injury. Fracture-dislocations from indirect force most commonly happen in the dorsolumbar region, but are met with in the cervical and dorsal regions. In the cervical region reduction can usually be secured, but in the lumbar region reduction is impossible.

Fractures of the cervical spine often cause immediate death and are particularly apt to crush the cord completely across. Fractures in the lower dorsal and lumbar region are apt to contuse partially the cord and nerves of the cauda equina. Edema of the cord follows injury.

Symptoms.—In fracture-dislocation great displacement is unusual, but some is almost always recognizable (irregularity of the spines or angular deformity). There are pain (which is increased by motion), tenderness, ecchymosis, and motor and sensory paralysis. Priapism, cystitis, and retention of urine often occur. Horsley has pointed out that in many cases paralysis passes away only to recur subsequently, the recurrence being due to edema of the cord. In some cases of spinal injury there is *temporary paralysis* due to *shock*. *Persistent paralysis* may be due to laceration of the cord, division of the cord, or compression of the cord by bone, blood-clot (Fig. 609), or products of inflammation. The extent of paralysis depends on the seat of the cord injury. We must always try and decide if the spinal cord is completely divided or hopelessly crushed (Fig. 610). When the symptoms are not immediate in onset; when all the muscles below the seat of injury are not completely paralyzed; when there is some retention of sensation; when reflexes are present and muscular rigidity exists, we may be sure that the cord

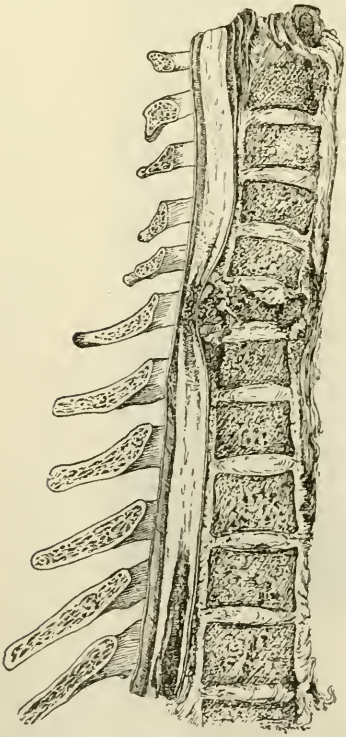

Fig. 609.—Fracture of the cervical spine, cord compressed by bone and blood. Hemorrhage into the cord at the seat of the lesion and below the lesion (Warren Museum). (From Scudder's "Treatment of Fractures." Drawn by Byrnes.)

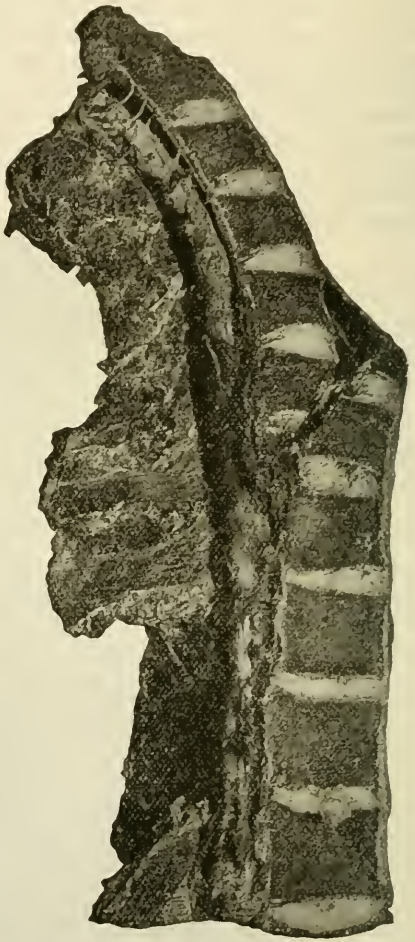

Fig. 610.—Spine sawed. Fracture of the spinous processes of the seventh cervical and first and second dorsal vertebræ. Fracture of the bodies of the fifth, sixth, and seventh cervical vertebræ with displacement *backward* of the upper fragment. Total crush of the cord. The section passes a little to one side of the cord, which is seen in place, and the staining of the cord by hemorrhage into its substance shows plainly through the membranes even in photograph. The spinous processes of the second and third dorsal vertebræ were found fractured at the operation, and were removed (Thomas).

is not completely divided. When the cord is completely divided the symptoms are immediate, there are absolute flaccid motor paralysis and complete sensory paralysis (loss of appreciation of pain, touch, and temperature). The line of anesthesia is definite and suddenly terminates (Walton). The bladder and rectum are paralyzed and there may be priapism. All the reflexes, superficial and deep, except, perhaps, the plantar have disappeared. There is pain, there are no muscular spasms, there is vasomotor paralysis with sweating of the paralyzed parts, and the symptoms persist and do not vary (J. J. Thomas, in "Boston City Hospital Med. and Surg. Reports"). There is usually tympanites (Walton). If this latter symptom-group is due to shock, it will usually be temporary, but occasionally, even when so caused, it persists some considerable time. It is also probable that concussion of the cord may in some

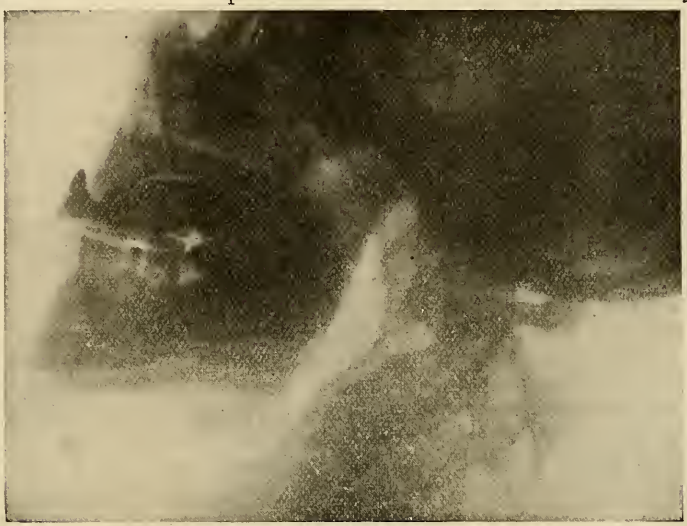

FIG. 611.—Fracture of the odontoid process of the second vertebra and dislocation between the first and second vertebra a number of years after injury. (From *X*-ray Dept. of Jefferson Hospital.)

cases simulate complete division. As Walton says, no symptoms *prove* a hopeless crush of the cord: it is the persistence of the symptoms which does prove it ("Jour. Nervous and Mental Diseases," Jan., 1902); I would add, the persistence of and lack of change in the symptoms prove it.

A. J. McCosh ("Jour. Amer. Med. Assoc.," Aug. 31 and Sept. 7, 1901) points out that definite pressure is indicated by marked symptoms and absence of reflexes. When there is not definite pressure the symptoms are irregular; there is incomplete palsy, or muscles of the same group show different degrees of paralysis; anesthesia is partial; signs of irritation are not distinct, and there are patches of hyperesthesia and zones of paresthesia. If in doubt at the end of twelve hours, perform an exploratory operation.

The **prognosis** depends on the amount of damage done to the cord. Fracture-dislocations in the cervical region produce obvious deformity, stiffness of the neck and irregularity of the spines, and a displaced vertebra may occasionally be detected by a finger in the pharynx. Crepitus can rarely be detected unless a spinous process is fractured. The Röntgen rays aid diagnosis immensely. The seat of cord injury may be determined by a study of the palsy and other symptoms.

Fracture-dislocation of the atlas or axis usually causes instant death. When the displacement is only trivial, the patient may recover, or may die of secondary cord disease. A dislocation of the atlas without fracture of the odontoid is extremely rare. If it occurs it will be unilateral, that

is, only one articular process will be displaced. A unilateral dislocation seldom compresses the cord, and gives a fair prognosis. A bilateral dislocation with fracture of the odontoid gives an extremely bad prognosis. Dr. N. J. Blackwood of the U. S. Navy records a case of fracture of the atlas and axis and forward dislocation of the occiput on the spinal column, life having been maintained for thirty-four hours and forty minutes by artificial respiration, during which time laminectomy was performed on the third cervical vertebra ("Annals of Surgery," May, 1908). Lofton has recorded a case of recovery after dislocation of the anterior arch of the atlas on to the odontoid process "New York Med. Jour.," April 18, 1908). Fig. 611 exhibits a case which recovered after fracture of the odontoid and dislocation between the first and second vertebræ. We had a man in Jefferson Hospital who could at will produce and then reduce a unilateral dislocation of the fifth cervical vertebra. Years before the dislocation was originated by striking the head when diving. The man made a living by getting himself apparently hurt in street cars and then collecting damages. LeBreton ("Am. Jour. Orth. Surg.," 1916, ix) records a case of fracture of the base of the odontoid, without paralysis. It was reduced by the patient himself and the man was cured.

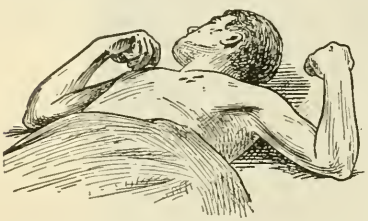

FIG. 612.—Lesion of spine between fifth and sixth cervical vertebræ. Note position of arms, due to paralysis of subscapularis. Brachialis anticus, supinator longus, and deltoid muscles intact. Elbow flexed, shoulders abducted and rotated outward (after Thorburn).

Griffith ("Am. Jour. Orth. Surg.," 1914, xii) reports three cases of partial luxation of the atlas on the axis. In none of the cases was the odontoid fractured. All recovered after reduction. In injury of the third cervical vertebra the phrenic nerve is involved, the diaphragm is paralyzed, and death soon occurs. In fracture-dislocation of the fifth cervical vertebra the subscapularis muscles are paralyzed, but the biceps, brachialis anticus, supinator longus, and deltoid muscles escape, and the patient assumes a characteristic attitude (Fig. 612). In Jones's case of fracture of the fifth cervical vertebra no operation was performed, but the patient partly recovered and became able to walk, but with a spastic gait ("Lancet," Nov. 28, 1903). If the sixth cervical vertebra is dislocated there is palsy of the muscles of the hand. In injuries below the sixth cervical vertebra no muscle of the arm, forearm, or hand is paralyzed at first, although after some days paralysis may develop. Damage to the cord above the sixth cervical vertebra produces anesthesia of the body below the injury and of the entire upper extremity except the shoulder. In injury just above the upper level of the seventh cervical there are body anesthesia and anesthesia of the outer surfaces of the arms and ulnar margins of the forearms and hands. In any cervical injury there are body anesthesia and diaphragmatic respiration, and in cases without paralysis of the arms there is sure to be pain. Injuries of the dorsal spine can be accurately located. There is paralysis of motion and sensation up to, or almost up to, the seat of injury. The arms are not paralyzed. Very great pain in the legs occurs if the lumbar enlargement is involved. In injury of the twelfth dorsal or upper lumbar vertebræ there are paralysis of the bladder and rectum, incomplete anesthesia, and partial motor paralysis of the limbs.

Treatment of Fracture-dislocations.—Unilateral dislocation of the atlas or the axis may be reduced by manipulation. Walton's plan for a unilateral cervical dislocation is as follows: Give the patient ether and hold him erect and sitting on a chair. The surgeon stands behind the patient and holds the head with both hands. The first motion is a slight degree of rotation to carry the dislocated process forward and "unlock" it. The head is then rocked toward the sound side and somewhat backward and finally the process is re-

placed by rotation. No force is used (Clopton, in "Interstate Med. Jour.," Jan., 1908. Quoted in "General Surgery," by John B. Murphy, 1909). After reducing a fracture-dislocation of the cervical region, place the patient in bed, elevate the head of the bed a few inches, and immobilize the neck and head. If complete dislocation of the body of a vertebra obviously exists the surgeon may attempt reduction by extension and rotation. The maneuver is very dangerous in the cervical region, and, as deaths have happened, some eminent surgeons advise against reduction when the injury affects that region. In fracture-dislocation of the dorsal or lumbar region the traditional plan is to straighten the spine, gently if possible, and to put the patient upon his back upon a water-bed or upon air-cushions. Empty the bladder every six hours with a soft catheter, which is kept strictly aseptic. Take every precaution to prevent bed-sores. Some surgeons advocate reduction of the deformity by extension and counterextension, and the application of a firmly fitting but removable jacket with the suspension collar (as used in Pott's disease). If this plan is employed, the head of the bed is raised and the collar is fastened to it. Every day extension is made gently—from the shoulders in dorsolumbar fracture and from the chin and occiput in cervical fractures. Extension may be maintained permanently until cure. Surgeons have come rather slowly to a belief in laminectomy. One deterrent factor has been the high mortality: Lloyd collected the records of 159 operations and found that 59 patients died almost at once and 39 died later. In Lloyd's collection of 185 cases there were but 24 recoveries and 40 improvements. In 82 immediate operations only 5 recovered. In 103 late operations there were 19 recoveries (John B. Murphy, in "Surg., Gynecol., and Obstet.," April, 1907). Some employ purely expectant treatment in vertebral fractures. My own feeling is that when simply a spinous process or some other part is fractured, and there are no cord symptoms, we may treat the patient expectantly, following Burrell's advice, and fixing the patient in bed on a Bradford frame and having him carefully nursed and watched. Reduction by extension and counterextension is dangerous and unjustifiable if there is marked kyphosis and if cord symptoms exist. I agree with Burrell that it should only be done if operation is refused, or if there are no cord symptoms and no marked kyphosis ("Annals of Surgery," Oct., 1905). If it is attempted it must be done slowly and as gently as possible because it may cause grave or even irreparable damage to the cord. I fear to delay, and, with Burrell, Lloyd, Walton, and others, operate when the patient recovers from shock, if there seems to be even a gleam of hope that operation may help him. To wait when pressure exists means that during every hour of delay the pressure is damaging the cord. Another reason for operating is that we cannot know the condition of the cord without direct inspection. The operation to be performed is laminectomy. As before stated, this is to be done even if we suspect division or hopeless crush of the cord. In some cases, it is true, we may commit the error of operating when there is only concussion, but such a mistake is less grave than to fail to operate when there is bone-pressure or hemorrhage. An objection filed by the neurologist against laminectomy is that portions of cord above and below the level of the fracture may be damaged (see Fig. 609), but, as Lloyd says, this fact does not forbid operation, but renders it necessary to make a wider exploration than has been the custom. In many cases after prompt laminectomy we get some considerable improvement, and this improvement may be sufficient to enable a man to earn a living. It is true that statistics would indicate that late operations have been more successful than early ones, but these figures must be analyzed in the light of the knowledge that many of the fatalities after early operation would have occurred if no operation had been done, and some improvements after late operation would have occurred to as great or a greater degree after early operation. The prognosis of any operation,

early or late, is never gratifying, and Thorburn feels no confidence in obtaining improvement except in injuries of the laminæ, hemorrhage, or injuries of the cauda equina, as he says laminectomy in the cervical region is followed by death, and laminectomy in the dorsal region, though not commonly fatal, is seldom followed by recovery of function. Our statistics of early laminectomy will show fewer deaths and fewer useless operations if we do not operate till shock abates. As Lloyd ("Phila. Med. Jour.," Feb. 5, 1902) says: "It is therefore evident that if we operate immediately after the injury we will have failures that should not be charged against the operation itself, and, if possible, we should wait before operating until the question can be settled whether the patient will overcome the shock or will succumb directly to the effects of the injury." All surgeons operate for compound fracture, for hemorrhage, and for cases with marked bone pressure. If early operation were not performed and if pachymeningitis arises, operation is called for.

My own convictions are that if symptoms are significant we should explore as soon as shock has passed away, even if we think it probable that the cord has been divided; and if it is found divided, it should be sutured. If in any case we are in doubt twelve hours after the injury as to whether or not pressure exists, we should explore. If soon after the accident we think pressure by bone exists, we should operate. If the case is improving, we should not operate even if there are pressure signs, unless there is a chance that pressure is due to bone, in which case we should operate. As McCosh says, pressure by blood or inflammatory exudate may pass away; pressure by bone cannot. Even long after an injury laminectomy may be productive of some benefit.

The rather radical views set forth above regarding the advisability of operating even if the symptoms point to complete division of the cord arose largely from a knowledge of the well-known case operated upon by Stewart for total division of the cord. In a case of gunshot-wound of the dorsal spine treated at the Pennsylvania Hospital by Francis T. Stewart, and reported by Francis T. Stewart and Richard H. Harte ("Phila. Med. Jour.," June 7, 1902), an exploratory incision made three hours after injury showed that the spinal cord was completely divided. There was a fracture of the laminæ of the seventh dorsal vertebra. The spines and laminæ of the seventh and eighth dorsal vertebræ were removed. The bullet-hole was recognizable in the membranes, and the bullet and some bone-fragments were removed. When the dura was opened, the ends of the completely divided dorsal cord were found to be ¾ inch apart. Stewart freshened these ends and brought them together with two sutures of chromicized catgut. In this case a considerable degree of restoration of function took place. At the time of the operation, three hours after the injury, there were complete paralysis and absence of reflexes below the seat of injury; but sixteen months later the patient was able voluntarily to flex the toes, flex and extend the legs, flex and extend the thighs, and, while sitting, lift an extended leg from the floor. The movements of the lower extremity became more forcible when reinforced by contracting the muscles of the upper extremity while making them. The patient could stand with one hand resting on the back of a chair, and could get herself from her bed to her chair by sliding. The bowels were under perfect control, and there was no incontinence of urine when she was awake, although there was occasionally some when she was asleep. There were occasional cramp-like pains in the lower limbs. The senses of touch, temperature, pain, and position were perfect all over the previously paralyzed parts. Below the knee the localization of sensation was not so accurate. There was a slight amount of muscular rigidity; and on each side, an ankle and patella clonus, which was easily exhausted. When the sole of the foot was tickled, the big toe flexed, the thigh abducted, and there was slight contraction of the anterior tibial, the hamstring, and the tensor vaginæ femoris muscles. There were no reactions

of degeneration and no trophic changes. There had never been any bed-sores. George Ryerson Fowler ("Annals of Surgery," Oct., 1905) operated on a gun-shot-wound of the dorsal spine eleven days after the injury. He removed the laminæ of the tenth, eleventh, and twelfth dorsal vertebræ and found the cord divided, the bullet lying between the severed ends. A piece of dura ⅛ inch wide was intact. The bullet and blood-clot were removed. The cord was sutured by three sutures of chromicized gut, which included the dura, and more sutures were taken through the dura only. The ends of the cord were easily approximated. The patient recovered from the operation. Twenty-six months later voluntary motion was found to be practically lost in the area below the injury, although when supported by the hands he could stand and when in a frame could move a little by a swinging movement. He is able to tell when his bowels or bladder are about to move, and, if furnished promptly with a utensil, does not soil himself. When asleep, he passes urine involuntarily. Both legs exhibit spastic rigidity, but there are no reactions of degeneration. Patella reflex on each side exaggerated. Ankle clonus is found on one side, but not on other. There is complete anesthesia of the affected area, except in a region 5 inches in length on the outer side of the right thigh. Touch is appreciated, but not correctly localized. In connection with the foregoing important cases we would note that Dr. Estes, of Bethlehem, has also operated upon a case of complete division of the spinal cord, in which suturing was apparently followed by some restoration of function.

In the light of these positive reports we must ask ourselves if we have not been wrong in the view that the spinal cord cannot regenerate. If there is even a chance that we have been wrong, we must reverse our former conservative treatment and follow a radical plan. The 3 cases strongly suggest the possibility of some regeneration, but do not prove it. The cord may have appeared to be completely divided and yet minute undivided bundles may have escaped recognition. Again, as Fowler suggests, there may be a nerve anastomosis through an uninjured portion of the dura or between adjacent nerve-trunks which arise above and below the lesion. At my request Dr. Samuel Lloyd, of New York, kindly wrote me a personal communication setting forth his views on this important subject. They are as follows: "The question of the regeneration of the spinal cord after traumatism of the spine deserves careful consideration in all cases that are operated upon. Up to the present time, however, although a number of operators have reported improvement following suture of the spinal cord in these cases, a careful analysis does not substantiate the fact that that improvement is due to an actual regeneration. It is a recognized fact on the part of all who have had experience with the surgery of the spinal cord that in almost every instance a certain amount of improvement is noted during the first few months. This is probably due to the fact that at the time of the injury minute hemorrhages occur into the adjoining segments, and that pressure is also increased in those portions of the cord by the inflammatory exudate and edema. Within a short time after the injury these conditions improve, and there seems to be an improvement in function; but in every case of spinal suture yet reported the amount of improvement may be explained by these facts. In no instance has there been a complete recovery of function, but in every one there has remained more or less permanent disability. This, however, should not discourage attempts at spinal suture, and in every case operated upon the dura should be opened and the condition of the cord examined. In those cases where a complete destruction has occurred and where the extent of it is not over ¾ inch, it may be possible to cut out the lacerated portions and coaptate the surfaces by a series of sutures placed in the dura. In all these cases the patient should be put up in a plaster retaining bandage in extreme extension, even the head being thrown back so as to relax as much as possible the tension on the line of suture. The

operator should be very sure, however, that there are no undestroyed fibers traversing the lacerated area, for the destruction of these in case regeneration did not occur would increase the amount of paralysis." With the views of Lloyd I am in entire agreement, and now I always follow this plan, bearing in mind that it is often impossible to tell whether the spinal cord is completely divided or seriously damaged without examining it, and it can be examined by exploratory operation only; therefore, if the serious symptoms already indicated exist after shock has passed away, exploratory operation should be performed; if pressure exists, it should be removed; and if the spinal cord is found to be completely divided, it should be sutured. It is well to remember that Abbe's experiments have shown that there may be great difficulty in bringing the divided ends of the cord into apposition. In order to effect this it may be necessary to resect a vertebra.

Operations on the Spine. **Operation for Spina Bifida.**—A. W. Mayo Robson[1] maintains that operation is not demanded when the sac is of small size and is well protected by sound integument; that operation is improper when a large portion of the column is fissured, or when paraplegia or hydrocephalus exists; that operation is advisable only in meningocele, in cases in which the integument is thin and translucent, in cases in which the cord is flattened out or the nerves are fused. Robson has closed the osseous defect by transplanting periosteum.

Surround the sac by elliptical incisions. Find the neck of the sac, and if it contains no visible nerves, ligate it and cut off the protrusion. Push the stump into the canal. Freshen the bone-margins and spring a piece of celluloid beneath them to close the gap (Park). Suture over the stump with small sutures of catgut.[2]

Treves's Operation for Vertebral Caries.—(See page 784.)

Laminectomy.—The patient lies prone and a sand-pillow is placed under the lower ribs. Make a vertical incision over and down to the vertebral spines, the middle of the incision corresponding to the seat of injury or disease. The sides of the spinous processes and the laminæ are cleared. The periosteum is incised in the angle between the laminæ and spines, and is lifted away from the arches. It is my custom to bore through a lamina on each side of a spinous process by means of Hudson's burrs. When this has been done the spinous process and lamina are easily bitten through and removed. The usual method of operating is as follows: The spinous processes are cut off close to their bases by means of bone-cutting forceps, the laminæ are removed on each side with the same instrument or the rongeur, and the dura is exposed. In some cases of fracture fragments will be found on exposing the vertebra, or a blood-clot will be seen between the dura and the bone; in other cases the dura must be opened by scissors vertically in the middle line while it is grasped by mouse-toothed forceps. After reaching and removing the compressing cause, or after failing to find or remove it, it is best not to close the dura completely, because, if we do so, cord pressure may result from hemorrhage. The dural wound is left open or is partly closed. I used to insert a drain of rubber tissue, but have given it up. Horsley shows that it is not necessary, and if we refrain from draining we lessen the tendency to headache, temporary pyrexia, and rapid pulse, which frequently follow laminectomy. The superficial parts are stitched with silkworm-gut and dressings are applied.

Albee's Method of Bone-grafting for Pott's Disease of the Spine.—In 1891 Hadra, of Galveston, advocated the treatment of Pott's disease of the spine by wiring the spinous processes of the diseased vertebræ to adjacent vertebræ for the purpose of securing fixation. Chipault, in 1895, and Calot, in 1896, did

[1] "Annals of Surgery," vol. xxii, No. 1.

[2] A full consideration of the various plans of operating will be found in an article by Marcy, in "Annals of Surgery," March, 1895.

this after forcible correction of angular deformity. Lange buried steel wires on each side of the spine and anchored each one at each end by silver wire (J. T. Rugh, in "Internat. Clinics," Vol. I, Twenty-third Series). The object of these operations was to do away with the necessity for an external supporting jacket or brace. The objection to them was the introduction of a foreign material, and the fact that strain caused that material to cut through the tissues and permit relaxation.

In 1911 both Hibbs and Albee, working independently, reported methods for producing fusion of the arches of the vertebræ.

Hibbs ("New York Med. Jour.," May 27, 1911, and "Annals of Surgery," May, 1912) takes strips of the periosteum from the spines and laminæ, transposes the spinous processes, and sutures the periosteum and the supraspinous ligament over these processes. The periosteum is depended upon to produce new bone, which fuses the parts together. This operation, if successful, lessens kyphosis and produces fusion of spines and laminæ. Albee, doubting the reliability of the periosteum as a bone producer, practises bone-grafting. An *x*-ray picture must be taken in order to determine that vertebral bodies are being broken down and the region of such destruction. We thus learn the vertebra or vertebræ which are diseased and where the graft is to be applied. The patient is placed prone. An incision is made to expose the spines of the diseased vertebræ and also one or two vertebræ above and one or two below. Some make a straight incision. Rugh makes a curved incision at one side of the spine and turns back a flap. Each spine is split vertically by a chisel and each split portion is broken and pushed over toward the corresponding side. The interspinous ligaments are cut so as to correspond to the split in the spines. We thus obtain a wedge-shaped incision through bone and ligament.

The length of the cut is measured on a probe. The wound is packed temporarily. The leg is flexed upon the thigh. An incision is made over the anterior surface of the tibia. A wedge-shaped graft of bone is cut by means of a surgical engine, a Gigli saw, or a chisel and mallet. The graft is covered with periosteum on one side and contains some medullary tissue on the other. It is $\frac{1}{3}$ inch thick at its base. This graft is fitted to the unbroken sides of the spinous processes. If the kyphosis is marked, numerous cross-cuts are made with a saw into the thin edge. Thus the graft will be made flexible. No attempt is made to correct forcibly the deformity. Here and there the periosteum is incised to favor the emergence of osteoblasts. The interspinous ligaments are sutured over the graft by sutures of kangaroo tendon. The incision is closed. The patient is put on a Bradford frame or plaster-of-Paris is applied. The patient remains recumbent for from six to twelve weeks, then he is allowed to sit up and soon after to walk, of course wearing a brace or plaster.

The brace or jacket is removed in five or six months. The results of this operation are excellent. The fate of the bone-graft is a matter of dispute. Some hold that it really lives. Others hold that it is simply a scaffold for new bone. One thing is certain—it strongly stimulates the production of new bone from the raw surfaces of the split spinous processes. New bone comes, and new bone, however formed, constitutes the permanent splint (Albee, in the "Post-Graduate," Nov., 1912, and in "N. Y. Med. Jour.," March 9, 1912; J. Torrance Rugh, in "Monthly Cyclopedia and Medical Bulletin," Feb., 1913, and in "International Clinics," Vol. I, Twenty-third Series).

Albee ("Am. Jour. Orthop. Surg.," 1916, xiv) reports 198 personal cases of Pott's disease that were operated on a year or more ago by bone-graft. In 184 cases the disease was arrested. In 2 improvement occurred, up to the date of the paper 12 had died. Six of the 12 were relieved of symptoms of Pott's disease and died of conditions unconnected with the operation.

Puncture of the spinal theca, or lumbar puncture, was devised by Quincke, for hydrocephalus in 1891, and has been carefully tested by many surgeons.

It is the operation for withdrawing cerebrospinal fluid from the subarachnoid space of the cord. It is employed as a means of diminishing cerebral pressure in hydrocephalus, cerebral tumor, uremia, infantile palsy, and tuberculous meningitis, but in these cases it has proved of little or only of temporary therapeutic value. It may be of some service in cerebrospinal meningitis, in acute anterior poliomyelitis and in delirium tremens. The condition of a patient with a fracture of the base of the skull is sometimes temporarily improved by the operation. Pain is often temporarily relieved. In the performance of a brain operation the brain may bulge so that the dura cannot be sutured. Lumbar puncture makes suturing possible. Puncture is the preliminary step of spinal anesthesia. In some cases the examination of the fluid has been of great diagnostic value. The fluid is not only subjected to a naked-eye study, it is also studied microscopically and bacteriologically. If the fluid from the puncture gives no positive finding, the operation should be repeated (Lorgo). When a diagnostic tap is made we must know the appearance, nature, and pressure of the fluid normally.

Normally the fluid is clear, transparent, alkaline, and under a pressure of from 40 to 60 mm. of mercury (Dana), its specific gravity is from 1.006 to 1.008, and from 5 to 10 c.c. will flow out at a tap. It contains a faint trace of coagulable protein, inorganic salts as does the blood-plasma, a carbohydrate resembling glucose but no formed elements. The carbohydrate is probably dextrose. In cases of increased tension the fluid flows out more forcibly, rapidly, and profusely (brain tumor, hydrocephalus, meningitis, pneumonia, influenza and some other infectious conditions). When there is meningeal inflammation the specific gravity is increased. In apoplexy and other hemorrhages beneath the cerebral arachnoid, in fracture of the base of the skull, and in hemorrhage beneath the arachnoid of the cord, the fluid contains blood. Laceration of the brain tissue without subarachnoid or ventricular hemorrhage does not make the fluid bloody. The fluid is turbid in purulent meningitis of the cord or brain, may contain many polymorphonuclear leukocytes, and also bacteria. Lumbar puncture is of great diagnostic use in the cerebral hemorrhage of the newborn and in some fractures of the base of the skull.

The *chemical* study of the fluid is sometimes of value.

In intracranial tumor, purulent meningitis, subarachnoid hemorrhage of the brain or cord, and apoplexy coagulable protein is increased. The carbohydrate substance resembling glucose is absent in purulent meningitis and is increased in saccharine diabetes. In most cases of tuberculous meningitis at some period of the disease there is a decrease in carbohydrate. In some cases there is no decrease.

In uremia the chlorids are diminished.

Cytodiagnosis (a microscopical study of the cells of the fluid) may furnish useful information; numerous polymorphonuclear leukocytes are found in meningitis. Lymphocytosis suggests a tuberculous lesion rather than an acute meningeal inflammation. Lymphocytosis occurs also in syphilis of the brain and cord, locomotor ataxia, paresis, and uremia.

Bacteriologic study by cover-glass preparations or cultures may give important information. In over 74 per cent. of cases of tuberculous meningitis of the brain membranes the fluid contains bacilli. Stadelmann has reported 37 cases in which tubercle bacilli were found in the fluid.[1] In tuberculous meningitis the fluid may or may not contain tubercle bacilli. In cerebrospinal meningitis the cerebrospinal fluid contains the meningococcus. In this disease diagnostic puncture is unnecessary if the nasal mucus contains the Diplococcus intracellularis. The operation of lumbar puncture is simple, and if done with proper precautions is harmless. The back should be carefully sterilized and thorough asepsis must be preserved in every detail. The patient may lie on the

[1] "Berliner klinische Wochenschrift," July 8, 1895.

right side with the left knee well drawn up, may lie prone, with a pillow under the belly, or may sit in a chair, with the body bent forward. He must not straighten up during the operation. If he does the needle may be broken. The site of the intended puncture may be frozen with ethyl chlorid, but no general anesthetic is required. A suction apparatus is not to be used as it might cause hemorrhage. A Pravaz syringe is employed. The needle, which should be 3 inches in length, is guarded by the surgeon's index-finger and the point is inserted ½ inch to the right of the median line and between the third and fourth lumbar vertebræ. It is pointed upward and a little inward under a spinous process. It enters the canal in the middle line. In a child the needle enters the canal at a depth of from 2 to 3 cm.; in an adult, at a depth of from 4 to 5 cm. The fluid is permitted to fall drop after drop into a sterile test-tube. In some cases only a few drops of fluid can be obtained; in other cases many cubic centimeters may be removed. It is not wise to draw for diagnostic purposes over 5 c.c. from a child and 10 c.c. from an adult. If we evacuate too much cerebrospinal fluid, the ventricles are emptied and compression of the cerebellum may arise. The flow should be spontaneous and suction ought not to be used. After operation the patient must remain in bed for at least twenty-four hours, with the head low for the first twelve hours. The erect posture is to be assumed gradually. To let a patient sit up or walk about soon after puncture is dangerous. Sometimes nausea, vertigo, and severe headache follow the operation, and sudden deaths have been reported. For a number of hours after tapping the patient should remain recumbent. It is probable that lumbar puncture is free from danger in a healthy person. It has certain dangers in uremia, intracranial hemorrhage and intraspinal hemorrhage. It brings definite peril in meningitis, brain abscess, and brain tumor because it may cause the brain-stem to sink in the foramen magnum and so be responsible for respiratory failure. If we decide upon puncture in a case in which brain tumor is suspected keep the patient recumbent for at least twenty-four hours before the operation, perform the puncture while the patient is upon his side and the head is lower than the body, keep him in bed for forty-eight hours after operation, the head being kept low for the first twelve hours of this period. The erect position is assumed gradually (Schoenbeck, in "Arch. f. klin. Chir.," 1915, cvii).

The Mingazzini-Foerster Operation in Tabes.—Painful crises of tabes are not connected with the vagus but originate in the posterior roots. Mingazzini suggested intradural division of the posterior sacrolumbar nerve-roots for unbearable pain in the lower extremities due to tabes.

Foerster follows a like method in treating gastric crises. He divides the posterior dorsal roots on both sides from the sixth to the ninth. Sauvé divides the posterior roots from the fifth to the eleventh. Some of these operations have been notably successful. Many have failed (Leriche, Delbet, Nocquot). In at least one case the condition was aggravated (Doerr, in the "Wien. med. Woch.," No. 45, 1911). Intradural operations have a decided mortality. For the pains and crises of tabes some surgeons advise extradural division within the canal of the posterior roots (Guleke). Frankl advocates an operation without laminectomy. He exposes the intercostals from the fifth to the seventh and avulses them with the corresponding posterior roots. Jaboulay employed stretching of the solar plexus. Delbet and others find it useless. It is necessary to remember that tabetic crises occur only early in tabes and cease later when the root fibers are destroyed. Operation is justifiable only when nutrition is dangerously interfered with, or when the pains occur so violently and often as to be unbearable. The posterior roots may be divided for spastic paralysis, for intractable neuralgia and for athetosis. The roots selected depend upon the area of palsy, the seat of pain or the region of athetosis.

Intradural Root Anastomosis in Cases of Vesical Paralysis.—Kilvington ("Brit. Med. Jour.," 1907, vol. i) suggested intraspinal anastomosis of nerve-roots. He found by experiments on dogs that the last lumbar root, when joined to the roots of the second and third sacral nerves, gives contraction to a palsied bladder. Bird, at the suggestion of Kilvington, did the operation on a human being, but it was a failure. Frazier, in a case of Mills's, anastomosed the root of the last lumbar to the roots of the third and fourth sacral nerves. There was decided improvement (Frazier and Mills, "Jour. Am. Med. Assoc.," Dec. 21, 1912). N. Sharpe ("N. Y. Med. Jour.," 1916, civ) advocates the operation for paralysis of the lower limbs when little or no improvement could be expected from braces or tendon transplantation. He advocates using the twelfth dorsal, the second lumbar or the third lumbar as the energizing root. He advocates a two-stage operation. The first stage is laminectomy, in the second, the theca is opened and the anastomosis made.

Horsley's Operation for Chronic Spinal Meningitis and the Decompression of Bailey and Elsberg.—Sir Victor Horsley ("Brit. Med. Jour.," Feb. 27, 1909) states that during the past ten years he has operated on a number of cases for what he calls chronic spinal meningitis. Such cases are commonly confused with tumor, are much more frequent than tumors, and are often cured or greatly improved by operation. The first published case of this sort was reported by Spiller, Musser, and Martin ("Univ. of Penna. Med. Bulletin," March, 1903). Martin performed laminectomy, found a "circumscribed meningitis," and cured the patient. In these cases a fluid accumulation is found and this fluid is stagnating and under pressure. The cord passes into a condition of sclerogliosis. The symptoms are pain, advancing loss of power in the legs, perhaps slight kyphosis, and eventually progressive and fatal paraplegia (compression paraplegia).

The pain in these cases involves an extensive area, not as in extramedullary tumor a small area supplied by one or two nerve-roots, and there may be hyperesthesia over an entire extremity, which does not occur in extramedullary tumor (Horsley, Loc. cit.). Horsley has never seen absolute abolition of tactile sense. The operation consists in laminectomy, opening the theca, washing it out with mercurial solution (1:500 followed by 1:2000), and closing without drainage. Bailey and Elsberg ("Jour. Am. Med. Assoc.," March 9, 1912) suggest the term *spinal decompression* for laminectomy and opening of the dura when no lesion is located or found. They believe that in such cases the laminectomy and opening of the dura do the good. A number of other intradural conditions may perhaps be benefited by the operation. Some remarkable cases have been reported. I operated on a case of supposed transverse myelitis. On inspecting the cord no lesion was discovered yet the patient made an apparently complete recovery from his trouble. I am satisfied that in some cases the operation is of great value. Why it ever improves a case I do not know. That it may I do know. In none of the cases reported by Bailey and Elsberg were there any signs of pressure. Elsberg ("Jour. Nervous and Mental Dis.," 1911) pointed out that laminectomy and incision of the dura often produce an immediate effect on spinal reflexes. In many cases within half an hour knee and ankle jerks become depressed and remain so from several hours to 24 hours. This condition probably results from change of pressure modifying circulation. Elsberg and Bailey ("Jour. Am. Med. Assoc.," June 10, 1916) advocate exploration in the cervical and dorsal regions but caution us not to expose the cauda equina without very strong indications. The cauda is extremely sensitive to pressure changes, and bladder and rectal symptoms may arise after mere exposure of the conus.

XXVI. SURGERY OF THE RESPIRATORY ORGANS

Asphyxia.—In drowning, strangulation, suffocation, and hanging the mode of death is by the same process, that is, by asphyxia or apnea. "Asphyxia," though the commonly used designation, is an unfortunate term, and apnea is the more correct one. By asphyxia we mean the non-oxygenation or the incomplete oxygenation of the blood, and yet even in this condition death is not immediate, for the heart may continue to beat for some little time after all breathing has ceased. A man may be apparently dead from asphyxia and yet be capable of resuscitation. In general, it may be said that asphyxia produces lividity, a struggle like a convulsion to obtain breath, and finally, in many cases, genuine convulsions. In the very beginning of non-oxygenation the senses may be remarkably acute, but consciousness is soon lost. The veins stand out and the pulse becomes weaker and weaker. The individual may bleed from the nose, from the rectum and other mucous membranes, and there may be involuntary passage of urine. For a short time the chest heaves, making respiratory attempts, and after a short time the heart stops beating.

Asphyxia is a common mode of death. It is the mode of death occasioned by a foreign substance in the air-passages, by paralysis or by tetanic fixation of the respiratory muscles, by great pressure upon the chest or abdomen, by acute traumatic pneumothorax, by a clot in the pulmonary artery which cuts off the blood-supply of the lungs, by hanging, throttling, drowning, absence of sufficient oxygen from the gases breathed, presence of quantities of irrespirable gases (CO, CO_2), or the presence of irritant gases (CI, SO_2) which cause spasm of the glottis.

The terms *smothering*, *stifling*, and *suffocation* mean prevention of entry of air into the lungs in sufficient quantity to properly aërate the blood.

Treatment in General.—Of course, each form requires some particular method of care. In general, it may be said that the surgeon should at once endeavor to determine the cause of the asphyxia and should particularly ascertain if it came on gradually or suddenly. As a rule, a gradual asphyxia is due to some intrathoracic lesion. If the asphyxia were sudden the surgeon must examine the neck and chest externally to see if there is any sign of injury. Then the mouth is opened, the tongue pulled forward, and the glottis felt by the finger to see that no foreign material is blocking the air-passages. The patient will do best in a free draft of fresh air, and it may be possible to excite respiratory activity by dashing hot water and then cold water on the face and chest and making a number of these alternate applications. The application of electricity to the phrenic nerve may do good (the anode at the root of the neck and the cathode over the epigastric region). If there is cardiac dilatation, bleeding is urgently indicated. When the patient is breathing, inhalations of oxygen do good. If there is laryngeal obstruction, tracheotomy or intubation should be done. In most cases of threatened asphyxiation artificial respiration is necessary. There are several different methods.

Artificial respiration is resorted to in case of suspension of breathing from any cause; among the more frequent causes are the inhalation of smoke or poisonous gases, drowning, profound anesthesia, opium-poisoning, and electric shock. It should be inaugurated at the earliest possible second and expectation of the arrival of special apparatus should never cause a moment's delay in making it. If the heart is still beating life can be prolonged more certainly by the use of an apparatus than by manual procedures, but one must not stand by with folded hands until an apparatus is obtainable.

After breathing has ceased for ten minutes from drowning, poisoning by illuminating gas, electric shock, effects of an anesthetic or any other form of asphyxia, its restoration is usually impossible (Y. Henderson, in "Jour. Am. Med. Assoc.," 1916, lxvii).

There are several methods of giving artificial respiration. One method may have an advantage over another in a certain type of case, as will hereafter be described.

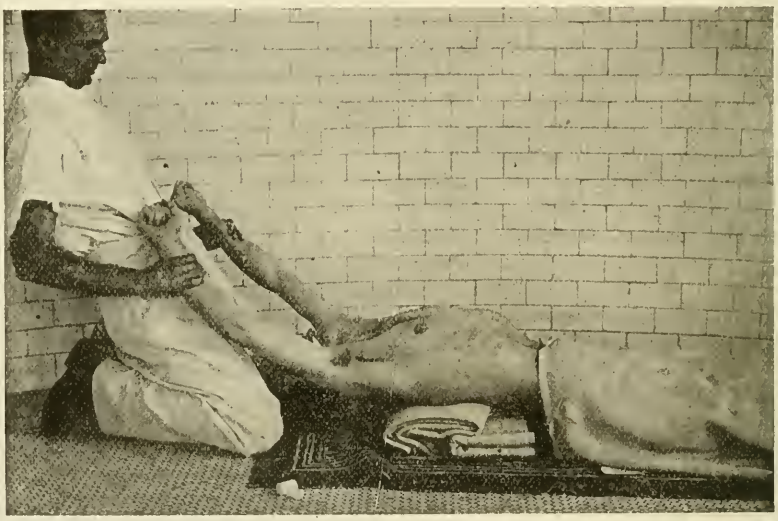

Fig. 613.—Sylvester's method. Inspiration.

Before resorting to any method the clothing about the neck, chest, and abdomen must be free and loose; the mouth unobstructed by foreign bodies, as false teeth, etc., the throat clear of mucus, etc.

If edema of the glottis, malignancy of the tongue, or an immovable foreign body should obstruct the air-passages, tracheotomy should be performed before attempting artificial respiration.

When giving artificial respiration the operator should not desist because respirations are not established in a few minutes, but, on the contrary, should persist (even using relays of men if necessary) for an hour or more. Many cases of drowning, opium-poisoning, asphyxia from smoke, etc., have been resuscitated after artificial respiration had been carried on for an almost incredible period of time.

During the manipulations of artificial respiration it should be remembered that the patient must be cared for as in shock: the body kept warm, friction applied by the hands or rough towels, and massage over the heart practised. Enemas of coffee by rectum and stimulating hypodermatic injections are important. The author prefers an enema of 5 oz. of hot coffee with 1 oz. of brandy and a hypodermatic injection of atropin sulph., gr. $\frac{1}{100}$, or strychnin, gr. $\frac{1}{20}$. One of the oldest methods of artificial respiration and the one most applicable in

children is *mouth-to-mouth insufflation*. In this method the operator holds the victim's tongue forward with a suture or with a piece of string tied around the tongue; with the other hand he closes the nostrils, and then, after taking a deep inspiration, blows directly into the patient's mouth. The air is then expelled from the patient's lungs by direct pressure on the walls of the thorax. This procedure is repeated 16 times a minute. Instead of the direct mouth-to-mouth inflation a soft-rubber catheter may be passed through the mouth into the trachea and the patient's lungs be expanded by the operator blowing through the catheter.

Artificial respiration must be stopped when the patient has taken one or two breaths, but should be continued until the respiratory movements are regular and normal. The patient must be carefully watched for fear of secondary apnea.

Sylvester's method is a popular one, and is probably the best in many cases of severe electric shock, but if there is any fluid in the lungs or air-passages (as in cases of drowning) or if an arm or forearm is broken, another method may be preferred.

Fig. 614.—Sylvester's method. Expiration.

To make artificial respiration by this method the patient is placed on his back with a folded coat or blanket under his shoulders. The tongue is pulled forward and held by forceps, a suture, or, in an emergency, may be tied with a string, or even a necktie can be used. The operator, kneeling at the head of the patient, grasps the forearms just below the elbows and circumducts the arms outward and upward, meanwhile making traction until the arms are perpendicular to the body (Fig. 613). By this movement the chest is expanded and inspiration is caused. The arms are now brought slowly to the sides of the chest and firm pressure is made for two or three seconds, thus forcing the air from the lungs and causing expiration (Fig. 614). This procedure should be repeated about 15 or 16 times a minute.

This method is best suited to those overcome by gas, smoke, or apnea other than that due to drowning.

Howard's Method.—If the patient has sustained fracture of the ribs some other method should be selected. Howard's method is now used by the United States Life Saving service in cases of drowning. The procedure as laid down by Dr. Howard is as follows:

"Rule 1: To expel water from the stomach and lungs, strip the patient to the waist, and, if the jaws are clinched, separate them and keep them apart by placing between the teeth a cork or a small piece of wood. Place the patient

face downward, the pit of the stomach being raised above the level of the mouth by a roll of clothing placed beneath it. Throw your weight forcibly two or three times upon the patient's back over the roll of clothing so as to press all fluids in the stomach out of the mouth."

"Rule 2: To perform artificial respiration quickly turn the patient upon his back, placing the roll of clothing beneath it so as to make the breast bone the highest point of the body. Kneel beside or astride of the patient's hips. Grasp the front part of the chest on either side of the pit of the stomach, resting the fingers along the spaces between the short ribs (Fig. 615). Brace your elbows against your sides, and steadily grasping and pressing forward and upward, throw your whole weight upon the chest, gradually increasing the pressure while you count 'one, two, three.' Then suddenly let go with a final push, which springs you back to your first position. Rest erect upon your knees while you

Fig. 615.—Howard's method of artificial respiration.

count 'one, two;' then make pressure as before, repeating the entire motions at first about 4 or 5 times a minute, gradually increasing them to about 10 or 12 times. Use the same regularity as in blowing bellows and as seen in natural breathing, which you are imitating. If another person is present let him, with one hand, by means of a dry piece of gauze, hold the tip of the tongue out of one corner of the mouth, and with the other hand grasp both wrists and pin them to the ground above the patient's head."

Schäfer's Method or the Prone Method.—Schäfer's method is not suitable if the patient has sustained fracture of the ribs. In this method, instead of lying on his back as in the Howard method, the patient lies on his stomach, his face being turned to one side. The arms are placed above the head. A roll of blankets or clothing is placed under the chest. The operator now kneels astride of the patient and grasps the thorax with both hands, the fingers running parallel with the ribs. Brace your elbows against your sides and press firmly inward and upward, throwing your whole weight against the chest. Release your pressure after two or three seconds, count "one, two," and again make pressure as before. This sequence should be repeated about 15 times a minute.

The advantages of this method are that fluid in the air-passages will gravitate out through the mouth and the tongue falls forward without being held.

Marshall Hall's method is more easily applied on the operating table than any other method of artificial respiration. On the other hand, it is not as efficient and is only justifiable when the patient's normal respirations are resumed after three or four applications of pressure. The patient lies on his

back, and the operator, with a hand on either side of the thorax near the costal region, makes pressure upward and inward. This pressure is continued for two or three seconds, then suspended for the same length of time, and then pressure again made. This procedure is repeated about 15 times a minute.

Laborde's method is not as efficacious as the foregoing, but has its uses in cases in which, because of injury to the chest, shoulders, or arms, Sylvester's or Schäfer's method or their modifications cannot be employed.

Laborde's method rests on the assumption that "systematic and rhythmic traction" upon the tongue produces respiratory reflexes and causes contractions of the diaphragm, hence establishing respirations.

The tongue is grasped by tongue-forceps or a piece of gauze held between the forefinger and thumb, and is pulled well out of the mouth with considerable traction. It is held for two or three seconds and then relaxed. This procedure is repeated about 15 times a minute.

When a certain amount of resistance is felt, it is a sign that respiratory function is being restored. Noisy respiration first occurs, termed inspiratory hiccup.

When the condition of the chest will allow, that is, if there are no fractured ribs, empyema, etc., Laborde's method and Marshall Hall's method may be combined.

It can be readily realized that Laborde's method cannot be used when there is disease or injury of the tongue.

Intratracheal Insufflation.—This consists in forcing air by external pressure through a tube which passes through the mouth and larynx into the trachea. The air, under the influence of the same force which drove it in, emerges between the tube and tracheal wall. "The air-stream has to be interrupted several times a minute for only about two seconds at a time" (S. J. Meltzer, in "Keen's Surgery," vol. vi). (See Insufflation Anesthesia, p. 1340.)

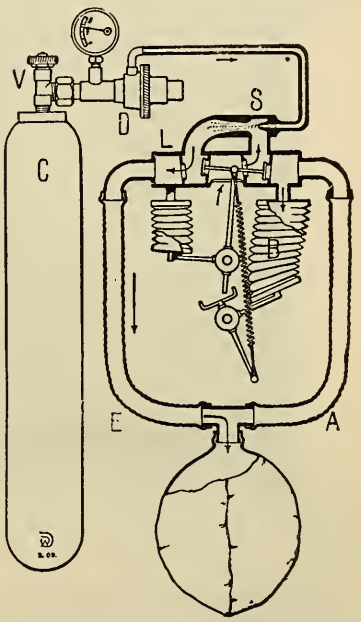

Fig. 616.—Diagrammatic illustration showing the action of the pulmotor. (See text for explanation of letters.)

Artificial Respiration by the Pulmotor.—The pulmotor is a most ingenious apparatus. It is for two purposes: (1) To give artificial respiration; (2) to administer oxygen.

Both the administration of oxygen and the production of artificial respiration are accomplished by means of oxygen which is under pressure. This fact makes the instrument especially valuable in cases of asphyxiation from illuminating gas or other poisonous vapors. The apparatus should be a part of the equipment of every modern hospital (for work on the ambulance, in the accident ward, and in the operating room), of every gas and electric company, of every mine, should be accessible at resorts where bathers congregate in any large number, and should be on the ground at every city fire.

The apparatus is contained in a narrow wooden case which can be carried by one person. The weight of the case with the apparatus is less than 50 pounds. A diagram of the apparatus (Fig. 616) is here given which shows its mechanism: C is a cylinder containing 11½ cubic feet of oxygen, which will keep the apparatus in operation and create artificial respiration for forty minutes; V is a valve which opens and closes the oxygen tank and which is the sole governor of the apparatus.

The mask is fitted on the patient's head as in Fig. 617. The oxygen is then turned on by the valve V. The oxygen passes through the reducing valve D to the injector S, which has the property of drawing in a large volume of air with a certain force of suction, and propelling that air forward with equal force through the flexible tube in front of the injector. This suction and delivery injector therefore serves as a motor, automatically filling the lungs by pressure and emptying them by suction. The suction is accomplished by the leather accordion bellows B, which effects without cessation the automatic reversal of the apparatus from suction to delivery and vice versâ. During inflation the same pressure obtains in the bellows as in the lungs, but as soon as the latter are filled the bellows becomes inflated, and in moving forward throws over the valve in the reversing chamber L, which becomes reversed into position for suction. This operation is now reversed, and as soon as the lungs have been emptied the bellows contracts and automatically reverses the valve into position for inflation.

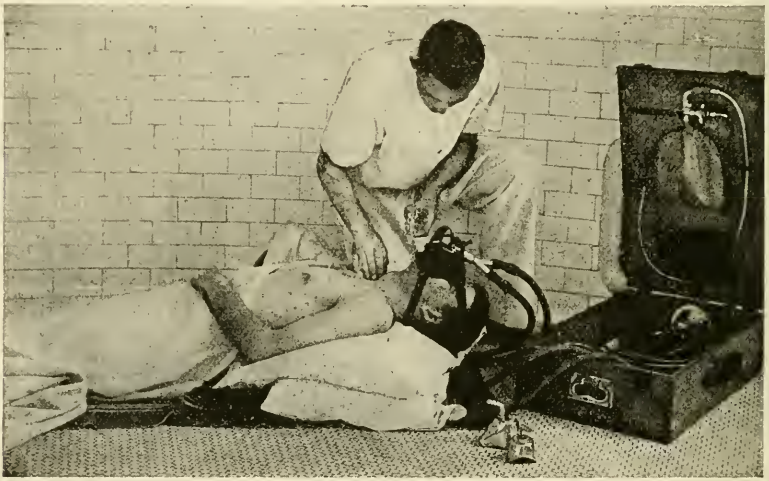

Fig. 617.—Application of mask of pulmotor, the tongue being held forward by forceps, and oxygen prevented from entering esophagus by pressure with right hand.

The apparatus adapts itself to any pulmonary capacity. The rhythm will be slow when the lungs are capacious and faster when they are of less capacity. It causes all the movements of respiration without any assistance being required from the hands other than to keep the windpipe of the patient open and the gullet closed in order that air will not be forced into the stomach. This latter maneuver is accomplished by placing the hand on the windpipe, as in Fig. 617, and making pressure sufficient to close the esophagus. The tongue must, of course, be held forward, as in Fig. 617.

The apparatus is devised so that no residual air from the system can find its way into the lungs again. In this way no air contaminated with poisonous or asphyxiating gas is breathed.

After respiration has been established, the lever, which is seen in Fig. 616, is thrown from pulmotor to inhalation, and oxygen is then given as shown in Fig. 618.

In addition to this regular sized pulmotor, there is an infant pulmotor which is especially adapted for use in maternity hospitals and by obstetricians. Both the adult and the infant apparatus have a lever with which the operator can regulate expiration and inspiration at will instead of using the automatic bellows.

If the mask fits, the pulmotor works as it should. If it does not fit, it fails.

The mask fits some faces and not others. A great need of the instrument is a certainly and universally adjustable mask.

The pulmotor has failed to reach our expectations. Experiments show that the air delivered by the pulmotor does not contain more than 30 per cent. of oxygen. The positive and negative pressures succeed each other so rapidly that the lungs are never properly inflated and the reducing valve is very apt to get out of order (Y. Henderson, in "Jour. Am. Med. Assoc.," 1916, lxvii).

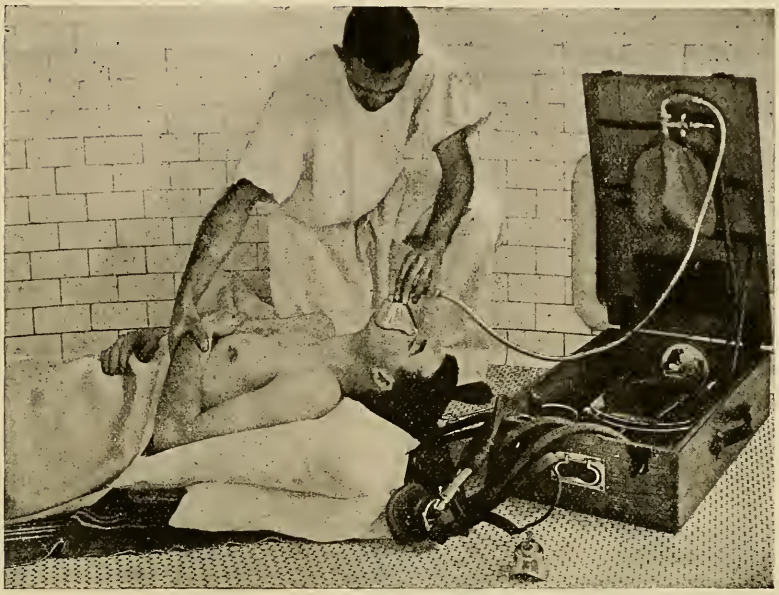

Fig. 618.—Administration of oxygen after respirations have been established.

Artificial Respiration by the Lungmotor.—This apparatus not only furnishes air to the lungs but also causes the thorax to exert the proper suction upon the great vessels and heart. This instrument is worked by hand and it can be adjusted to any subject with great rapidity. Before using the instrument a tube is inserted into the esophagus. By squeezing a hand bulb a bulb within the esophagus is distended so as to block that canal. In this way it is made certain that air will not enter the stomach instead of the lungs. The mask is then fastened in place and the air pumps are worked. One makes pressure, the other suction. When the handle is lifted cylinder E (Fig. 619) fills with air drawn from the lungs and cylinder A with air, with O or with air and O, as may be desired. When the handle is pushed downward the air or the O mixture is forced into the lungs and the expired air is forced out of the suction cylinder. The marks on the handle of the piston indicate the degree of movement necessary for age periods.

Drowning is asphyxia brought about by having the mouth and nose submerged in fluid, air being thus excluded from the lungs. It is not only water that may be responsible for drowning. An individual may be drowned in mud or in a cesspool. Drowning is a common accident. Every year in the United States there are at least 15,000 deaths from drowning.

Phenomena of Drowning.—As asphyxia begins the victim struggles frightfully and clutches at anything that seems to be within reach. He usually sinks and rises an uncertain number of times. The old rule of three times has no particular force. It may be that the victim sinks and rises oftener, it may be that he does so less frequently. He may not rise at all. During the

awful struggle air and water are inhaled, and, as a rule, some of the water is cast out by vomiting and violent cough. During drowning water is certain to be drawn into the bronchial tubes. It is doubtful if any water enters the air-vesicles. They become distended with CO_2 and other gases (J. M. Booher). While this struggle is going on the blood becomes less and less oxygenated, exhaustion deepens; finally the patient sinks to rise no more, some air is forced from the lungs causing bubbles on the surface of the stream, the ears ring, the muscles are convulsed, the mind wanders, merciful insensibility arrives, and death follows. During the mental wandering the memory may take clear and extensive or irregular and incoherent journeys through the events of years or a lifetime, but this does not always happen.

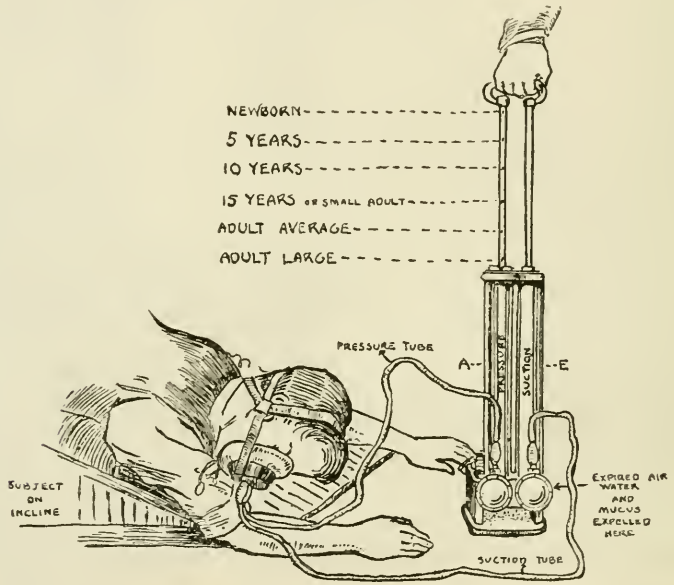

Fig. 619.—This illustration shows the lungmotor giving air only. A small self-contained oxygen generator is regularly supplied with the outfit. The instrument can be used with an ordinary oxygen tank.

The duration of the death struggle is uncertain: it may be very brief, it may last a considerable time. The weaker a person is, the sooner it is over. It is probable that death occurs in two minutes after the final sinking. In spite of some specially trained divers being able to remain in water as long or even longer than this, "we may conclude, from all data, that fatal asphyxia is probable at the end of two full minutes' submersion of the head" (Draper's "Legal Medicine").

A man may die when under water from some cause other than drowning, for instance from syncope, apoplexy, or cardiac disease. If a man should be taken from the water apparently drowned his face will be swollen and cyanotic, the conjunctivæ reddened, the tongue swollen and not unusually caught between the teeth, the hands may clutch weeds or mud from the bottom, the body will be cold to the touch, the mouth contains fluid which may be bloody, fluid of an identical nature can be poured from the air passages, the stomach also contains water which has been swallowed. In most cases the victim is pulseless and there are no respirations. In less grave cases there is a pulse or perhaps only an occasional heart-beat and possibly an occasional gasp.

Treatment.—Because it is probable that a person is dead after two minutes' continuous immersion is not a sufficient reason for refusing to attempt resusci-

tation when it is alleged that the body has been immersed for longer than that period.

As Draper says, "the evidence as to time may be incorrect, and there are probably exceptional people who would not drown in two minutes. Recuscitation has been successful after five minutes and 1 case is recorded of recovery after twenty-five minutes" (Draper's "Legal Medicine"). The common practice of blowing into the victim's mouth is of no avail as most or all of the breath goes to the stomach. The immensely popular practice of rolling on a barrel is usually insisted upon by Life Savers. It is a poor excuse for artificial respiration and exhausts a living subject. The *ordinary emergency treatment* should be conducted out of doors. The mouth is emptied by turning the body on the face, with the head on a lower level than the body, and holding it so for a few seconds. While this is being done the mouth is opened, the tongue is drawn out, and any foreign matter is removed. The body is turned upon the back, the head and shoulders being slightly elevated. The clothing is rapidly removed, and, while artificial respiration is being made (see page 976), hot bottles and hot blankets are being placed around the body and legs, and the mouth and nostrils are kept free of froth. If the individual makes an effort to breathe, help each respiration along. Give hypodermatic injections of brandy and strychnin.

Artificial respiration is continued until the patient breathes naturally and all cyanosis has passed away. As soon as he can swallow he should be given hot coffee and brandy. If minute follows minute and the patient does not attempt to breathe, we must still continue our efforts. Artificial respiration should not be abandoned for a full hour. Even after he begins to breathe he must be carefully watched for some time, as secondary respiratory failure is not uncommon.

On a battleship and upon the beach of a large seaside resort, where every preparation has been made to treat such accidents, more can be done than is described above. Artificial respiration can be made by the pulmotor by the lungmotor or by the insufflation apparatus of Meltzer and Auer (see page 977). Adrenalin may be injected centripetally, as advised by Crile (see page 538). Hot enemata may be given and galvanism may be applied to the phrenic nerve.

After resuscitation there is danger of exhaustion and of bronchopneumonia.

Hanging.—A physician is occasionally called to a case of attempted suicide by hanging. In these cases there is no fracture and no dislocation of cervical vertebræ, as may occur in legal execution by the drop. The victim is dead or almost dead because of obstruction to the pulmonary air-way, the pressure upon the great vessels of the neck, and perhaps also upon the pneumogastric nerves.

Treatment.—The subject, after being cut down, is treated much like a case of drowning. Resuscitation is always difficult, no matter how soon the victim is cut down. It is impossible if asphyxiation is far advanced.

The neck and chest are bared, cold water may be applied to the head or face, as it sometimes will incite respiration. Artificial respiration is begun at once, external heat is applied, a hot enema containing brandy and hypodermatic injections of brandy are given. When there is distinct lividity, bleed from a vein of the leg (to do so from a vein of the arm might interfere with artificial respiration). Galvanism of the phrenic nerve is advisable. Even when breathing begins there is for some time the gravest danger of relapse and death.

Throttling.—When the assailant grasps the opponent's throat with the hands and squeezes the wind-pipe or larynx and forces it against the vertebræ the victim is said to be throttled. The ordinary fighter makes the attack from in front. The garroter seizes the throat from behind. Death from throttling is death from asphyxia plus an influence from the pressure upon the great vessels.

Treatment.—As for hanging.

Smoke Asphyxia.[1]—One of the first duties required of an intern in a hospital of a large city is ambulance service, and in performing such duty he is not infrequently called upon to attend fires. In fact, any physician may be called upon in such an emergency, and while on the fire ground may meet cases of asphyxiation by smoke. The clinical aspect and the treatment of such cases are not taught in the classroom. Literature on the subject is scanty. It is for these reasons that the author has deemed it expedient to insert a few words regarding it.

There are several factors which govern the character of smoke cases. In the first place, there are many different kinds of smoke. All smoke is hard to bear, but some kinds are worse than others. Some smoke is merely irrespirable, while other smoke is not only irrespirable, but is highly poisonous. Smoke from lumber, varnish, furniture, paper, rags, and wet hay is difficult to tolerate, whereas smoke from pitch, tar, and oils is not so pungent. Smoke impregnated with the fumes of ammonia, sulphur dioxid, chlorin, or pepper and other spices is frightfully irritant. Smoke containing nitric acid is highly irritant, and is apt to produce edema of the glottis and lungs. The hotter the smoke, the more irrespirable it is.

Again, the individual idiosyncrasy or susceptibility of the person plays an important part. It is remarkable how firemen can accustom themselves to remaining in a smoke-laden atmosphere. The older members of a fire department can tolerate smoke much longer than those recently appointed. Firemen learn that the best air is near the floor or near the nozzle of the hose. There is a current of air along the floor, as the smoke naturally tends to rise, and the water carries through the hose a certain amount of air.

For clinical purposes, smoke asphyxia may be divided into three stages: the first stage is that in which the victim is conscious; the second is when consciousness is lost, but respirations are still present; the third stage, when respirations have ceased.

The first symptoms which occur are a choking sensation, severe throbbing in the head, dizziness, nausea, and muscular weakness. If at this time one is able to reach a window or able to leave the building and get fresh air he will probably recover quickly. His eyes are red and watery. He coughs and tries to vomit, and although his face may be hot and sweaty, yet his hands will be cold and clammy. His pulse is slow but bounding. Headache is intense and the eyes burn violently.

A patient in this condition should be rapidly removed to a spot where the air is free from smoke. He should be laid on a blanket. All constricting clothing should be loosened and he ought to be fanned. If he gags or attempts to vomit, but cannot do so, he may be given a drink of an effervescing salt, such as a Seidlitz powder or a dessertspoonful of effervescent sodium phosphate in a tumbler of water. Firemen have great faith in weiss beer. It usually makes them belch and vomit and thus relieves them of much of the mucus and the gases in their lungs and in their stomach. In this manner it acts as does an emetic dose of ipecac in the first stage of bronchitis. A drink which is often given, but which is most injurious, is whisky. The fireman who is a whisky drinker stands smoke poorly, and to take whisky after having been overcome with smoke only adds to the headache and nausea. Usually after vomiting has been induced and after he has had fresh air the fireman is able to return to his work. If he does not rapidly recuperate or should he be overcome a second time, he should not be allowed to return to the smoky atmosphere. If a man who has been overcome by smoke has a chill he must be sent to a hospital. His usefulness is at an end for that fire. When a man becomes unconscious his comrades carry him to the street. Pictures of a very quick and

[1] The author, in "Therapeutic Gazette," March, 1903.

satisfactory fire carry are shown in Figs. 620–622. It is unusual for a man to leave a smoky building conscious and to lose consciousness after reaching the fresh air unless the smoke has been impregnated with Illuminating Gas (page 985).

When an unconscious man is carried from a smoky building he must be taken to a spot where the air is free from smoke, his clothing must be loosened, and his body kept warm with blankets. His hands and face should be rubbed with a coarse towel, and oxygen (which should be carried on all ambulances and on all patrol wagons) should be administered. If the circulation or respiration is weak, he should be given a hypodermatic injection of strychnin or atropin, and when he is able to swallow he can be given a stimulant by mouth (as Hoffmann's anodyne or aromatic spirits of ammonia), or if he is trying to vomit he may be given weiss beer, effervescent sodium phosphate, or Seidlitz powder. He should not be given anything by mouth until he is entirely conscious and able to swallow. I mention this emphatically because I have often seen attempts made to pour whisky or some other stimulant down the throat of an unconscious fireman. The danger of such a procedure is obvious. As soon as practical he should be removed to the nearest hospital. The man should be taken to the *nearest* hospital unless the receiving ward of that hospital is overcrowded. He should then be taken to the next nearest hospital.

The third stage of asphyxiation by smoke is that in which respirations have been suspended. The lips are cyanotic, the skin is cold and clammy, the pupils are fixed, and usually dilated. The conjunctival reflex may be gone. The mouth may be open or, on the other hand, the teeth may be tightly clenched. The pulse is weak and fluttering, even imperceptible. There is frequently bleeding from the nose and mouth and involuntary evacuations of urine and feces may occur. A man in this state should never be placed in an ambulance to be taken to the hospital until respirations have been re-established. I have seen stupid and assertive policemen on many occasions insist on putting such cases in ambulances. He should be quickly laid on his back, all mucus cleared from his throat and mouth, all constricting clothing loosened, torn, or cut away. Artificial respiration is started at once. The pulmotor or lungmotor described on page 977 is most useful under such circumstances. If Sylvester's method is used, oxygen may be administered with a tube through the nostrils. The body must be covered with blankets and the man must be stimulated with strychnin, atropin, camphor, etc. When respirations have been established he may then be removed to the nearest hospital. As a rule, the man should be kept in a hospital at least twelve to twenty-four hours and may then be allowed to go home if there is no complication or sequel. In severe smoke cases there is a tympanitic percussion note extending well above each collarbone and due, I believe, to blocking of bronchial tubes by spasm. It lasts often for several hours and then fades away.

In cases of edema of the glottis from the inhalation of irritant vapor, tracheotomy should be performed and artificial respiration given, oxygen passing in through the tracheotomy tube. It is imperative that the first-aid kits of all ambulances should contain a tracheotomy set. I have been compelled to do a tracheotomy with a penknife upon a fireman lying on the pavement.

A chill or a series of chills not infrequently follows smoke asphyxiation, and a man who has or has had a chill must always be sent to a hospital. If the smoke has been impregnated with ammonia, a piece of gauze or a handkerchief should be saturated with vinegar and held over the face so that the vapor may be inhaled. On the other hand, a few whiffs of diluted ammonia should be given after the inhalation of fumes from acids. The eyes should be carefully treated. Ice-compresses are most grateful. Pieces of lint or gauze are placed on ice and are transferred, when cold, to the eyes. They are changed at frequent intervals. The eyes must be washed with a saturated solution of boric acid at frequent intervals. Even after the acute symptoms have subsided it may be necessary to wear blue glasses for several days and to use an astringent eye-wash twice a day.

To relieve headache an ice-bag can be applied to the head and bromid

should be administered by mouth. Bromid also relieves the severe nervousness which often ensues. Occasionally bronchitis or even bronchopneumonia may occur. Even after mild smoke cases there is usually a cough for several days, the sputum being streaked with black, carbonaceous material.

Inhalation of the vapor of nitric acid is apt to cause edema of the lungs and glottis and death. The acute edema may not come on for some hours after the inhalation. The *treatment* of edema of the lungs consists in venesection, hypodermatic injection of camphorated oil, the administration of alcohol and digitalis, and counterirritation of the chest. The treatment of edema of the glottis is set forth on page 984.

Illuminating Gas-poisoning.—Poisoning by illuminating gas is becoming more common. The statistics for the city of Philadelphia during 1912 showed that 152 cases died from illuminating gas-poisoning. Of these 77 were suicides and 75 were accidental. The number of cases has increased since the substitution of the so-called water-gas for coal-gas. The coal-gas formerly used was not nearly so dangerous. Coal-gas contains a small amount (about 7 per cent.) of carbon monoxid. In comparatively recent years, however, in order to reduce the cost and simplify the manufacture the new water-gas has been used. This is developed by forcing steam through hot coals or coke. To this water-gas hydrocarbons are added (methane, ethane, etc.). The amount of carbon monoxid in water-gas is about 38 per cent.

Jones ("Amer. Jour. Med. Sci.," 1909, vol. cxxxvii) gives as further reasons for the marked increase in poisoning by illuminating gas: first, concentration of population in cities; second, increased susceptibility to emotional states and insanity.

Suicide from illuminating gas is growing in frequency, due to the means being at hand, the known painless nature of the death, and also to the fact that the sale of certain toxic drugs to laymen is now forbidden.

Carbon monoxid has a marked affinity for hemoglobin. It completely destroys the oxygen-carrying power of the red blood-cells and this deprives the tissues of oxygen. It enters the system solely through the lungs. An atmosphere becomes dangerous when it contains 0.05 per cent. of carbon monoxid (Gruber, cited by Edsall, in Osler's "System of Medicine;" Haldane, "An Investigation of Mine Air," 1895). It is not proved whether carbon monoxid has any direct action of its own, or whether it acts solely by robbing the blood of its oxygen. Edsall ("Amer. Jour. Med. Sci.," 1907, and Osler's "System of Medicine") says it is highly probable that both conditions occur. McCombs ("Amer. Jour. Med. Sci.," 1912, vol. cxliv) says that carbon monoxid has a direct toxic action on a human being.

Suicide cases make up approximately one-half of all the fatalities from illuminating gas in Philadelphia and in Massachusetts (McCombs, "Amer. Jour. Med. Sci.," 1912, vol. cxliv). Cases of accidental poisoning are due either to a leak from a gas-pipe or failure to close a gas-jet. Pettenkofer (cited by Edsall, in Osler's "System of Medicine") has shown that the leak may not be in the building itself, but the gas, having escaped from a broken main, may travel through the ground for some distance and finally enter a house. This is especially liable to occur in the winter when the heating of the building causes active motion of the atmosphere, thus drawing gas into the house by aspiration. Numbers of the employees of the large gas companies are overcome while working in the ditches in the city, yet among all such cases that have occurred in the city of Philadelphia there has been but one fatality. This is due to the careful instruction given to the men by the physicians connected with the gas company. The men are not only instructed, but they also carry a first-aid kit and are competent to give immediate treatment.

Illuminating gas-poisoning has been divided into the acute and chronic forms. There is little evidence, however, to support the theory of chronic gas-

poisoning. McCombs (Loc. cit.) has examined the blood of men who are constantly in contact with carbon monoxid, some of whom have been frequently overcome by it. He has found the average blood-count shows polycythemia. He has not noted any cases of muscular weakness, irregularity of the heart, bradycardia, lack of concentration, poor memory, cardiac dilatation, splenic enlargement, or pleural effusion. The acute cases are, of course, well known.

The symptoms of an acute case are ushered in by a sensation of vertigo or dizziness, headache, and muscular weakness. They are often accompanied or even preceded by a throbbing sensation in the head and throbbing of the vessels of the neck. McCombs (Ibid.) states that at first the pulse is slow, from stimulation of the pneumogastric. I have probably never seen a case in so early a stage, as every case I have examined has had a rapid and weak pulse.

During the early stage there is occasionally cerebral excitement. The pupils are dilated and the respirations are increased, both in depth and in frequency. There is no irritation of the mucous membranes. The victim has an odor of gas emanating from him. Unconsciousness now ensues. In some cases, however (as in the case of firemen working in smoke impregnated with illuminating gas), the irritant and suffocative qualities of smoke may overshadow all early symptoms of illuminating gas, and the victim may drop as suddenly as though he had been shot.

The foregoing symptoms have been called by McCombs the first stage of gas-poisoning. He then states that the second stage begins with syncope and ends with apnea. In the second stage, therefore, the patient is unconscious, but respirations are still in progress.

The respirations may be rapid and stertorous or may be of the Cheyne-Stokes type. The face is cyanosed. There is often frothing at the mouth. The froth may contain blood. The blood-pressure falls, but the temperature is usually elevated. There may be general tetaniform convulsions. The pulse is rapid and weak. The temperature varies from 99° to 103° F. Occasionally the temperature may rise rapidly, reaching 105° to 110° F., these cases usually terminating fatally. A great rise of temperature is usually coincident with the development of edema of the lungs. The high temperature is not due to the edema, but is probably due to the overwhelming toxemia. The toxemia is purely hemolytic in origin. The tongue is swollen and is cherry red, and the same peculiar cherry-red color makes its appearance on the skin of the neck, trunk, and buttocks. The blood, if drawn, is bright cherry-red in color and will show by the spectroscope the presence of carbon monoxid.

Edsall ("Amer. Jour. Med. Sci.," 1907) believes that, with the exception of the spectroscope, the best test for carbon monoxid in the blood is the Hoppe-Seyler test. The blood containing carbon monoxid, if treated with twice its volume of a solution of sodium hydrate, yields a beautiful red color when spread on a porcelain plate, while blood not containing carbon monoxid is changed into a dirty, brownish mass.

Katagama's test consists in adding to 10 c.c. of blood, diluted with water, 2 c.c. of ammonium sulphate solution and 0.2 c.c. of 30 per cent. acetic acid. Carbon monoxid blood gives a bright red precipitate, while normal blood gives a greenish precipitate. These tests should be used in cases of coma of uncertain origin.

Pettenkofer insists upon the importance of searching for gas-poisoning as the cause of the trouble, when various persons in the same house have a tendency to wake with headache or nausea.

In the third stage there is coma with apnea. The pulse is more rapid and is weaker. It is often impossible to count the rate. The skin is usually cyanosed, is cold and dry, and occasionally blebs appear on the extremities and the back. Blebs usually occur in chains and are most apt to appear in cases in which the coma persists for twelve hours or longer. The blebs

contain clear serum and have frequently been mistaken for burns from the application of hot-water bags. The reflexes are abolished. There is paralysis of the sphincters. Coma may last for days and yet be followed by a recovery.

Gilman Thompson ("N. Y. Med. Record," July 9, 1904) considers it a bad sign if leukocytosis, which is usually present, is of high degree. Reported cases, however, do not seem to substantiate this belief. The leukocytosis varies from 10,000 to 22,000. Thompson, moreover, reports an increase in the number of red blood-cells. The same observation is made by McCombs, but is denied by Glenn Jones.

Glenn Jones ("Amer. Jour. Med. Sci.," 1909, vol. cxxxvii) found the red cells reduced in number. The specific gravity and the coagulability of the blood are increased.

The pathology of gas-poisoning consists principally of the characteristic cherry-red spots on the surface of the body, the cherry-red color of the blood, and the same color of many or all of the organs. There is usually intense hyperemia of, and occasionally small free hemorrhages into, all the organs. Nephritis is usually present and is apt to be of the acute hemorrhagic type. There may be small scattered hemorrhages throughout the brain and cysts may form as the result of softening. Cardiac dilatation, fatty degeneration of the heart, and splenic enlargement have been described by Koren in cases of supposed chronic gas-poisoning.

The sequelæ of gas-poisoning are principally nervous manifestations. In the milder class of cases nervousness, insomnia, and headache are usually present for several days; in the more severe cases, intention tremors, loss of sexual power, delirium, neuritis, transient hemiplegia, confusional insanity, leptomeningitis, and encephalomyelitis have been reported. Prolonged fever and glycosuria have also been found.

There may be acute congestion of the lungs, edema, emphysema, or bronchopneumonia. McCombs states that all of the sequelæ usually clear up within six months or less, and that cases with sequelæ constitute less than 2 per cent. of all cases, and are usually confined to those persons who have absorbed large amounts of the carbon monoxid. Sequelæ are, of course, more apt to occur in those of advanced years and feeble condition than in those who are young and vigorous.

The prognosis should be based upon the duration of the exposure, the age of the victim, the degree of coma, the condition of the blood, and the character of the pulse and respiration. Usually a short exposure to illuminating gas means a case amenable to treatment and which will promptly recover. Longer exposure, or exposure of the aged and feeble, means a far worse prognosis.

Edsall cites 39 cases treated in the Episcopal Hospital of Philadelphia, of which 34 recovered. Of the 5 fatalities, several were due to sequelæ. If the onset of the symptoms is rapid, if edema develops, or if pronounced hemolytic changes are present, the prognosis is unfavorable. The persistence of coma is highly unfavorable, and Jones states that all cases that develop cutaneous blebs end fatally.

The treatment of poisoning by illuminating gas must be prompt and heroic. In the milder cases, in which there is neither coma nor apnea, the patient must be removed to an atmosphere free from the poison and must be given oxygen freely. The object of all treatment is to give oxygen in sufficient quantities to displace the carbon monoxid from the blood. Nausea and the feeling of fulness in the stomach can be relieved by the administration of effervescent sodium phosphate, Seidlitz powder, or a bottle of weiss beer. These procedures will usually cause vomiting and give relief. The patient should be kept quiet, an ice-bag being applied to the head to relieve the headache. Doses of bromid of potash will give comfort. Hoffmann's anodyne and aromatic spirits of ammonia act as useful stimulants and carminatives. Caffein, digitalis, strychnin,

and camphor should be given if necessary. They will hardly be necessary, however, unless the victim is in the second stage or the stage of unconsciousness. When the patient is unconscious, venesection should be performed, followed by transfusion, or by the intravenous injection of salt solution.

The patient must be kept quiet, as many victims have died from sudden exertion. Venesection without the injection of salt solution or without transfusion is usually condemned, but Halsted reported 2 cases in which he thought it did good. Transfusion of defibrinated blood was practised in the 70's and 80's and successful cases were reported. Reinfusion of blood was attempted by Halsted in 1884, at which time he reported a successful case: 512 c.c. of blood were withdrawn from the radial artery, defibrinated and strained, and 280 c.c. were reinfused into the artery. In 1907 Crile and Lenhart reported studies of transfusion, and their procedure supplanted all former methods of treatment.

Of course, in the third stage, that of coma with apnea, artificial respiration must be made, and for this purpose the pulmotor is most valuable, as it not only gives artificial respiration, but at the same time administers large quantities of oxygen under pressure.

Massage is an important feature of treatment. It increases circulation in the extremities. Transfusion, of course, requires the presence of a skilled surgeon, whereas intravenous injection of saline solution is not nearly so difficult a procedure. It is most important that artificial respiration should not be abandoned for a number of hours, as cases have been reported in which artificial respiration was finally successful after a period of six hours. In conditions which lead one to suspect that chronic poisoning may be present, the cause should be sought and, if found, removed, and the case be treated symptomatically. The general public should be instructed as to the danger of acute gas-poisoning.

Diseases and Injuries of the Nose and Antrum

Foreign bodies in the nose (see Poulet on "Foreign Bodies in Surgery") are usually introduced through the anterior nares, but in rare instances during swallowing they enter by way of the posterior nares, a sudden expiration being the cause of the entry. During vomiting foreign bodies may enter the posterior nares. Small particles are often expelled spontaneously; larger pieces collect mucus and epithelium and become fixed. Some materials swell after lodgment. Others become encrusted with lime salts. Seeds may sprout. In very rare cases insects enter and lodge. Cases are on record of leeches, taken in with drinking-water, passing into the nasal fossæ from the pharynx. In the tropics flies may deposit within the anterior nares larvæ which develop with great rapidity. A foreign body is usually near the floor and may be between the vomer and turbinate bones. It may shift after lodgment.

Treatment.—In many cases general anesthesia is required. Illuminate the nostril, and, if the foreign body can be seen, insert a hook back of it and effect its removal by means of forceps. Some foreign bodies must be pushed back into the nasopharynx. Occasionally expulsion may be effected by inserting a rubber tube into the unblocked nostril and telling the patient to blow forcibly through the tube. In serious cases a specialist should be summoned to remove a portion of the turbinated bone or to perform whatever operation he may think best.

Inflammation and Abscess of the Antrum of Highmore (the Maxillary Antrum).—The source of this disease may be inflammation within the nose or periostitis around the roots of the teeth which are in relation with the antral floor. Apical disease of the roots may be demonstrable by the *x*-rays only. In some cases the natural opening into the meatus is patent; in other cases it is partly or completely blocked. Caries and necrosis may arise. The **symptoms** are pain, edematous swelling of the face, and thinning of the

bone so that it may crepitate under pressure. When pus has formed, if the antral opening is patent, certain positions of the head will cause a purulent flow from the nose, and if a speculum is inserted pus may be seen as it flows into the nose. The opening of the maxillary antrum into the nasal channel is at the summit of the antrum; hence the antrum drains when the head is inverted. The ethmoidal cells and frontal sinus drain best when the patient is upright. Wipe the interior of the nose and place the patient with his head between his knees. If the nostril fills with pus, it comes from the antrum (Cobb). In severe cases the jaw expands, the eye protrudes, and great tenderness of the alveolus exists. Percussion exhibits a dull note. In making a diagnosis it is well to take the patient into a dark room, insert an electric light into the mouth and note the diminution of light transmission on the diseased side as contrasted with the sound side. Transillumination may be easily practised by the use of a cautery electrode, protected by a small glass vial. Any cautery battery may be employed (plan suggested by Ohls). Exploratory puncture will settle a doubtful diagnosis. This may be by way of the lower meatus, the canine fossa, or the alveolar process.[1]

Treatment.—Before pus forms order the use of hot fomentations and remove any diseased teeth. When pus has formed, evacuate it at once. Before performing a severe operation try the effect of opening into the antrum from the nose, by means of Krause's trocar, followed by insufflation of iodoform. If this procedure fails, other means may be employed. If the disease arises from a carious tooth, pull the tooth and push a trocar through its socket into the antrum. If the teeth are sound, bore a hole with a large gimlet or with a bone-drill above the root of the second bicuspid tooth and 1 inch above the edge of the gum. A counteropening should be made into the inferior nasal meatus. A drainage-tube is pulled from the first opening into the nose and is allowed to protrude from the nostril. Irrigate daily with normal salt solution. In three or four days discontinue through-and-through drainage, but prevent the first opening closing until the discharge ceases to be purulent. In severe cases make a free incision through the canine fossa by means of a chisel.

Distention and Abscess of the Frontal Sinus.—The anatomy of the frontal sinus is extremely variable. It is not constant in size or in shape. The right and left sinuses are nearly always asymmetrical and "either or both may be present in duplicate or triplicate" (J. Parsons Schaeffer, in "Annals of Surgery," Dec., 1916). The usual cause of abscess is an injury which may long antedate the symptoms. This injury causes or leads to blocking of the infundibulum; secretion accumulates and distends the sinus, and in some cases pus forms. In many cases the fluid slowly accumulates, and it may require years to produce marked symptoms. In other cases infection takes place early or existed from the start, and the symptoms are positive and violent. If the outlet into the nose is not permanently blocked, the fluid may discharge itself from time to time. In the chronic cases there is seldom much pain. The chief sign is a swelling of the inner or upper part of the orbit, which swelling progressively increases and finally displaces the eye. If at any time acute symptoms supervene, there will be pulsatile pain, discoloration, and tenderness.

Treatment.—In some cases it is possible to pass a trocar upward from the nose into the sinus, and so drain and irrigate. In most cases an incision should be made through the soft parts, and the sinus be opened by a trephine or chisel. After the sinus has been opened it must be curetted. The opening into the meatus should be restored and enlarged, and a drainage-tube must be passed from the forehead incision into the nostril. I usually prefer to open the sinus by making an osteoplastic flap in the anterior wall.

[1] Cobb, in "Boston Med. and Surg. Jour.," May 7, 1896.

Diseases and Injuries of the Larynx and Trachea

Edema of the Larynx (*Edema of the Glottis*).—The causes of edema of the larynx are: acute laryngitis; chronic diseases, such as tuberculosis, malignant disease, or syphilis; inflammatory disorders, such as diphtheria and erysipelas; acute infectious diseases; Bright's disease; aneurysm; whooping-cough, pneumonia; quinsy; wounds of the larynx; wounds of the neck; scalds and burns of the larynx, and the inhalation of irritating vapors, such as those of ammonia, nitric acid, or sulphur.

The symptoms are sudden and rapidly increasing dyspnea, respiratory stridor, huskiness of the voice, and finally aphonia. The swollen epiglottis may be felt with the finger and may be seen with the help of a mirror.

Treatment.—In cases in which edema of the larynx is not excessively acute, introduce a gag between the teeth, hold the mouth open, take a knife wrapped to within ¼ inch of its point, make multiple punctures into the epiglottis, and favor bleeding by the inhalation of steam. In severe cases perform intubation or tracheotomy.

Wounds and Injuries of the Larynx.—The larynx may be injured internally by foreign bodies, and externally by blows and cuts. A condition often met with is *cut throat*, the result usually of a suicidal attempt on the part of the patient or a homicidal effort on the part of an assailant. The cut of the suicide is usually in front; as a rule, it misses the great vessels, but divides the cricothyroid or thyrohyoid membrane. The epiglottis may be incised, or even be cut off. If a large vessel is cut, death rapidly occurs. The immediate dangers of cut throat are hemorrhage, suffocation by blood in the wind-pipe and bronchi, or by displacement of parts, and entrance of air into veins. The secondary dangers are bronchopneumonia, infection and sepsis, exhaustion, and secondary hemorrhage. The remote dangers are stricture and fistula (Keetley).

Treatment.—In wounds of the throat arrest hemorrhage, remove clots from the larynx and trachea, bring about reaction, asepticize the parts as well as possible, suture the deeper structures with silver wire, catgut, or kangaroo-tendon, and the superficial parts with silkworm-gut, dress antiseptically, and place a bandage around the head and chest so as to pull the chin toward the sternum. If laryngeal breathing is much interfered with, perform tracheotomy. Feed the patient through a tube until union is well advanced. The old method of leaving the wound open is to be condemned. When sutures are used, primary union may be obtained. This fact was proved by Henry Morris.

War Wounds of the Larynx and Trachea.—Because of its mobility, the larynx is seldom injured. Sudden death may occur when the larynx is struck. If a bullet penetrates the larynx or trachea stenosis is apt to follow. These cases may be treated by division or by gradual dilatation. Gradual dilatation is carried out above the tracheotomy tube (Canuyt, in "Jour. de med. de Bordeaux," 1916, lxxxvii).

Scalds of the Glottis.—(See section on Burns and Scalds.)

Foreign Bodies in the Air-passages.—The lodgment of foreign bodies in the air-passages is a frequent accident. A multitude of different things have been reported as having lodged in the air-passages. Small solid bodies are usually expelled by coughing. Liquids and solids rarely pass beyond the larynx (except in laryngeal disease or palsy, wounds of the floor of the mouth, cut throat, and in people unconscious or very drunk). In vomiting during or after the administration of an anesthetic or in the vomiting of drunkards the vomited matter may find its way into the larynx or lungs. There is great danger of this accident in an operation upon a patient with intestinal obstruction who has stercoraceous vomiting. In most instances of foreign bodies lodged in the air-passages it will be found that the object was being held

in the mouth when a sudden deep inspiration was taken (often during laughter).

The **symptoms** are *immediate*, due to obstruction by the body and by spasm; and *secondary*, due to the situation of the body and the changes it undergoes or induces.

Lodgment in the pharynx causes violent dyspnea. The body can be seen or felt.

Lodgment in the Larynx.—A foreign body may lodge in the superior opening of the larynx, in the rima, or in the ventricle. In a severe case the patient fights madly for air; his face becomes livid and cyanotic; his veins stand out prominently; speech is impossible, though he may make noises and utter harsh cries; violent coughing begins, and then vomiting; he tries to force a finger down his throat and clutches at his neck; sweat pours from him; he feels a sense of impending dissolution, and he falls unconscious, with incontinence of feces and urine.[1] In a less severe case violent dyspnea gradually departs and the patient lies exhausted; but dyspnea and cough are liable to recur suddenly at any time because of spasm, and they may be induced by a change of position. These attacks of fierce spasmodic cough are not at first linked with expectoration, but after inflammation begins there is a profuse and often bloody expectoration. Inflammation follows more rapidly the lodgment of a sharp or irregular body than it does that of a round or smooth one. Inflammation is apt to produce edema of the glottis, bronchopneumonia, or ulceration and necrosis of the larynx. Any sort of foregin body in the larynx may at any moment produce spasmodic dyspnea, and is always very liable to cause edema of the glottis. The body if bony or metallic can be detected by the *x*-rays. A body may remain lodged in the ventricle for a long time without producing symptoms.

Lodgment in the Trachea.—The immediate symptoms of a foreign body in the trachea depend on the shape and weight of the body, and whether it becomes fixed in the mucous membrane or moves to and fro with the air-current. A smooth, heavy body falls to the tracheal bifurcation, and, if it does not enter a bronchus, moves with every breath, and by its movement causes violent laryngeal spasm, cough, and whooping inspiration without aphonia. The patient is often conscious of the movements of the foreign body, and the surgeon may detect them by the stethoscope. The foreign body may be found by the Röntgen rays. A foreign body in the trachea is liable to cause death by suffocation, or it may ascend so as to be caught in the larynx, or may even be expelled. Irregular or sharp bodies lodge in the mucous membrane, produce inflammation, frequent cough and expectoration, and finally lead to ulceration. Bodies which swell from heat and moisture tend to lodge and to become fixed (seeds may sprout).

Lodgment in a Bronchus.—Foreign bodies in the bronchi seriously endanger life. They usually lodge in the right bronchus. The right bronchus is more nearly the direct continuation of the trachea than the left bronchus. When a small area of lung is obstructed the obstructed side shows diminished respiratory movement and murmur with occasional whistling sounds and large moist râles; the percussion-note is at first normal and later dull. When an entire lobe is obstructed all respiratory sounds are absent over it, and over the unobstructed lung respiration is exaggerated; the percussion-note over the obstructed area is at first resonant, but becomes dull. The *x*-rays will often enable the surgeon to detect foreign bodies in a bronchus. Lodgment in a bronchus may cause bronchopneumonia, abscess, hemorrhage, and even gangrene. In some cases the body has been expelled spontaneously. In rare instances people have lived for years with lodged foreign bodies. If death does not soon follow the lodgment of a foreign body, an abscess is very apt to form.

Professor Chevalier Jackson ("Am. Jour. Med. Sciences," Nov., 1918) points

[1] See Moullin's graphic description in his "Treatise on Surgery."

out an important symptom of the presence of a foreign body in the trachea or bronchi. He calls it the *asthmatoid wheeze*. The surgeon listens for it with his ear near the patient's open mouth. In some cases it is audible at a considerable distance. In asthma the wheezing is more apt to be associated with râles than in a foreign body case.

Fig. 623.—Author's case of pin in bronchus removed by low tracheotomy.

Treatment.—If a foreign body lodges in the pharynx, try to pull it forward; if this fails, it may be wise to push it back into the esophagus. In lodgment in the larynx or below, if the symptoms are very urgent, at once perform quick laryngotomy or tracheotomy. If the symptoms are not so urgent, get a complete history of the accident and find out the nature of the foreign body. Be sure that a foreign body is really retained in the respiratory

Fig. 624.—Gibbon's case of tack in the right bronchus removed by low tracheotomy, child six years old.

tract, and then try to determine what its situation may be. A person sometimes imagines a body is lodged when it has been expelled or even when it has never been in the larynx, trachea, or bronchus, but has been swallowed. Often a laryngologist can remove a foreign body from the larynx by means of forceps, a mirror and lamp being used for illumination. The fauces and upper portion of the larynx should have cocain applied to them to lessen pain and spasm. If the surgeon fails in extraction by forceps, and laryngotomy has been per-

formed, continue the search through the opening in the cricothyroid membrane; if laryngotomy has not been performed, let the larynx be opened by *thyrotomy* (a vertical incision between the alæ of the thyroid cartilage, and the separation of these alæ to permit of exploration). After a thyrotomy suture the perichondrium with catgut. If the foreign body is in the trachea, perform ordinary tracheotomy; if it is in a bronchus, perform low tracheotomy. Tracheotomy prevents suffocation from laryngeal spasm or edema of the glottis. It may be possible to remove the body in the bronchus through the incision of a low tracheotomy, and this ought to be tried. By this method I succeeded in 5 cases, removing a pin, a bone, a bean, a tack, and a broken tracheotomy tube from the right bronchus. The foreign body may be expelled through the tracheotomy wound; if it is not expelled, search the trachea and bronchi with Gross's forceps, with probes, with hooks, or with the finger. If the foreign body cannot be found, put the patient to bed and maintain a moist atmosphere in the room. As a rule, when the foreign body is not found, insert a tube. If the foreign body be extracted, do not insert a tube (unless edema of the glottis exists or is likely to come on), do not suture the wound, but cover it with moist gauze and let it heal by granulation. Morphin and sedative cough-mixtures are given. Gross says that even when a foreign body has long been retained an operation should be performed if the air-passages are not seriously diseased. What shall be done when a foreign body is lodged in a bronchus and we are unable to extract it through a tracheotomy wound or by tracheobronchoscopy? Truc said if "the patient is in danger of death" cut through the chest-wall and attempt to remove the body. He said this with a full knowledge of the difficulty of locating the body. This difficulty has been partly overcome by the *x*-rays, and it seems now more certainly our duty to operate than it was a short time ago. Nasiloff proposed to reach the obstruction by the posterior route after rib resection. Curtis attempted this, and though the patient died, his operation proves that the method is feasible. An operation by the posterior route should be performed at once if low tracheotomy fails. The danger of pulmonary collapse will be abolished by the use of a suitable apparatus to prevent it (see pages 1020 and 1032).

Tracheobronchoscopy.—Killian, of Freiburg, devised a bronchoscope for introduction through a tracheotomy wound. I have used the endoscope in this manner. Later Killian devised a straight instrument which could be used through the mouth and larynx, tracheotomy being unnecessary. During its introduction the head was held far back.

Brüning, of Freiburg, improved the instrument. His tube is long enough to reach between the vocal cords to the divisions of the bronchi. In 1907 Killian was able to collect 164 cases of foreign bodies removed by this direct method.

My colleague, Professor Chevalier Jackson, has devised a tracheobronchoscope through which he has succeeded in removing foreign bodies from the trachea and from a bronchus. In 10 cases of foreign body in the bronchus he removed the offender in 7. In 7 cases of foreign body in the trachea he was successful in each case, but 2 of the cases required tracheotomy. Whenever there is dyspnea he always prepares to do tracheotomy ("Annals of Surgery," March, 1908). In Jackson's highly trained hands the instrument is incomparably useful, but an untrained man with it would be like, or rather would be worse than an untrained man with a cystoscope. When used by a fully trained man the instrument prevents many cutting operations and saves many lives (see page 996).

Operations on the Larynx and Trachea

Tracheotomy.—In a formal operation give ether or chloroform, but in an emergency this cannot be done. The patient may be placed supine with a sand-pillow under the neck and with the head thrown over the end of the

table. If a child, Liston used to wrap it up to the neck in a sheet to prevent movements of the limbs, would seat himself on a chair, place the child upon the nurse's lap, and take its head between his knees. The head must be exactly in the middle line and extended (in an adult this gives 2¾ inches of trachea above the manubrium; in a child of ten, 2¼ inches; in a child of six, about 2 inches). The operator stands to the right side when the patient is supine. If bleeding is profuse when the surgeon is ready to open the trachea, place the patient in the Trendelenburg position with the neck extended. The trachea may be opened above or below the isthmus of the thyroid gland. The isthmus in an adult usually lies over the second and third rings (Figs. 625 and 626). The isthmus in a child usually lies over the first ring or even over the space between the cricoid cartilage and the first ring. The high operation is always chosen except in cases in which it is desired to search for a foreign body in a bronchus.

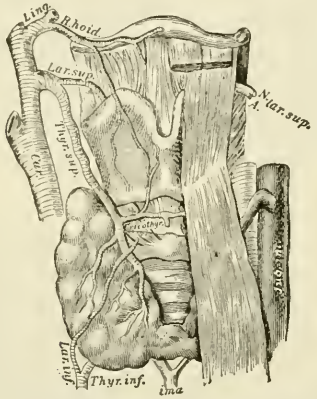

Fig. 625.—Blood-supply of the larynx and trachea (Esmarch and Kowalzig).

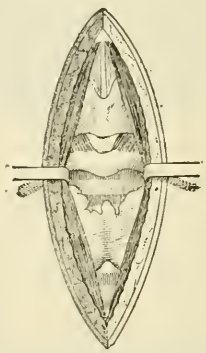

Fig. 626.—Parts exposed in tracheotomy (Esmarch and Kowalzig).

High tracheotomy is preferred because in this region the muscles are distinctly separated (Fig. 625), the main vessels of the neck and the inferior thyroid vessels are not encountered, the anterior jugular veins are small and have very few transverse branches, and the trachea is near the surface (Treves). The surgeon accurately locates the cricoid and thyroid cartilages. An incision is begun at the upper border of the cricoid cartilage, and is carried down precisely in the middle line for about 1½ inches. Treves advises the operator to steady the skin of the neck with the fingers of the left hand and to cut with the unsupported right hand (if the hand be supported, the respirations will interfere with the operation). The skin, the superficial fascia, and the anterior layer of the cervical fascia are incised, the sternohyoid and sternothyroid muscles are separated, and the fascia over the trachea is divided. This fascia is attached above to the cricoid cartilage, and it divides below into two layers to invest the thyroid body and its isthmus. If veins are in the line of the incision, they are pushed aside, but it is not necessary to take the time to apply double ligatures. Even if bleeding is profuse, as soon as the trachea is opened and air enters freely into the lungs, venous congestion is relieved and bleeding is apt to cease. If hemorrhage be violent and the veins are not at once caught by forceps, it may be well to place the patient in the Trendelenburg position before incising the windpipe, in order to prevent the entrance of blood into the lungs. Before opening the trachea the isthmus of the thyroid gland is pushed downward; if it cannot be pushed down sufficiently, a transverse incision is made through the fascia at the upper border of the cricoid cartilage, and the fascia and the isthmus with it are lifted off the trachea (Bose's method). A tenacu-

lum is inserted into the cricoid cartilage in order to steady the tube. The back of the knife is turned toward the sternum, a finger being held upon the blade to prevent too deep a cut being made. The knife is plunged, as if it were a trocar, into the midline of the trachea above the isthmus, and two or three rings are divided from below upward. The hook is not removed until the operation is completed. If a foreign body is present, an attempt is made to remove it; if success attends the effort, no tube need be worn; but if the body is not found, a tube must be used. In croup or diphtheria remove membrane (by means of a feather and a solution composed of bicarbonate of sodium 2 oz., glycerin 1 oz., water 10 oz.—Parker) and insert a tube. The edge of the cut is grasped with the dissecting forceps, the mucous membrane being included in the bite; the head is placed erect, the tube is introduced, and the tenaculum is removed. Secure the tube by tapes, and suture the wound below the tube. Remove the tube at the first moment consistent with safety. After tracheotomy put a screen around the bed; have the air kept moist by steam; remove the inner tube and clean it every few hours at first; clean the outer tube whenever required. In croup or diphtheria put the patient in a croup tent and keep the air moist by a steam atomizer or a croup kettle. Remove and clean the inner tube every two hours. Clean the larynx and trachea from time to time by means of a feather and Parker's solution.

Quick laryngotomy must never be attempted upon a child under thirteen years of age, because of the small size of the cricothyroid space before this age (Treves). In view of the difficulty of introducing a tube and of wearing it so near the vocal cords, laryngotomy should not be performed for croup, diphtheria, or for any condition in which a tube must be long worn. The operation is performed as follows: Make an incision 1¼ inches in length in the middle line, from above the level of the lower edge of the thyroid cartilage to below the level of the lower border of the cricoid cartilage. Divide the skin, superficial fascia, and deep fascia, separate the cricothyroid and sternothyroid muscles, divide the deep layer of fascia, and cut the cricothyroid membrane transversely just above the cricoid cartilage. The tube must be shorter than the ordinary tracheotomy tube. An operation which opens vertically the cricothyroid membrane, the cricoid cartilage, and the upper rings of the trachea is called *laryngotracheotomy*.

Intubation of the Larynx (*O'Dwyer's Operation*).—Bouchot conceived the idea of intubation; O'Dwyer perfected it and made it a genuine scientific proceeding. The instruments required for the performance of this operation are a mouth-gag, an instrument to hold the tube and introduce it, and an instrument for extracting the tube. The collar of the tube has a perforation through which is fastened a piece of silk with which the tube can be withdrawn. The child is wrapped in a sheet to secure the limbs, is seated in a nurse's lap, and its head is held by an assistant. The jaws are opened and held apart by the self-retaining mouth-gag. The surgeon sits in front of the patient, wraps a piece of rubber plaster about the index-finger of his left hand, and passes the finger into the child's mouth until its tip touches the epiglottis. He introduces the holder and tube (observing if the silk is free) along the surface of the tongue until the obturator touches the epiglottis; raises the epiglottis with the left index-finger, and passes the tube into the larynx; places the left index-finger against the tube, and withdraws the holder with the right hand. The silken thread is tied to the ear, and the nurse is directed to employ the thread to remove the obturator if it becomes obstructed or is coughed up. The tube is removed in two or three days; if breathing is easy, it is not reintroduced; but if dyspnea recurs, it is replaced for two or three days more. If, in introducing the tube, a mass of false membrane is pushed before it into the trachea, breathing ceases, and, if the mass is not at once coughed up, tracheotomy must be performed. Feed these patients on semisolids rather than upon liquids (mush, soft eggs, and cornstarch); and if trouble occurs in swallowing these articles,

feed by the rectum or by means of a nasal or an oral tube. In opium-poisoning, in asphyxia, in acute traumatic pneumothorax, and in cerebral injuries, intubation may be associated with the use of Fell's apparatus (see page 1021).

Chevalier Jackson's Direct Laryngoscopy, Bronchoscopy, Esophagoscopy and Gastroscopy (My distinguished colleague, Prof. Chevalier Jackson did me the honor to write the following section for this book).—These are procedures using self-illuminated tubes that serve as specula for the endoscopic examination and treatment of the interior of the larynx, trachea, bronchi, esophagus and stomach.

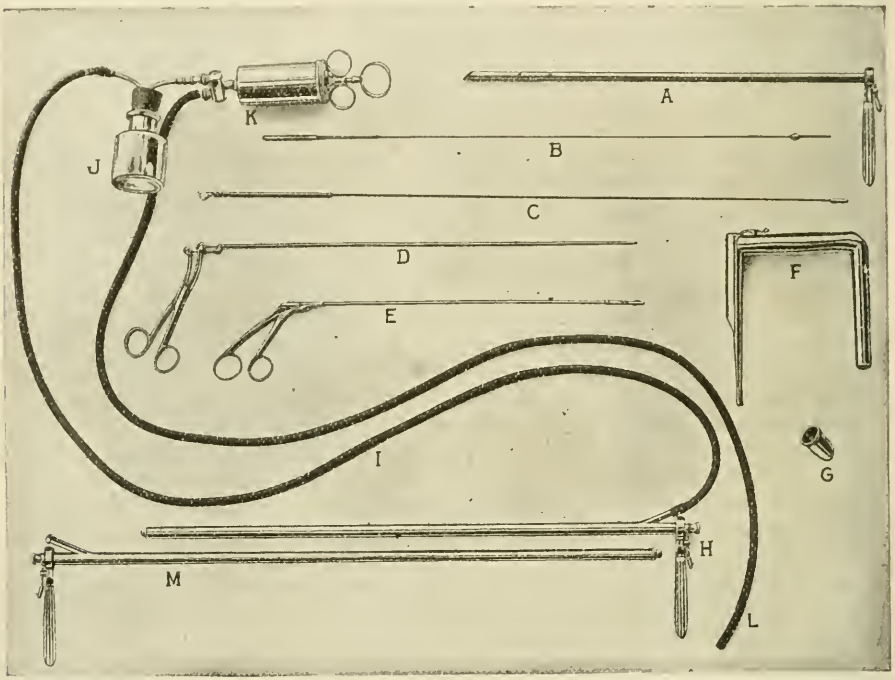

Fig. 627.—Jackson's instruments for direct laryngoscopy, bronchoscopy, and esophagoscopy: *A*, Bronchoscope; *B*, olive bougie for esophagoscopic bouginage; *C*, sponge-holder for sponging the field and obtaining specimens of secretion; *D*, forceps for removing foreign bodies; *E*, forceps for removing tissue; *F*, laryngeal speculum, called also slide speculum and direct laryngoscope; *G*, bite-block; *H*, esophagoscope with tubing (*I*) leading to aspirator (*J*, *K*) for removal of secretions. The tubing (*L*) is connected with the positive pressure side of the syringe (*K*) for use when needed to blow out obstructions, such as clots of pus, food, etc., that have been aspirated into the drainage canal of the esophagoscope. At *M* is shown a gastroscope. The filiform bougie (Fig. 646) has superseded the olive bougie shown above at *B*.

The endoscopic tubes (Fig. 627) are without lenses and are straight and rigid instruments, serving, as do other specula, to draw out of the way tissues that obstruct direct vision, or to draw the tissues to be inspected into a new position in the line of sight. Through these tubes many ingenious instruments, such as forceps, sponge-holders, loops, hooks, bougies, etc., are used for various procedures, such as removal of foreign bodies, dilatation of strictures, diagnosis of disease by inspection and by removal of specimens of tissues and secretions.

Anesthesia.—For direct laryngoscopy, bronchoscopy and esophagoscopy in children no anesthetic, general or local, is needed after skill in peroral endoscopy is acquired. The procedures are not painful, though disagreeable and somewhat terrifying. Cocain is dangerous in children and other local anesthetics

are unsatisfactory Ether anesthesia is only slightly more dangerous than in ordinary surgical work. General anesthesia is absolutely contraindicated in dyspneic patients, either adults or children. In adults no anesthetic is needed for esophagoscopy or gastroscopy. For direct laryngoscopy and bronchoscopy in adults the cough reflex may be lessened by the hypodermatic injection of morphin in full dosage. This, with the local painting with a small quantity

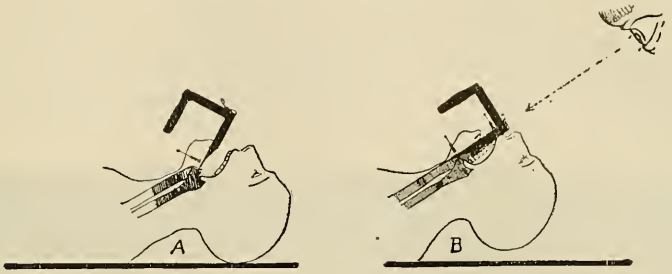

Fig. 628.—Schema illustrating manner of exposure of the larynx with the direct laryngoscope. At *A* the laryngoscope has been inserted posterior to the dorsum of the tongue until the epiglottis has come into view. The laryngoscope is then inserted about 1 centimeter deeper, the spatula tip going posterior to the epiglottis. A strong lifting motion is now exerted in the direction of the dart, even lifting the patient's head from the table as shown at *B*. The glottis and the tracheal axis thus are brought in line with the observer's visual axis.

of a 10 per cent. solution of cocain, using small gauze sponges (Fig. 629) held in the sponge carrier (C, Fig. 627), will suffice in skilful hands. The inexperienced operator will require the patient to be fully relaxed by general anesthesia, preferably ether.

Direct laryngoscopy is so called in contradistinction to ordinary indirect laryngoscopy in which the operator looks, not directly at the larynx but at a reversed image of it in a mirror. Instead of looking down back of the tongue

Fig. 629.—Manner of keeping endoscopic sponges. About a dozen of one size are transfixed on a safety pin, wrapped, the size marked on the wrapper, and then sterilized, to be opened only as needed. About 5 dozen sponges of each of the 4 sizes should be kept on hand. Only one sponge is placed in the sponge-carrier at a time. These sponges are made for the author by Messrs. Johnston and Johnston, of New Brunswick, N. J., and are known as "bronchoscopic sponges."

with the aid of a throat-mirror the tongue is dragged forward out of the way with the direct laryngoscope. Though easier of accomplishment in some patients than in others, the larynx of any human being can be exposed to view by direct laryngoscopy unless the jaws are so ankylosed that the mouth cannot be opened. The technic of the method is shown in Fig. 628. The error which everyone makes on first attempt is the use of the upper teeth as a fulcrum in an effort to *pry* the tongue anteriorly out of the way. Instead, the tongue, the hyoid bone and attached tissues should be *lifted* out of the way with the spatular tip of the laryngoscope. Great care should be taken to avoid pinching the patient's upper lip between the laryngoscope and the teeth. This will cause real pain, vastly harder to endure than any annoyance from the presence of the laryngoscope in the laryngopharynx. For the insertion of a silk-woven

catheter for insufflation anesthesia (Fig. 630) and for endolaryngeal operations the patient's head should be on the table, not hanging over the end. An assistant holds the head, keeping the patient's nose toward the ceiling and extending the head only at the occipitoatloid joint. Rotation of the head would distort the interior landmarks, and extension distributed throughout the cervical spine would obtrude a rigid convexity of the posterior pharyngeal wall. The essential part of the procedure in exposure of the larynx with the direct laryngoscope is, however, the lifting motion (Fig. 628) made as if to suspend the patient by his hyoid bone with the tip of the spatular end of the laryngoscope. Everything else is secondary to this. Much less anteriorly displacing effort is required if the laryngoscope is passed at the side of the tongue (preferably the right side), but experience is required to recognize the thus distorted landmarks.

FIG. 630.—Direct laryngoscopy for the introduction of a silk-woven catheter for intratracheal insufflation anesthesia. The patient's head is on the table, but extended. The anesthetist has exposed the larynx by lifting strongly with the spatular tip of the laryngoscope inserted posterior to the epiglottis.

Papilloma and other benign growths of the larynx are removed with the crushing alligator forceps. Specimens are removed with cutting forceps (E, Fig. 627). In case of large growths, the forceps or snare may be passed along the outside of the laryngoscope, the latter being used only for ocular guidance of the forceps when it comes into view at the distal end of the tube.

Bronchoscopy.—The first step in the introduction of the bronchoscope and the chief technical difficulty to be mastered is the exposure of the glottis by direct laryngoscopy (*q. v.*). Once the art of doing this is mastered, both procedures, exposure of the larynx and the introduction of the bronchoscope, should not require more than a minute, usually less. The bronchoscope can be inserted in any patient whose mouth can be opened. As in all manual procedures practice is necessary. When direct laryngoscopy is done for the introduction of the bronchoscope, the patient's head is brought beyond the head of the table sufficiently far to bring the middle of the patient's scapulæ to the edge of the table. This permits of the patient's head and neck being moved about so as to facilitate following with the bronchoscope various bronchial axes; *but during*

the introduction of the bronchoscope the patient's head must be maintained as high as though the occiput were on the table. If the head is allowed to drop into the Rose position great difficulty in introduction will be encountered. The head is held by an assistant, as shown in Fig. 642.

In Fig. 631, a repetition of Fig. 628 is shown at A, a strong lifting motion being exerted in the direction of the dart. When the glottic chink is seen the bronchoscope, lighted by its own separate cord, is inserted, its handle pointing outward horizontally to the right. The eye of the bronchoscopist is then transferred from the laryngoscope to the bronchoscope. The lip of the latter is then insinuated through the glottis into the trachea. The laryngoscope is then removed by withdrawal of first its slide, afterward itself. If the laryngoscope is allowed to come outward during the removal of the slide there will not be room enough for the withdrawal of the slide without pulling out the bronchoscope so far as to risk withdrawal of the distal end of the bronchoscope from the trachea. This accident would require repetition of the whole procedure. The fact that the bronchoscope is in the trachea and not in the esophagus, is recognized by the strong expiratory blast, the absence of voice and the visible tracheal rings. It must be remembered, however, that there is a slight pseudorespiratory current through a tube in the esophagus, that a very small bronchoscope in the trachea may permit phonation, and that endotracheal inflammation may obliterate the visibility of the rings. The trachea stands open, whereas the cervical esophagus does not; but the posterior wall of the trachea collapses forward, especially in children, and the thoracic esophagus remains somewhat open when an endoscopic tube is in place Some practice is therefore required to be prompt in making sure that the bronchoscope does not enter the esophagus instead of the trachea. To prevent this accident it is well to give a little additional lift to the laryngoscope at the moment when the bronchoscopic tube-mouth is

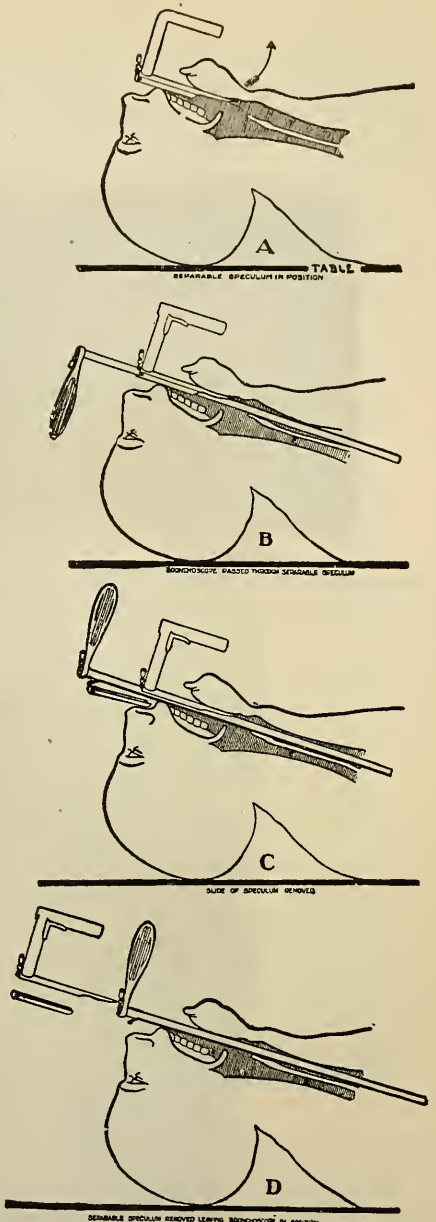

Fig. 631.—Schema illustrating the technic of oral bronchoscopy. The portion of the table here shown under the head is, in actual work, dropped all the way down perpendicularly. It appears in these drawings as a dotted line to emphasize the fact that the head must be above the level of the table during introduction of the bronchoscope into the trachea. *A*, Exposure of larynx; *B*, bronchoscope introduced; *C*, slide removed; *D*, laryngoscope removed, leaving bronchoscope alone in position. The handle of the laryngoscope in *C* and *D* should be shown as rotated down to the left.

inserted into the glottis. Once assured the bronchoscope is in the trachea, the laryngoscope is detached and the bronchoscope is inserted deeper into the tracheobronchial tree. The bifurcation is the first important landmark to be identified. To avoid missing it, and passing unknowingly into the right bronchus, the patient's head is moved slightly to the right, and the left wall of

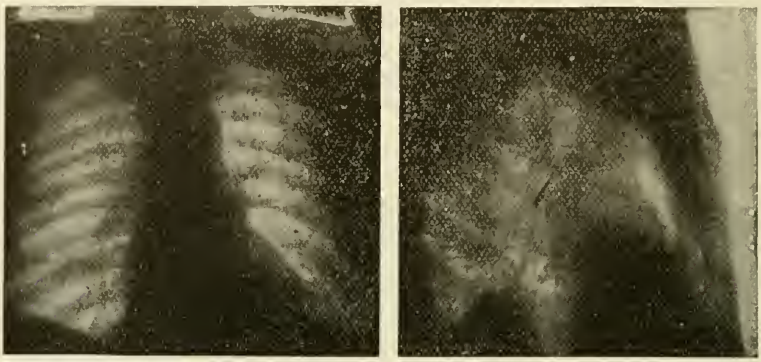

FIG. 632.—Large fence staple in lung of man aged 43 years. Removed bloodlessly by bronchoscopy through the mouth after 2 year's sojourn. Complete cure of septic pulmonary focus resulted.

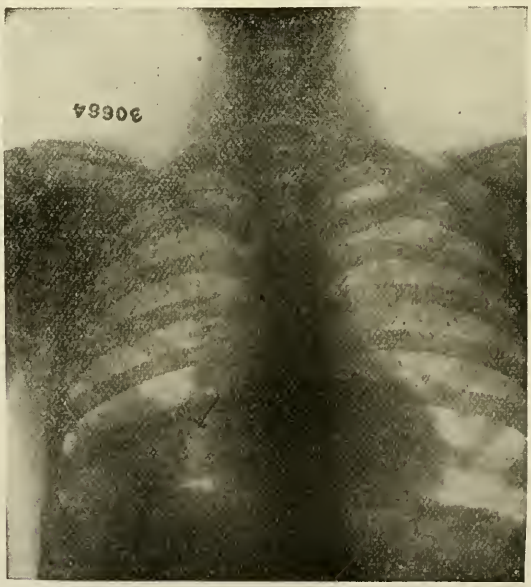

FIG. 633.—Radiograph showing tack in the right main bronchus of a boy, aged eight years. Tack removed by oral bronchoscopy without anesthesia, general or local, in four minutes.

the trachea is watched in order to be certain of exposing the left bronchial orifice. The lip of the bronchoscope, which corresponds to the handle of the instrument, is always turned toward any orifice it is desired to enter, the patient's head being moved to the opposite side. The middle-lobe bronchus is given off anteriorly, being the largest of all anterior branches. To enter it, the lip

of the bronchoscope is turned upward and the patient's head is lowered far below the position proper for introduction of the bronchoscope through the glottis. All the time the bronchoscope is in place, great care must be taken not to pinch the patient's lip between the bronchoscope and the upper teeth, which would cause pain and distress infinitely greater than the presence of the bronchoscope in the lung. The lip is held out of the way by the bronchoscopist's left thumb, after the laryngoscope is removed, the thumb and index finger together fixing the tube against the upper teeth. As with any other surgical procedure, a "dry" field is necessary for clear vision. In bronchoscopy, the sponge is inserted with a carrier (C, Fig. 627) until the sponge emerges at the distal

Fig. 634.—Roentgenogram showing atomizer-tip in right lung of a man, aged fifty-eight years, where it had been for a year and a half. Removed in two minutes, fifty-five seconds under local anesthesia by peroral bronchoscopy. Complete cure of lung condition resulted.

end of the bronchoscope. If the patient does not cough, he is asked to do so. In either case the secretions are coughed into the bronchoscope, from which they are withdrawn by pulling out the sponge-carrier, just as a pump lifts the water that is above the plunger. This "sponge-pumping" is much more rapid and efficient than any form of aspirator with the thick secretions usually encountered in bronchoscopy.

Duration of Bronchoscopy.—This is of such vital importance, especially in case of children, as to merit a separate paragraph. The author's work has demonstrated that the reaction after bronchoscopy, other things being equal, is directly as the duration, and, after a certain limit, directly as the square of the duration. A 15-minute bronchoscopy may be repeated every ten days for months without injury to the health of an infant, whereas a single bronchoscopy may be fatal if continued for an hour. This refers only to the procedure of bronchoscopy *per se*. Of course it may be modified by various factors, such as

the disturbance of the epithelium in the presence of pus, the use of unsterile instruments, etc. A safe working rule, to be modified as deemed best in the individual case, is: One hour in adults, half an hour in children, 15 minutes in infants. As a matter of fact, however, in most cases in our clinic the foreign body is removed by the bronchoscope in less than five minutes.

Bronchoscopic removal of foreign bodies from the trachea and bronchi has been successful in our clinic in over 98 per cent. of our cases. In 386 cases there were 6 failures to remove. The mortality, taking the cases as they came, the condition being good or bad on admission, was 1.7 per cent. In no case was mortality directly attributable to bronchoscopy. Of 41 cases of lung abscess due to foreign body of prolonged sojourn (1 to 26 years) complete cure followed oral bronchoscopic removal in 39 cases.

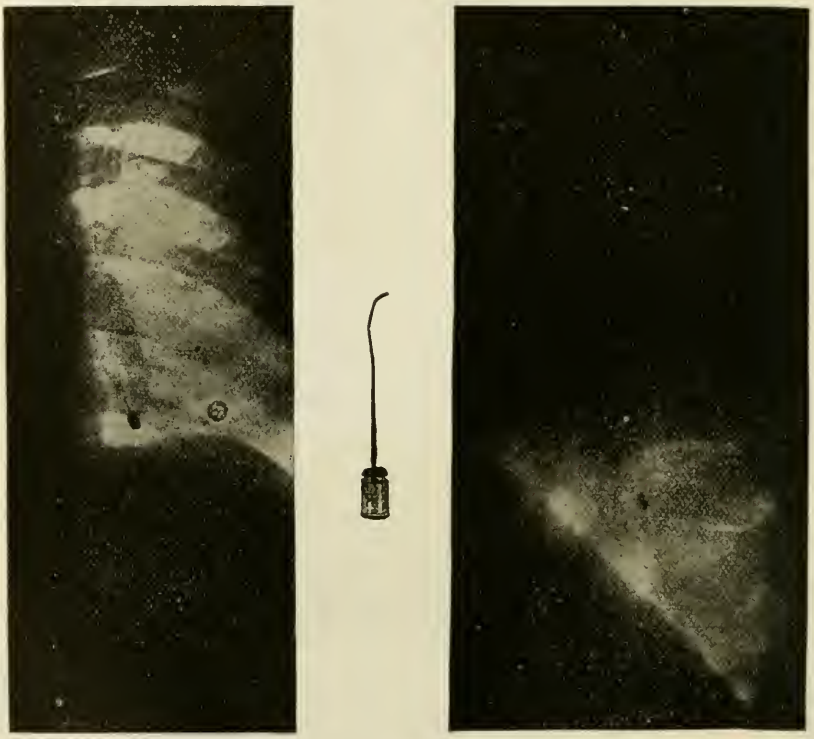

FIG. 635.—Radiographs showing a dental root-canal broach in a small posterior branch of a larger posterior branch of the inferior-lobe bronchus of a man of thirty-nine years. The foreign body is seen just above the dome of the diaphragm in the anteroposterior radiograph, though really in the part of the lung down back of the dome, as shown in the lateral radiograph. Removed through the mouth by bronchoscopy under local anesthesia. This is the lowest position from which a foreign body has ever been removed by bronchoscopy. The full length of a 40-centimeter bronchoscope was barely sufficient to reach it. (Author's case.)

Extreme care is necessary to avoid tearing the bronchi in the use of forceps, and especially in the extrication of entangled pointed foreign bodies such as tacks, nails, pins, safety-pins, etc. In all cases of pointed objects (which are almost invariably point upward) great care is necessary to extricate the point first and to get it into the tube-mouth before any traction is made; otherwise the slightest traction will cause the point to rip in, and crosswise fixation will not only defeat removal but will rupture the bronchial wall and result almost certainly in death from mediastinal emphysema or septic mediastinitis. The cardinal rule is that no harm should be done and if gentle methods are

not successful, in say 25 minutes in case of children, further effort should be postponed for a week, when another radiograph should be made and a new bronchoscopic effort may be made. While it is true that if not removed a

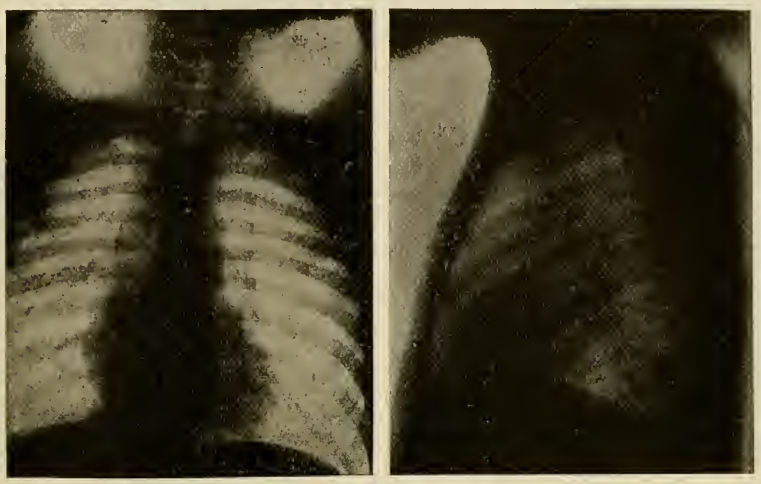

FIG. 636.—Radiograph of a boy, aged eleven years, showing nail that had been in lung for about four years, producing all the symptoms of bronchiectasis. Bronchoscopic removal of the foreign body without anesthesia resulted in complete cure.

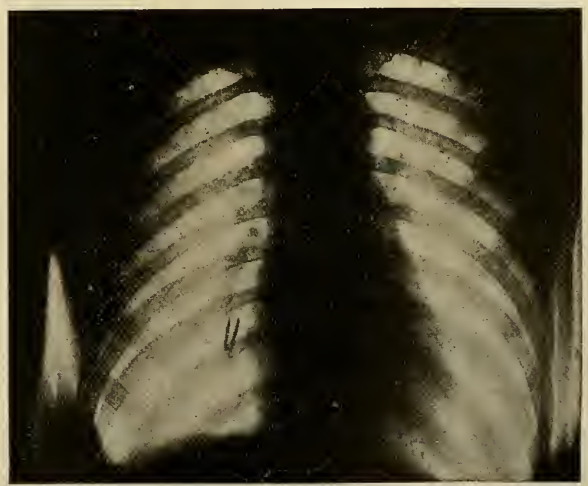

FIG. 637.—Radiograph showing a staple in a posterior branch of the inferior-lobe bronchus, 10 centimeters (4 inches) below the bifurcation of the trachea, in a man aged forty-four years. Staple was turned (version) and removed bloodlessly by bronchoscopy through the mouth. (See Fig. 639.) (Plates made by Dr. George W. Grier. Author's case.)

foreign body in the lung will prove fatal, there is no immediate danger that would justify ruthlessly tearing the foreign body out at all hazards. If no harm is done further study of the mechanical problem involved will almost certainly succeed in solving the problem of safe removal. A few of the many problems and their

solutions are illustrated in Figs. 639, 640, and 647. If the greatest care be not taken a very simple and easy problem of removal may, by an improper touch

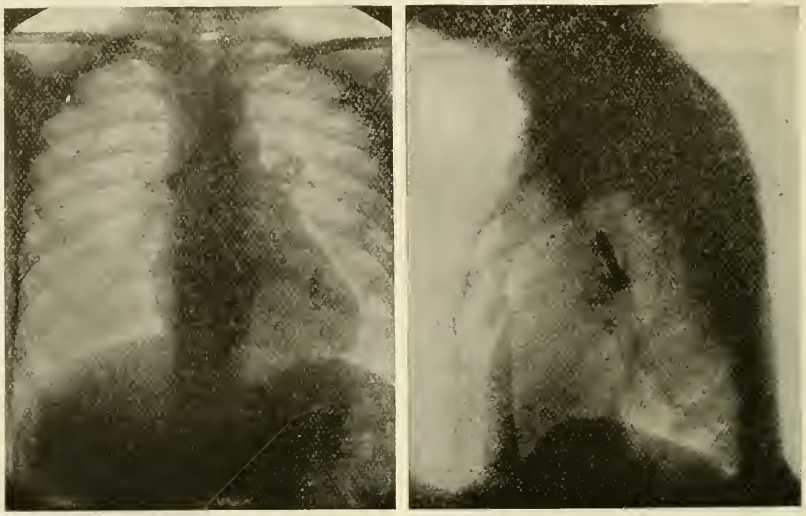

Fig. 638.—Radiographs showing an iron casting in the right bronchus of a child of eight years. Foreign body removed by peroral bronchoscopy without anesthesia in six minutes, fifty-two seconds.

or traction, be converted into an exceedingly difficult problem. In fully half of our cases this has happened before coming to our clinic. Soft, friable objects,

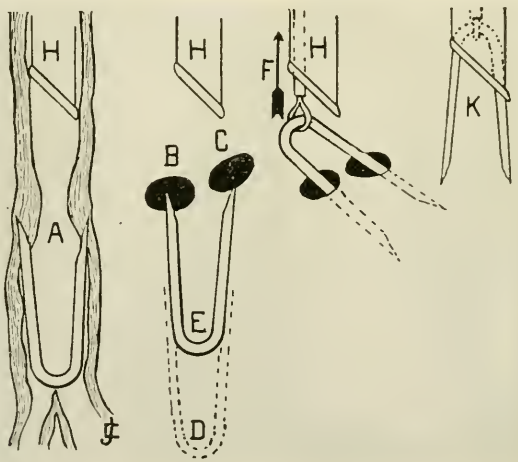

Fig. 639.—Schema illustrating the method of removal of bronchially lodged staples or double-pointed tacks. *H*, Bronchoscope; *A*, swollen mucosa covering points of staple. At *E* the staple has been manipulated upward with bronchoscopic lip and hooks until the points are opposite the branch bronchial orifices, *B*, *C*. Traction being made in the direction of the dart (*f*), by means of the rotation forceps, and counterpressure being made with the bronchoscopic lip on the points of the staple, the points enter the branch bronchi and permit the staple to be turned over and removed, with points trailing harmlessly behind (*K*). This method slightly modified has now been successfully used in 9 cases, without mortality. (See Fig. 637.)

such as nut-kernels, maize, beans, egg-shells, glass, and the like, must be grasped with a delicately calculated forceps-pressure sufficient to hold the foreign body

and prevent its being stripped off at the glottis, yet not sufficient to crush it. The latter disaster is usually fatal from scattering the fragments which are promptly aspirated into many minute bronchi. In the removal of any kind of a foreign body that is too large to come through the bronchoscope, the latter is removed along with the forceps and the foreign body. To get through the glottis the intruder must be turned with its greatest plane sagittally. Other-

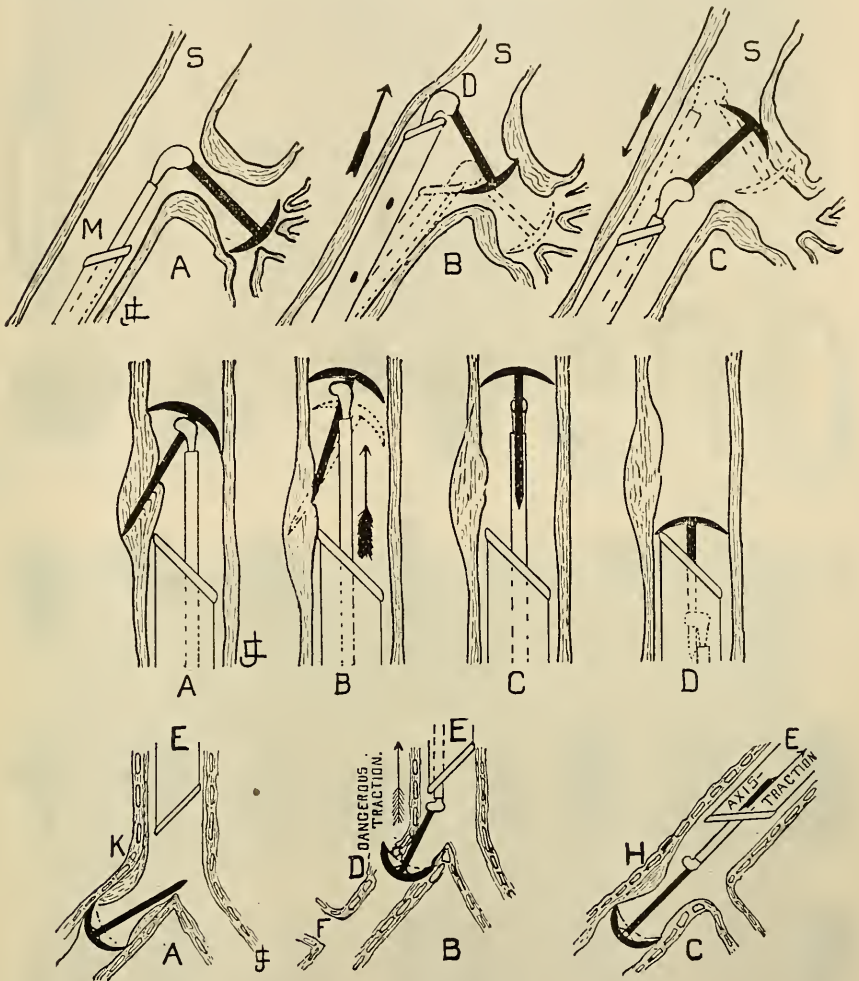

Fig. 640.—Schemæ showing various manipulations in the disengaging and safe removal of tacks from the bronchi by peroral bronchoscopy without general anesthesia. In 18 cases of this kind of tack all have been successfully removed without anesthesia and without mortality in our clinic.

wise it may jam, the forceps slip off, and then only prompt work with precision will be required to remove the foreign body before the patient is asphyxiated.

Introduction of the esophagoscope is easy of accomplishment in any patient whose mouth can be opened; but like all technical manual procedures practice is necessary. Fatal trauma is readily inflicted by the inexperienced, and readily avoided by the facile. The esophagus has very thin, delicate walls, and is very intolerant of trauma, in addition to its being surrounded by many vital struc-

Fig. 641.—Foreign bodies removed from the bronchi by peroral bronchoscopy without general anesthesia and without mortality.

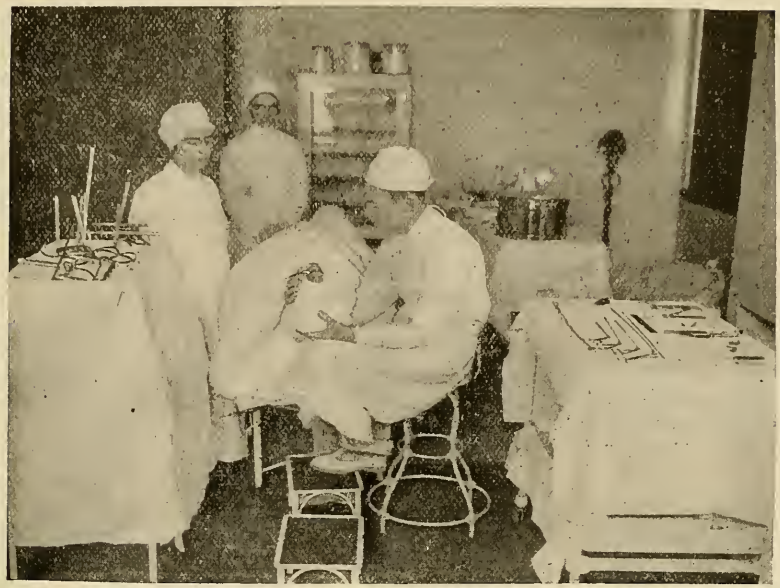

FIG. 642.—Position of patient and second assistant in bronchoscopy and esophagoscopy (Boyce position). The left hand is supported on the left knee, the left foot being elevated on a stool. The right forearm is under the patient's neck, the right index carrying the bite-block. The right forearm carries little weight, most of the extension being done with the left hand.

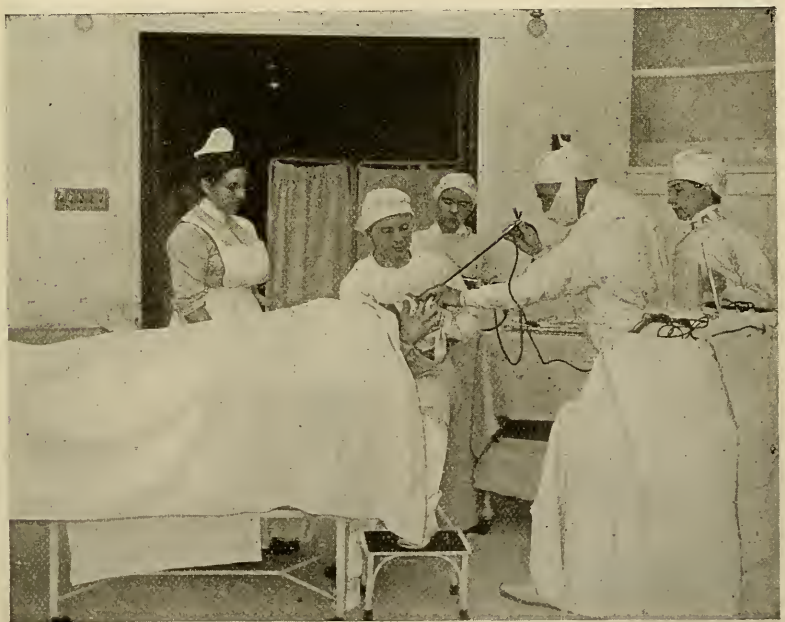

FIG. 643.—Esophagoscopy by the author's "high-low" method. First stage. Finding the right pyriform sinus. In this and the second stage the patient's vertex is about 15 centimeters above the level of the table and in full extension limited to the occipito-atloid joint.

tures. There is no mortality associated with a carefully done esophagoscopy. The position of patient and assistant for esophagoscopy is the same as that described for bronchoscopy (Fig. 642). The easiest and most satisfactory

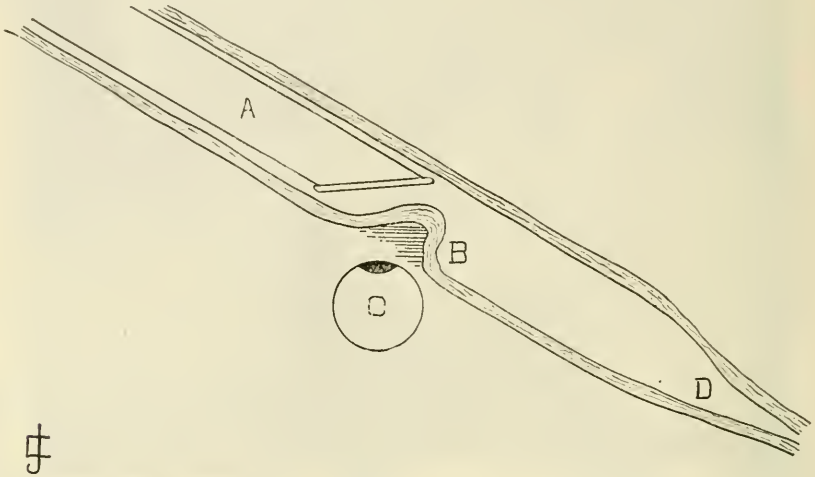

Fig. 644.—Schema showing how the tube-mouth (*A*) is lifted forward to raise it over the cricopharnygeal fold (*B*) as the latter relaxes, and the lumen opens up at the top of the field (*C*).

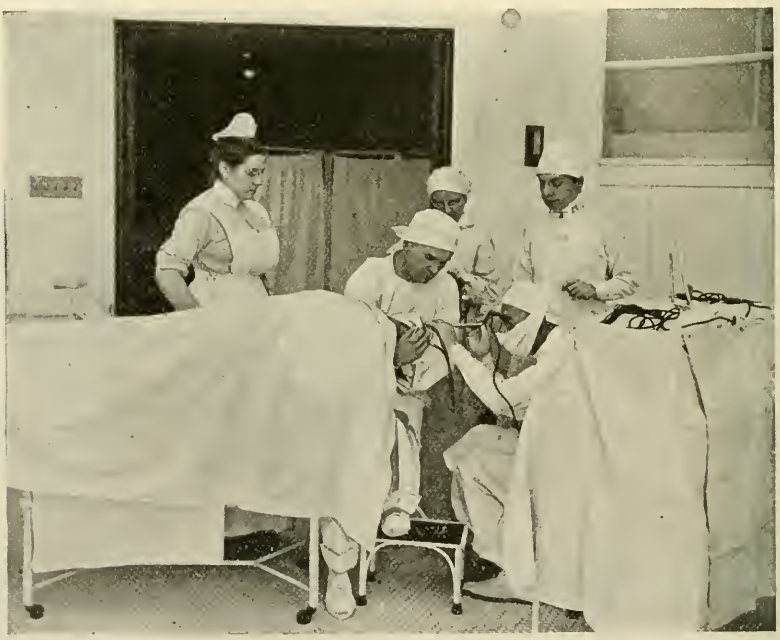

Fig. 645.—Esophagoscopy by the author's "high-low" method. Stage 4. Passing the hiatus. The patient's vertex is about 5 centimeters below the top of the table.

way of introducing the esophagoscope is that known as "Chevalier Jackson's high-low method of esophagoscopy" (Fig. 643). The handle is upward; the thumb and finger of the right hand lightly grasp the proximal end of the tube,

while the left hand supports the distal end and at the same time pushes back the patient's upper lip with the thumb, on which the tube-mouth rests. The fingers of the left hand are on the inside of the upper alveolus back of the teeth, steadying the tube. The long axis of the esophagoscope at this, the first stage, is nearly vertical (Fig. 643). The tube-mouth then is passed down along the right side of the patient's tongue, under guidance of the eye watching the landmarks through the tube, until the bottom of the right pyriform sinus is reached, the proximal end of the esophagoscope being gradually lowered to about 20 degrees above the horizontal. Here firm resistance is encountered, due to

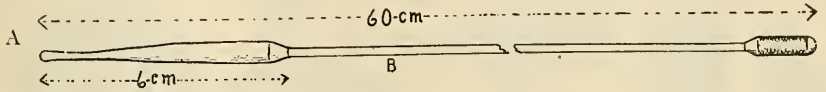

Fig. 646.—Filiform bougie for minute cicatricial strictures of the esophagus. The filiform silk-woven end, *A*, is joined securely to a spring steel shaft, *B*, thus giving all the advantages in safety of a silk-woven bougie at the tip, with a stiff shank that enables the bougie to be carried down rigidly through the length of the esophagoscope. Twelve sizes are made. The great safety of these instruments lies in the accuracy with which they are used through the esophagoscope, under guidance of the eye.

contraction of the cricopharyngeus muscle. Though not apparent through the tube, this muscle raises a rigid fold from the posterior pharyngeal wall, as shown in the schema, Fig. 644. The best way to overcome this obstacle is to raise the tube-mouth forward with the thumb, without depressing the proximal end of the tube. At the same time the eye watches through the tube for the opening up of the lumen at the anterior portion of the endoscopic field. Moderate but continuous pressure downward (*i.e.*, toward the deeper esophagus)

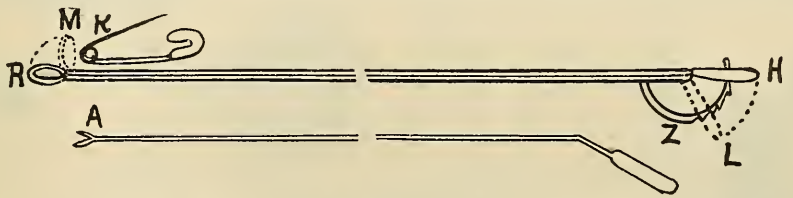

Fig. 647.—Schema illustrating the endoscopic closure of open safety pins lodged point upward. The closer is passed down under ocular control until the ring, *R*, is below the pin. The ring is then erected to the position shown dotted at *M*, by moving the handle, *H*, downward to *L* and locking it there with the latch, *Z*. The fork, *A*, is then inserted and, engaging the pin at the spring loop, *K*, the pin is pushed into the ring, thus closing the pin. Slight rotation of the pin with the forceps may be necessary to get the point into the keeper. Altogether 44 safety pins have been removed by this and other endoscopic methods without anesthesia and without mortality in the author's clinic.

the long axis of the esophagoscope coinciding with the long axis of the esophagus, should be made on the esophagoscope until the cricopharyngeal contraction yields and the lumen opens. Intermittent contraction fails here as it does in using a tongue depressor. The pressure, though continuous, must be very moderate. If anything approaching force be used, the esophagoscope will be forced through the posterior esophageal wall in the weak place in the support between the circular and the oblique fibres of the cricopharyngeus; that is, in precisely the place where the esophageal hernia, known as pulsion diverticulum, occurs. Fatal perforation with the esophagoscope, and even with the silk-woven bougie, has occurred here many times in inexperienced hands. Once the cricopharyngeus yields, usually no further difficulty is encountered until the hiatal region is encountered. The thoracic esophagus, unlike the cervical, opens its lumen before the tube-mouth on inspiration and does not completely close on expiration. The ridge formed by the crossing of the left bronchus

may be noted on the anterior wall of the esophagus if searched for with the tube-mouth. When the tube-mouth passes back of the heart it is noted that the lumen deviates anteriorly so that to follow the lumen axially it is necessary to drop the patient's head lower and lower. This should be done and constitutes the last stage of the "high-low" method (Fig. 645). Just before the hiatal level is reached careful observation of the direction of the lumen will note the deviation to the left. Then the tube-mouth encounters an apparently insur-

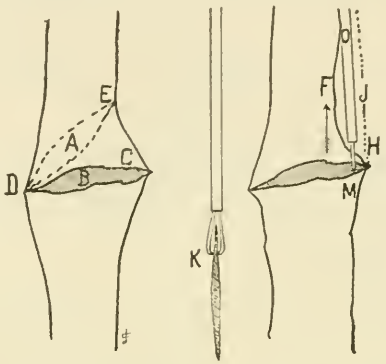

Fig. 648.—The problem of the horizontally transfixed foreign body in the esophagus. The point, *D*, had caught as the bone, *A*, was being swallowed. The end, *E*, was forced down to *C*, by food or by blind attempts at pushing the bone downward. The wall, *F*, should be pushed laterally out to *J*, permitting the forceps to grasp the end, *M*, of the bone. Traction in the direction of the dart will disimpact the bone and permit it to rotate. The author's rotation forceps are used as at *K*.

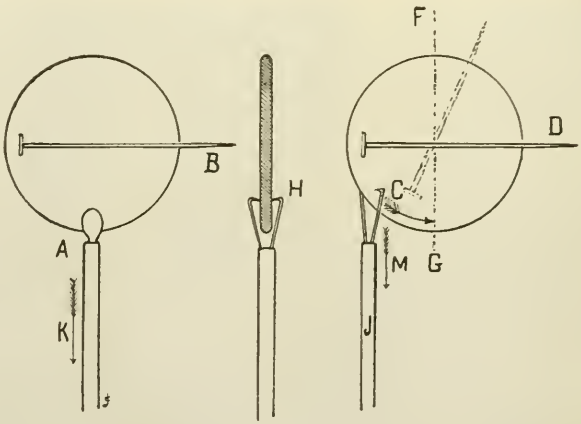

Fig. 649.—Solution of the mechanical problem of the button or other disk-like object with a sharp point. If withdrawn with a plain forceps applied as at *A*, the point, *B*, will rip open the esophageal wall. If grasped at *C*, the point, *D*, will rotate in the direction of *F* and will trail harmlessly behind. To permit rotation, the author's rotation forceps are used as at *H*.

mountable obstruction. This is the constriction made in the esophagus by the contraction of the diaphragmatic musculature. To overcome this, moderate but continuous pressure in the right place is necessary. The proper place is a rosette-like slit to be found by aiming the tube in the direction of the left anterior superior spine of the ileum. As soon as the hiatus yields the tube-mouth traverses the abdominal esophagus (about 3 cm. in length in the adult) so quickly that the tube seems at once to enter the stomach. So deceptive is this that until demonstrated by the author, esophagoscopists mistook the

Fig. 650.—Foreign bodies removed from the esophagus by peroral esophagoscopy without anesthesia and without mortality.

hiatal constriction for the cardia. The so-called "cardiospasm" is really an exaggeration of the normal spasmodic contraction, not at or of the cardia but of the diaphragmatic musculature at the hiatus esophageus. Throughout an esophagoscopy the aspirator, I, F, K, Fig. 627, is kept going by a nurse This is efficient with the usually thin secretions encountered. Sponges on carriers as described under bronchoscopy are used as adjuncts.

Esophagoscopy and Gastroscopy for Surgical Diagnosis.—The ease and certainty with which diagnoses can be made in a few minutes without anesthesia and without pain in cases of esophageal disease, have resulted from development of a perfected technic. Endo-esophageal lues, tuberculosis and

Fig. 651.—Safety pin, open and point upward, in the esophagus of a child, aged eleven months. Removed by peroral esophagoscopy.

malignancy are readily diagnosticated by clinical appearances and by the taking of specimens for biopsy. With the forceps, E, Fig. 627, a specimen of tissue is very readily taken, and it is safe to do so in case of fungating, ulcerating or projecting growths, or any process involving the esophageal wall itself. In the case of peri-esophageal growths compressing the esophagus, and covered with normal mucosa, it doubtless involves risks and may prove disappointing because the disease lies beyond reach and the specimen will include only the intervening normal covering. Growths in the left half of the stomach can be found with the esophagoscope, and specimens taken, constituting gastroscopy; but doubtless this procedure will be most frequently of use in cases that refuse exploratory operation. In cases of pulsion diverticulum the diagnosis is made by the discovery of a blind pouch which seems like a continuation of the pharynx, and in the upper anterior part of which the opening into the subdiverticular esophagus is found.

Cicatricial stenosis of the esophagus is treated with all the safety afforded by ocular inspection. The filiform bougies (Fig. 646) in increasing sizes are inserted into the lumen of the stricture under guidance of the eye.

Esophagoscopy for foreign bodies has reached such a high state of development that the exceedingly dangerous blind methods with bougie, probang, Graefe's basket, Bond's forceps and the like are relegated to districts remote from medical centers. It usually requires but a few minutes without anesthesia and without pain or serious risk to remove a foreign body by esophagoscopy in practiced hands. Any foreign body that has gone down the natural passages can be brought back the same way, provided it be turned so as to present the

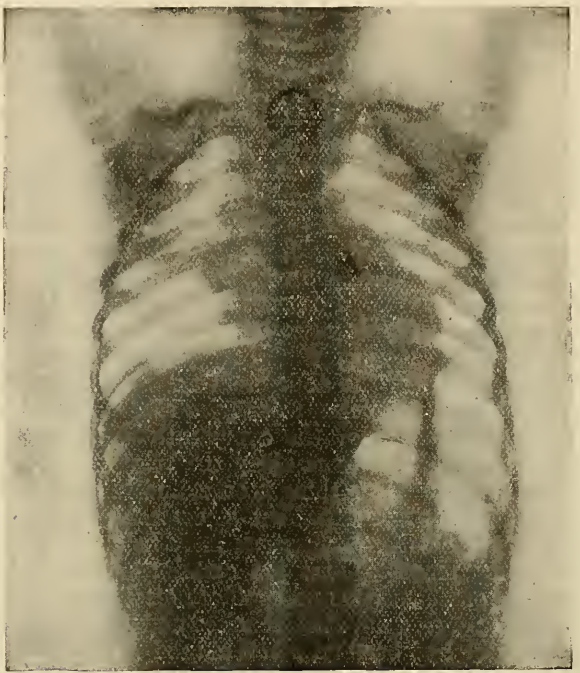

Fig. 652.—Pin button in the esophagus of a child, aged two and one-half months. Turned and removed by peroral esophagoscopy in two minutes without anesthesia, general or local.

same way relatively to the upward direction that it previously presented relatively to its downward course. This can be done by an experienced esophagoscopist in probably every case. Foreign bodies without points or projections may be seized and withdrawn with the forceps, D, Fig. 627. If the foreign body is too large to come through the tube, as is usually the case, the forceps holds the foreign body close up against the distal tube-mouth while forceps, foreign body and esophagoscope are all withdrawn together.

In cases of pointed objects, such as safety-pins lodged point upward, if the intruder be grasped and pulled upon by the presenting part, the point or points will catch, the intruder will become transfixed and cannot be removed at all, or fatal trauma will be inflicted. A radiograph should be taken and the position of the intruder should be studied esophagoscopically and a safe method of seizure, and version if necessary, be devised before any traction is made. Too much emphasis cannot be placed upon the necessity of care in esophagoscopy for foreign bodies. Various methods of working out mechanical problems are shown in Figs. 647, 648, and 649. In cases of bones, which are very fre-

quent intruders, the foreign body should be manipulated so as to bring its greatest diameter into the long axis of the esophagus. The next-to-the greatest diameter must be transverse to get the intruder past the cricoid cartilage.

Diseases and Injuries of the Chest, Pleura, and Lungs

Traumatic Asphyxia (*Pressure Stasis; The Ecchymotic Mask*).—This is a condition that occasionally arises when the trunk is subject to sudden and violent compression (caught under an elevator, caught under a heavy box, cave in of earth, crushed in the rush of a panic, etc.). The compression may be upon the chest, the abdomen, or both; and in the majority of cases it has been very temporary. The discoloration arises immediately, and is manifested over the head and neck down to and sometimes below the clavicle. The hue is a violet lividity. There are a great many spots in the skin in which the color is much deeper, which have been supposed to be hemorrhages, and similar spots exist on the labial, buccal, glossal, palatine, and pharyngeal mucous membranes. Subconjunctival hemorrhage is the rule. There may be bleeding from the nose, mouth, and ears. There is brief or prolonged unconsciousness, circulatory and respiratory depression, sometimes cough and bleeding from the lungs. There has never been a reported instance of intracerebral hemorrhage. There are (rarely) convulsions, there is no paralysis and no delirium. The lividity may clear up in a few hours. The spots seldom fade for days. The spots do not fade at all from pressure, the livid area fades but slightly.

If death occurs, it results from associated injuries. The condition in the cases without severe associated injuries has soon disappeared, and entire recovery has followed. The view generally taught is that traumatic asphyxia is the result of compression of the abdominal veins, causing distention of the superior cava and its tributary veins, this region of the body showing the effect more than the limbs, because of the comparative feebleness of the valves (Villemin). The blood is forced back along the veins and into the capillaries, and capillary paresis ensues. One thing is sure, and that is, that the condition is particularly apt to arise if the patient struggles violently to free himself from the compression; and many observers have held the opinion that actual vascular ruptures take place. There are certainly some cases, however, in which there is simply great venous and capillary distention in the skin without rupture, because pieces of skin have been excised and microscopical examination has indicated that there had been no blood effused. The selection of the face and neck as the regions of discoloration is due, perhaps, to absence or incompetence of valves in the jugular and facial veins. The fluid state of the blood which has been noted occurs in all forms of asphyxia. (See Winslow, "Medical News," Feb. 4, 1906; Birge, "Cleveland Medical Journal," Sept., 1905; Beach and Cobb, in "Annals of Surgery," April, 1904; Villemin, "Bull. et mém. de la Soc. Chir. de Paris," No. 9, 1906.) Despard ("Annals of Surgery," June, 1909) has reported 1 case and collected 17 from recent literature. Ettinger in 1907 collected 36 cases and added 1 of his own ("Wein. klin. Wochen.," 1907, vol. xx). I have seen 2 cases.

Pleuritic effusion may arise from the lodgment of foreign bodies, from injury by fragments of a broken rib, from tumors, and from inflammation of the lung, but most usually is due to pleuritis. The commonest cause of primary pleuritis is tuberculosis. Inflammatory effusion is nearly always unilateral (except in tuberculous pleuritis; but even in this form it is often one-sided in origin).

The **signs** of pleuritic effusion are: dulness on percussion over the area of effusion, this dulness, when the patient is erect, being at the lower part of the chest and ascending higher posteriorly than anteriorly (alternation of position alters the situation of the dulness); the intercostal spaces are widened, the intercostal depressions are obliterated, the intercostal muscles are rigid, and

their rigidity lessens the mobility of the ribs (Przewalski). No breath-sounds can be detected in the area of percussion flatness when the collection of fluid is large, but in small effusions deeply situated the breath-sounds are often audible; the percussion-note above the liquid is hyperresonant or tympanitic, and is often associated, at the edge of the liquid, with a friction-sound; posteriorly, high up and near the spine, there are bronchial respiration and bronchophony. In cases of pleurisy with effusion pain almost or quite disappears with the advent of effusion, dyspnea comes on, and the patient lies upon the diseased side. Cough always exists if there is pleuritic effusion, and fever is usually present. In serous effusions the diagnosis may be confirmed by the aseptic introduction of a clean aspirating-needle. Ramond has pointed out that in serofibrinous pleurisy the iliocostal and longissimus dorsi muscles are always noticeably enlarged on the side of the effusion ("Bull. de la Soc. Méd. des hôp.," 1910, vol. xxvii).

The **treatment** in this stage is to discontinue arterial sedatives and to stimulate if the circulation calls for it. The exudation may be removed by the administration of salines, compound jalap powder, or elaterium. If these means fail, if the effusion is excessive, or if it is producing severe dyspnea, at once aspirate. Aspiration should be performed for an effusion which fills the whole chest, which produces great dyspnea, or which has lasted for three weeks. In tuberculous pleuritis early aspiration is not advisable, but aspiration should be performed if the fluid becomes purulent, if the effusion displaces the heart considerably, and if it adds notably to the dyspnea. If a non-tuberculous effusion becomes purulent, the proper procedure is incision, resection of a portion of a rib, and drainage.

Empyema is a collection of pus in the pleural cavity displacing and compressing the lung. It may begin suddenly, but rarely does so. Among the causes of empyema are those of serious effusion. Empyema is due to infection of the pleura, and in every case a bacteriological study should be made of the exudate to discover the causative bacterium. The pneumococcus, the streptococcus, the staphylococcus, the bacillus of influenza, or the colon bacillus or the typhoid bacillus may be found. The pneumococcus is the causative micro-organism in many of the cases which follow pneumonia. There may be mixed infection of pneumococci and streptococci, or other mixed infection. Pneumococci live but a short time, and in empyema due to pneumococci these micro-organisms may not be discoverable when the pus is evacuated, only streptococci or staphylococci being found. These micro-organisms may appear in an empyema induced originally by pneumococci (Stephen Paget). In empyema developing during or after typhoid fever typhoid bacilli may be discovered. In putrid empyema various bacteria are found. Bouchard thinks acute empyema has a special organism. Bacilli of tuberculosis are present for a time a least in tuberculous empyema, but may disappear, and are particularly apt to after mixed infection with pyogenic bacteria. In adults many cases, in children few cases, are secondary to tuberculosis. In empyema blood cultures are usually sterile unless taken from the moribund. If an organism is found it is usually a hemolytic streptococcus though occasionally pneumococci are demonstrated. Empyema may be due to a wound or contusion, an attack of pneumonia, bronchopneumonia, bronchitis, tonsillitis, pharyngitis, tuberculous pleuritis, phthisis, influenza, pyogenic infection of a serous effusion, caries of a rib, specific fevers, especially measles, typhoid, peritonitis, abscess of the liver, suppurating hydatid cyst of the liver, subphrenic abscess, malignant disease of the pleura, gangrene of the lung, and pneumothorax. Pneumonia is the common cause in children. In them we find streptococci in only 15 per cent. of the cases and sterile fluid in 20 per cent. In 65 per cent. of the cases we find pneumococci. In adults the pus is often thin and very putrid. In children the pus is nearly always thick. Pneumococcic pus is

fairly thick, contains some clots, and is white or greenish white. In our military camps during the winter of 1917–18, almost 20 per cent. of pneumonia victims developed empyema. (See the study of various reports by Evarts A. Graham, M. R. C., from the office of the Surgeon General, U. S. A.)

Acute Empyema.—The physical *signs* are, in reality, those of pleuritis with effusion—viz., dulness on percussion, absent breath-sounds over the purulent matter, bulging of the intercostal spaces, and sometimes edema of the skin of the chest. The intercostal muscles are rigid. The effusion may be large and in some case it forms very quickly. It may be thick or thin. In some cases there is very little effusion and adhesions form. In such cases thick pus is liable to pocket. The *symptoms* of acute empyema are pain, dyspnea, pallor, cough, sweats, chills, and usually irregular fever, but fever may be absent. There is marked leukocytosis. The fingers may become clubbed. Pericarditis, endocarditis, peritonitis, synovitis, or empyema of the other side may arise. Streptococcic empyema is an acute, violent and very fatal malady in which there are evidences of grave systemic infection and in which there is a strong tendency to involvement of other serous membranes (the other pleura, the pericardium, the synovial membranes, the peritoneum, the endocardium). Many cases begin with a chill and in twenty-four to forty-eight hours the pleural sac contains a very large effusion. The effusion swarms with streptococci which can usually be demonstrated by smears. Sometimes blood cultures are positive. The effusion is usually serofibrinous and devoid of odor. There is a decided tendency to the development of peritonitis and other dangerous complications.

Streptococcic empyema may arise after pneumonia, bronchopneumonia, tonsillitis, or pharyngitis. A peculiarly fatal form is seen after measles. Streptococci may attack the pleura even when the lung is free, the empyema being primary. If thick pus forms it is apt to be pocketed between the lobes or between the upper lobe and pericardium back of the sternum. If peritonitis arises adhesions form and pus gathers in pockets. An empyema may pulsate, particularly an empyema of the left side. The cause of *pulsating empyema* has been much debated. The most probable explanation is that of W. J. Calvert ("Am. Jour. Med. Sciences," Nov., 1905). He says the requirements for such a condition are: "A firmly fixed, pulsating organ; distention of the pleural sac with fluid or air or solid material; and a collapsed condition of the lung." In all probability the thoracic aorta is the "fixed pulsating organ." The left parietal pleura is in close relation with the aorta, and most pulsating empyemas are left sided. The right parietal pleural may be "pushed against the aorta." If a lung contains air, it is elastic and compressible to a degree that enables it to absorb the aortic impulse; if it is collapsed and solid it cannot, and aortic pulsations are transmitted to fluid in the pleural cavity and the thoracic wall pulsates. A neglected empyema may break into the lung, esophagus, or pericardium, through an intercostal space, or may point in the lumbar region. When an empyema is pointing externally, the condition is called *empyema necessitatus*. A *total empyema* is a condition involving the entire pleural sac. In a *partial* or *localized empyema* the purulent matter is encapsulated. A *closed empyema* is one in which no opening has been made by the surgeon and no opening has formed spontaneously. In a closed empyema the pus is rarely putrid; in an *open empyema* the pus is often putrid. After an empyema ruptures spontaneously it rarely heals without surgical interference, a *pleural fistula*, as a rule, persisting. A *subphrenic abscess* may follow an empyema. When an empyema ruptures into a bronchus, pneumothorax arises, as a rule. Empyema may cause death by compression of the heart and lung, pulmonary embolism, pericarditis, peritonitis, cerebral embolism, cerebral abscess, septicemia, exhaustion, or rupture into a bronchus. Empyema is particularly fatal in childhood. In empyema of the early months of life nearly all the victims die. In those under one year of age 50 per cent. of the affected will

die (Holt). In older children 30 per cent. die. In civil practice the mortality of pneumonic empyema is from 12 to 20 per cent. The mortality of streptococcic empyema is much higher. In our military camps the average mortality has been over 30 per cent. In one camp it was over 53 per cent. In another it was over 84 per cent. Streptococcic empyema is far more fatal than pneumococcic empyema. Empyema following measles or the pneumonia or bronchopneumonia of measles has a dreadful mortality (Graham, Ibid.).

A small empyema due to pneumococci occasionally, though very rarely, undergoes spontaneous cure, the pus being absorbed (Stephen Paget).

A small empyema is occasionally cured by encapsulation by fibrous tissue.

Under exceptional circumstances even a large empyema may be cured by breaking externally or into a bronchus.

Empyema is so rarely cured spontaneously that it does not do to trust to Nature at all, and practically almost all cases die without surgical treatment.

Double empyema is an extremely fatal condition. In civil practice I have seldom seen it. In our military camps 8.7 per cent. of the cases of empyema have been bilateral (Graham, Ibid.). Exploratory puncture is of great value in diagnosis. If there is massive fibrinous deposit it may lead to a dry tap below and a tap higher up may obtain fluid. If a needle is caught in an adhesion there will be a dry tap. So there may be in a case with pocketed pus. Any matter obtained should be studied bacteriologically. The *x*-rays are of decided value in diagnosis.

Chronic empyema may follow acute empyema, or the condition may be chronic from the beginning. It is more common in adults than in children. In chronic empyema the lung is compressed, shrunken, does not expand and is strongly adherent, and the pleura is very thick. In some cases the pleura is over an inch thick. This thickening is brought about by the deposition of layer after layer of fibrin. In not a few cases a chronic empyema succeeds an acute one. Sometimes chronic empyema is maintained because a drainage-tube has slipped into the pleural cavity and remains lodged.

Treatment of Empyema.—The treatment is purely surgical, and the earlier it is applied the better. To delay allows the pleura to thicken and permits adhesions to form, conditions which prevent lung expansion and retard or even prevent cure. The results of operation for chronic empyema are better in children that are not very young than in adults. In acute empyema the prognosis is better in small collections than in large; in recent than in advanced cases; in pneumococcus empyema than in empyema due to other organisms. The surgical methods for various stages of empyema comprise aspiration, incision, rib-resection, the operation of Schede, the operation of Estlander, and the operation of Fowler (see pages 1036 to 1040 inclusive).

I do not believe in any of the appliances to drain with a small tube and maintain negative pressure in the chest to favor lung expansion. The Thiersch method consists in introducing a trocar into the cavity, passing a Nélaton catheter through the trocar, and removing the trocar. The external end of the catheter is attached to an easily collapsible rubber tube, the other end of which is in a bottle of water. The catheter is fixed to the side by rubber tissue and rubber plaster. "The theory is, that when the patient expires, the pus runs out through the tube, and on inspiration the collapsible walls of the tube are sucked together and prevent the entrance of air, and cause negative pressure in the chest, favoring expansion of the lung" (Lund, "Jour. Am. Med. Assoc.," August 26, 1911). In any method of suction so far devised the tube is so small that it blocks up, and though the drainage-tube may at first make an air-tight joint with the chest, it always loosens sooner or later and leaks air.

In acute empyema general practitioners are very apt to *aspirate*, and yet aspiration is almost never curative. It may cure a pneumococcus empyema in a child and an encysted empyema, but even in these it will usually fail.

Aspiration is not to be considered a method of curative treatment. It is to be regarded as the surgical treatment only in a tuberculous empyema in a young person with rapidly progressing phthisis, because in such a case incision will probably prove fatal (Lockwood). It is a very useful diagnostic expedient, and enables the surgeon to prove the existence of pus, and the pus which is obtained can be examined bacteriologically. In a verylarge effusion it is wise to aspirate and withdraw part of the effusion a short time before operating. This enables the patient to take an anesthetic with greater safety and obviates the danger attending the rapid evacuation of a large amount of pus.

In a recent empyema, *incision* and *drainage* or *rib resection* and *drainage* will often cure the case, and yet many of the results are unsatisfactory. In some cases the discharge ceases and yet pulmonary function is not completely restored. In other cases a pleural fistula persists. If a profuse discharge is maintained, amyloid disease may arise. An acute empyema is to be drained by intercostal incision or by resection of a rib (see page 1036). Of late I have tried washing out empyemata with Dakin's fluid. The irrigation is practised every two hours. It lessens putridity but does not seem to me to shorten the duration of the case notably. The same may be said of Dakin's oil. Occasionally a convulsive seizure known as pleuritic epilepsy occurs (page 1037). Dr. Toland, U. S. N. R. F., had four cases of pleuritic epilepsy following irrigation with Dakin's fluid, but no fatality. A chronic closed empyema is drained in the same manner as an acute empyema, and if the lung will not fully expand and remains stationary for one year, Schede's or Estlander's operation is required. An open chronic empyema, in which the lung will not expand, requires the operation of Schede, Estlander or Fowler (see pages 1038 and 1039). The results of operation for acute or chronic are best in children almost in the teens. Extensive decortication is sometimes impossible, and then Ransohoff's operation may be done. He calls it *discission of the pulmonary pleura* (see page 1040). When there is an external opening which persists and which joins a long, narrow cavity, the condition is spoken of as *pleural fistula*, and pleural fistula is often produced by the prolonged use of a drainage-tube and sometimes by caries of a rib. Even if there is no opening on the cutaneous surface, there may be one into a bronchus. A pleural fistula may sometimes be cured by dilatation of the sinus. If this fails, and it usually does, it is the custom to resect one or more ribs.

Before resorting to operative treatment in chronic empyema we may try, in some open cases at least, the injection of bismuth paste. We owe this method to Dr. Emil Beck. This plan will sometimes succeed. Ochsner has strongly commended it ("Annals of Surgery," July, 1909). The injection is made by a glass syringe and the material should fill but not stretch the cavity. After injecting the paste the external opening of the fistula is plugged with gauze. The treatment is begun with solution No. 1 (1 part of subnitrate of bismuth devoid of arsenic and 2 parts of yellow vaselin).

This is used every second day until pus has practically disappeared. Then solution No. 2 (30 parts of bismuth, 60 parts of yellow vaselin, and 10 parts of paraffin) is substituted for it. The injections are made often enough to keep the sinus and pocket full. They are made at first every day, then every other day, and so on until, finally, every eighth or tenth day is often enough. If poisoning should arise from these injections Beck advises the injection of olive oil at a temperature of 110° F. to dissolve the paste and favor its evacuation. McKelvey Bell recommends a paste which is more stimulating than Beck's. He takes 1 oz. of subnitrate of bismuth and 2 oz. of white petrolatum, dissolves over a hot-water bath, and stirs until cool. Then, while stirring, he adds 72 gr. of iodoform (5 per cent.). This must be kept in a dark place to prevent decomposition of the iodoform ("New York Med. Jour.," May 4, 1912). (See page 708.)

Treatment of Empyema in Army Camps (From report by Graham, Ibid.).—Empyema has been very common in our training camps. The Surgeon General

of the Army directed a thorough study of it. Various plans of treatment have been tried and the greatest differences of opinion are manifest. The high mortality shows that treatment, on the whole, has not been satisfactory. The reason is that no treatment has been devised to combat the multiple lesions of streptococcic empyema, such an empyema being often but part of a generalized trouble (Graham, Ibid.). Some surgeons maintain that early repeated aspirations are better than immediate operation. Some operate at once unless the pneumonia is still active. Some surgeons will not operate while the fluid is thin and serofibrinous preferring to wait until it is distinctly purulent. Some drain as soon as the diagnosis is made. Most surgeons operate by rib resection. Some make intercostal drainage. Most operations have been done with the aid of a local anesthetic.

Some have used antistreptococcic serum. If given in considerable doses intravenously it may be of service.

In only one camp was postoperative negative pressure used at all extensively. The surgeons of that camp praise it. Other surgeons abandoned it because it caused pain and bleeding.

In several camps blowing bottles meet with approval. In a number of camps irrigation has not been employed. Some have used Dakin's fluid, some dichloramin-T, others 2 per cent. formalin and glycerin, others tincture of iodin, others normal salt solution, others peroxid of hydrogen, others boric acid. A number of surgeons fail to approve of Dakin's fluid and claim that it brings no benefit except the diminution of the odor of the pus. Some surgeons recommend it strongly.

Non-traumatic Pneumothorax.—By the term "pneumothorax" is meant the presence of air in the pleural cavity. As a rule, besides air there is serous fluid or pus. It may be due to the rupture of an empyema into a bronchus; to the rupture into the pleural sac of a tuberculous area, an area of gangrene, an abscess of the lung, an air-cell in a state of emphysema, or of pulmonary tissue softened because of hemorrhagic infarction. The condition is by no means uncommon in phthisis. In 473 autopsies held in the Henry Phipps Institute of Philadelphia upon persons dying of pulmonary tuberculosis there were 41 cases of pneumothorax, or in 8.6 per cent. of the autopsies this lesion was found (J. M. Cruice, "Med. Record," Sept. 23, 1911). In 60 per cent. of the cases the lesion is on the left side. It is inaugurated by cough, straining at stool, vomiting, or lifting. It is more frequent in men than in women and is most common between the ages of thirty and forty. The immediate effect of the entrance of air into the pleural sac is to compress the lung, the degree of compression being in proportion to the amount of air present. In severe cases the lung is squeezed against the vertebral column, and the heart and diaphragm are displaced. In a right-sided case the liver may be displaced. In some cases, when the admission of air does not continue, the amount set free in the pleural sac is absorbed. In most cases pyopneumothorax (empyema) follows.

The **symptoms** usually arise suddenly (in three-fourths of the cases), and consist of distressing dyspnea, pain in the chest, lividity, and rapidity and weakness of the pulse. In some cases of phthisis the symptoms are gradual and not very severe. There may be pain and dyspnea or only dyspnea. In the latter case, if dyspnea existed before, the accident may be unrecognized. It has been pointed out that occasionally in phthisis pneumothorax seems actually to benefit the tuberculous area in the lung. There is nothing characteristic in the attitude. The patient usually lies on the opposite side, but may lie on the side of the trouble or on the back. He may sit erect or semi-erect. He may place himself in a knee-chest position. The physical signs of pneumothorax are as follows: The affected side of the chest is often bulged, movements are lessened or absent, and the heart is displaced, especially if the condition affects the left side. Palpation discovers that vocal fremitus is lessened or absent. On auscultation it is found that the breath-sounds are very feeble

or absent in 70 per cent. of cases. Occasionally they are amphoric, bronchovesicular, or cavernous. The voice may be transmitted as a metallic sound (this is present in about half the cases), râles may sound metallic, and on coughing there may be metallic tinkling. The percussion-note is hyperresonant or tympanitic in 95 per cent. of cases. Very seldom it is normal. In some rare cases the percussion-note is dull. When fluid gathers, there is a positively dull note on percussion over the fluid.

Treatment.—Osler says the treatment should be the same as that for pleurisy with effusion. In many cases it is wise to perform paracentesis without suction to remove air and serous effusion. If pus forms, a rib should be resected and a tube inserted (see Empyema). In pneumothorax occurring during chronic phthisis operation is of service. In cases with rapidly progressive phthisis it is practically useless.

If the opening into a bronchus or air-cell remains patent, aspiration will not get rid of air; the air will enter into the pleura as rapidly as the aspirator removes it. Incision has dangers of its own: the diaphragm is flapping during respiration and may be injured (Fowler), and when the pleura is opened there is a great alteration produced in the air-pressure in the chest, and the patient may "drown in his own secretions." After incision irrigation is not justifiable, because the fluid may enter a bronchus and produce suffocation (Fowler).

West's rules[1] are those which I follow. West says early incision is dangerous. In an early stage use paracentesis without suction. This will often relieve the patient. If paracentesis does relieve him, wait a while and perhaps repeat the operation if the symptoms again become severe. If paracentesis does not relieve, incise, resect a portion of a rib, and drain. If pus forms, an incision must be made and a portion of a rib be resected to afford exit to the fluid.

Fowler pointed out that if the lung is bound down by adhesions, incision is dangerous but justifiable. Operation at the proper time often prevents the lung being bound down by adhesions.

Acute Traumatic Pneumothorax.—This is produced by the sudden admission of a quantity of air into the pleural cavity as a result of a wound of the chest wall. A small quantity of air, or the gradual introduction of considerable air, does not, as a rule, produce very serious symptoms. The sudden admission of a quantity of air causes very dangerous symptoms and even death. A quantity of air may be admitted rather suddenly as a result of an accident or during the performance of a surgical operation which opens the pleura. It sometimes arises during the removal of tumors from the chest wall, during operations upon the lung, and during empyema operations. As a rule, when pulmonary adhesions exist, dangerous symptoms do not arise, even when the pleura is widely opened, and adhesions exist in 25 per cent. of empyema cases seen by the surgeon.[2]

It was formerly taught whenever the pleura is opened there is a strong tendency to the development of pneumothorax, but West has shown that the surfaces of the pleura often cohere with a force superior to pulmonary elasticity, and in such cases pneumothorax does not arise.

In surgical operations in which it is necessary to open the pleura widely (as in operation for sarcoma of the chest wall) the surgeon endeavors to prevent acute pneumothorax, which may prove fatal. This may be done by operating in the Sauerbruch negative pressure chamber (see page 1032) or by applying positive pressure (see page 1033).

Symptoms.—When the pleura is opened during an operation or by an injury, the symptoms may be trivial and transitory, may be tolerably severe,

[1] "British Medical Journal," Nov. 27, 1897.
[2] Rudolph Matas, "Annals of Surgery," April, 1899.

may be extremely grave, and the patient may quickly die (Quénu and Longuet). Rudolph Matas[1] sets forth the symptoms as presented by the French observers.

The mild symptoms are weak, slow pulse and irregular, noisy respiration.

The severe symptoms are slow pulse, slow and irregular respiration, and dyspnea, continuing after the anesthetic has been withdrawn.

The grave symptoms are cyanosis; collapse; small, weak pulse; shallow and noisy respiration; and spells of syncope. Death may occur suddenly from inhibition, or later from mechanical asphyxia (Matas).

Treatment.—Various plans have been adopted; suturing the opening in the pleura; plugging the opening; pulling the diaphragm into the wound in the chest wall and suturing it; and grasping the lung and suturing it to the wound. Whenever the pleura is to be widely opened, operate in a Sauerbruch chamber or use a positive pressure apparatus, and when the operation is complete, suture the lung to the margin of the opening in the pleura with a continuous catgut suture. The apparatus for insufflation anesthesia accomplishes the object. Parham, Keen, and the author followed this plan, using the Fell-O'Dwyer emergency apparatus, and the lung was kept from collapsing.[2] This apparatus is shown in Fig. 653.

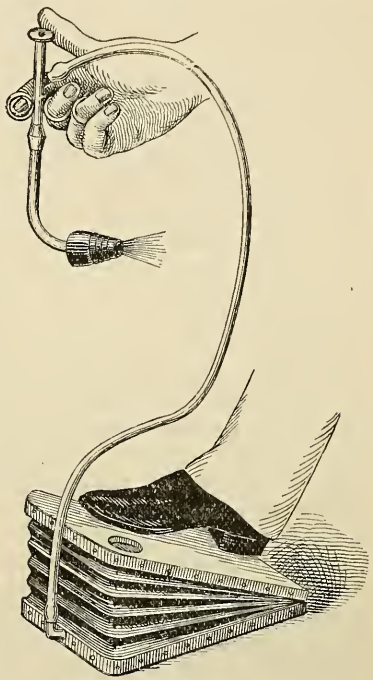

Fig. 653.—The Fell-O'Dwyer apparatus. This illustration shows an early model; since then the bellows has been improved by the addition of a strong wooden frame, which holds it steadily, and is provided with a long arm that acts as a powerful foot-piece for compressing the machine with the least amount of muscular effort.

O'Dwyer's tube is introduced into the glottis as is the tube in intubation, and is attached to a bellows, the lung is inflated, respiration is maintained by the use of the bellows, and collaspe, with all its dangers, is avoided. The modern positive pressure apparatus or the apparatus for insufflation anesthesia is better (see page 1033). So is the pulmotor and lungmotor (see pages 977, 979).

Contusions and Wounds of the Chest.

—Contusions.—A contusion may be trivial and limited to the superficial parts of the chest wall; it may involve the muscles; it may be associated with fracture of the ribs or sternum or with visceral injury.

Symptoms.—In an ordinary contusion without visceral injury there are considerable pain, discoloration, and often much swelling. The patient prefers to lie upon the back and the respiration is abdominal. After a severe blow upon the chest there is great shock and may even be instant death. The condition of shock so produced is called *concussion of the chest.* After a severe blow upon the chest a limited area of inflammation may arise in the pleura (*traumatic pleuritis*). Severe visceral injury is announced by positive symptoms. A *contusion of the lung* causes extravasation of blood and leads to pain, cough, expectoration of bloody mucus, dyspnea, and possibly distinct hemophthisis. Over the contused region the percussion-note is dull and on auscultation crepi-

[2] F. W. Parham's paper on "Thoracic Resection for Tumors Growing from the Bony Walls of the Chest." Read before the Southern Surgical and Gynecological Association, November, 1898.

tus is audible. It may be mistaken for phthisis, but complete and early recovery soon dispels this fear. *Traumatic pneumonia* always follows. This usually involves a limited area of lung tissue, but genuine croupous pneumonia may arise after injury of the chest even when no rib has been broken. The physical signs and symptoms are not evident until two or three days after the accident (Sir Thomas Oliver, in "Brit. Med. Jour.," April 30, 1910). Traumatic pneumonia may be caused by other things than external violence, viz., inhalation of illuminating gas, of dust, or of a foreign body.

In **rupture of the lung** the physical signs are dependent on the extent and situation of damage. A minute rupture would not produce definite physical signs. If the lung is ruptured and the pulmonary pleura is not, there will not be pneumothorax, but there may be cellular emphysema first becoming evident at the root of the neck. If the pleura is torn as well as the lung, there will be pneumothorax and hemothorax, the amount of hemorrhage depending upon the situation and extent of the injury.

Robt. G. Le Conte ("Annals of Surgery," March, 1908) points out five ways in which rupture may be caused: (1) *Bruising* (simply causes subpleural ecchymosis); (2) *bursting* (violent force—a lung unable to empty itself of air is broken as an inflated paper bag is broken by a sharp blow); the question as to whether the glottis must be closed for such an injury to occur is not settled; (3) *penetration* by a green-stick fracture of a rib; (4) *compression* of the lung against some resistant structure; (5) *tearing* (when the lung has previously been adherent to the wall of the chest).

These five causes might be sententiously designated as bruising, bursting, puncturing, squeezing, and tearing.

The *symptoms* are shock, dyspnea, cough with or without bloody expectoration, rapid and irregular pulse, cyanosis, emphysema (appearing first over the region of injury if a broken rib penetrated the lung; at the root of the neck if there is ruptured lung but intact pleura), and in some cases pneumothorax and hemothorax (Le Conte, Ibid.).

Rupture of the diaphragm causes pain, dyspnea, and often vomiting. The stomach or intestine may pass into the pleural sac. If this happens, there will be a tympanitic percussion-note over the displaced viscus and symptoms will vary with the viscus involved. Such a diaphragmatic hernia may become strangulated (see page 1291 and 1303). In a case in the Jefferson Medical College Hospital, in which the stomach passed into the left pleural sac, there were persistent vomiting, violent pain in the chest and upper abdomen, great thirst, and displacement of the apex-beat. The condition may be confused with pulmonary rupture causing pneumothorax, but in rupture of the diaphragm persistent nausea and vomiting are prominent features; whereas, in pulmonary rupture, if they exist at all, they are early and temporary; further, in rupture of the diaphragm the tympanitic percussion-note is not found over the pleural apex, but in pulmonary rupture with pneumothorax a tympanitic note is found all over the entire pleural cavity (Le Conte, Ibid.).

Treatment of Contusions of the Chest.—A contusion of the chest wall is treated as directed in the section on Contusions (see page 285), and the chest is strapped with adhesive plaster, as in the treatment of fractured ribs. In concussion of the chest the treatment for shock is applied. It may be necessary to employ artificial respiration for a time. If a diaphragmatic hernia is diagnosticated, the abdomen should be opened, the displaced viscera restored to their proper abode, and the diaphragm sutured. The diaphragm may also be reached by resecting several ribs and opening the pleural sac. In contusion of the lung cold is applied to the chest early in the case, and any inflammation which arises is treated according to general rules. In rupture of the lung the case may be treated expectantly, but dangerous and continued bleeding or pneumothorax may render surgical interference necessary. For pneumothorax

paracentesis without suction is employed. If this fails, it may be repeated. If it fails again, resect a portion of a rib and put in a tube. If bleeding is dangerously profuse resect a portion of a rib and insert a drainage-tube into the pleural cavity.

Wounds of the Chest.—Non-penetrating wounds are not particularly grave, and are treated according to general principles, the chest being immobilized. Penetrating wounds are extremely grave, as viscera are apt to be injured. In such a wound an intercostal artery may be severed or the internal mammary artery may be divided. An intercostal artery is rarely divided unless a rib is broken. The surgeon should always examine carefully in order to determine whether an intercostal artery or the internal mammary artery has been divided, and, in doing so, should bear in mind the admonition of Matas—that is, the bleeding from these vessels may be internal, the blood collecting in the pleural sac. The pericardium or heart may be injured (see page 460). A wound of the pleura is usually, but not always, associated with a wound of the lung. If the lung is injured, there are usually great shock, pain in the chest, dyspnea, and cough. In a large wound, damage to the lung will be indicated if air is sucked into the wound during inspiration and expelled during expiration, and if blood is forced out of the wound by coughing. The lung may be visible or may protrude (*protrusion of the lung*). In a small wound it is often difficult and sometimes impossible to determine whether the lung has been injured. Pneumothorax with pulmonary collapse proves it has. Severe hemothorax strongly suggests it. Spitting blood does not prove it. In some severe cases there is no hemoptysis; in some slight bruises the amount of blood coughed up is large. Emphysema about the wound does not prove lung injury. An incised wound of the lung is apt to produce rapid death from hemorrhage, especially if the wound is at the root of the lung. A pistol-bullet or a sporting-rifle bullet may not be productive of great primary hemorrhage; but infection will probably follow, and secondary hemorrhage will be apt to occur. The modern military-rifle ball, if it strikes exactly point on, passes through, rarely lodges, and is practically aseptic if it has not struck the ground in its course and if the victim's skin and clothing have not been seriously soiled. It often produces astonishingly little trouble. If the bullet enters side on it produces grave laceration. A pistol-bullet and an old-time rifle-bullet may lodge or may perforate. A bullet lodged in the lung seldom causes much pain. If it is in contact with the pleura or pericardium it causes severe pain. Pain from pericardial irritation is felt in the side of the chest or in the shoulder (either side or both sides).

Treatment.—Bring about reaction as previously directed (see page 290).

An incised wound of the chest, if large, should be carefully inspected. If the wound is small, cut down layer by layer until the depths of the wound are reached. Disinfect the wound and arrest hemorrhage. If the pleura is not open, proceed according to general rules. If the pleura is found to have been opened, suture it with catgut, close the superficial wound, dress with gauze, and immobilize the chest wall.

The above proceeding should be carried out whether it is or is not believed that the lung has been damaged, provided there is no pneumothorax and no violent hemorrhage. What course should be pursued if the lung has been injured by a stab? If hemorrhage does not threaten life and there is no pneumothorax, the patient is kept at rest and observed. If pneumothorax occurs, the pleural sac must be drained by means of a tube, because clots must be evacuated and infection should be anticipated. If hemorrhage into the pleural sac persists, active measures become necessary. The use of ice-bags and drugs is but waste of time. Some surgeons believe that the mere closure of the external wound leads to arrest of hemorrhage, blood accumulating and making pressure. It is true that hemorrhage often ceases after suturing or plugging a

wound and strapping the chest, but it is not probable that it ceases because of these measures. It has long been taught that blood in the pleura usually remains unclotted for several or many days. Elliot and Henry ("Lancet," 1917, ii) as a result of experience in this war assert that clotting occurs quickly because of ferment liberated from the wounded tissues, though complete clotting may be hindered by the respiratory movements. Further, as Le Conte[1] shows, as the blood is forced against the root of the lung the right heart is engorged, the blood-pressure is raised, and the bleeding continues.

Bleeding from the lung can sometimes be arrested by aspiration of blood and injection of the pleural sac with nitrogen gas. It may often be arrested by inserting the end of a drainage tube into the pleural sac. In cases in which a drainage-tube is inserted into the pleural cavity and free drainage established the pleura is immediately filled with air, and the muscles of respiration are kept from acting on the lung. The lung contracts by its own elastic tissue, as well as by the pressure exerted by the pneumothorax, and at the same time the presence of the air favors clotting in the severed vessels.[2] Baudet maintains that all grave wounds of the lung should be operated upon. If the insertion of a tube fails, or if the bleeding is rapid and obviously threatens life seriously, several ribs must be rapidly resected and the bleeding part explored. In some cases the bleeding may be arrested by ligation, in some cases by packing a small wound with gauze, in some cases by the suture-ligature. Two cases of lung suture have been recorded by Philadelphia colleagues (Jopson, in "Annals of Surgery," 1906, vol. xliii; Kelly, in "Annals of Surgery," 1910, vol. li). In a violent secondary hemorrhage following a gunshot-wound of the lung I packed the entire pleural cavity with sterile gauze to obtain a base of support, and arrested the bleeding by carrying iodoform gauze directly against the oozing surface.[3] The man recovered. I did the same thing on a Chinaman suffering from a gunshot-wound of the lung. The hemorrhage was arrested and he lived three weeks, dying finally from pericarditis. After directly arresting hemorrhage from the lung, turn clots out of the pleural sac and insert a drainage-tube. In a perforating wound inflicted by a bullet, reaction must be brought about, the wound dressed antiseptically, the chest strapped, and the patient kept quiet. If pneumothorax occurs, the pleura should be drained with a tube. If hemorrhage occurs, it should be met as directed above. In a wound in which the bullet has lodged, an examination should be made to see if the bullet is under the skin, and if it is, it is removed after the patient has reacted. It should always be borne in mind that a pistol-bullet may be deflected by a rib or may pass from the front to the back part of the chest by making a burrow under the skin (*a contour wound*). If a bullet is lodged, no attempt should be made to remove it unless an operation must be done for bleeding, unless the bullet causes trouble, or unless it is felt under the skin. Under no circumstances conduct a long search for a bullet. If emphysema of the chest walls is moderate, strapping or a bandage will control it; if it is great, make multiple punctures and then apply pressure. In protrusion of a portion of the lung try to restore the protrusion; but if restoration is impossible or if gangrene seems likely to occur, ligate the base of the protrusion with silk and cut away the mass.

Moller ("Archiv. f. klin, Chirurgie," 1909–10, vol. lvi) collected 26 cases of gunshot-wounds in civil life, which were operated upon, and 11 died (42 per cent.). In 20 suturing was done, with 7 deaths. In 2 the wound was sutured to the pleural opening, with 1 death. In 2 lung resection was followed by death. One, in which pleural packing was used, recovered. He collected 10 stab-wounds: 7 were sutured, with 1 death. In 3 the pleura was packed and all recovered.

Wounds of the Chest Involving the Diaphragm.—In such a case abdominal viscera may pass through the wound in the diaphragm and appear in the wound of the chest. If there is no indication of a wound of the abdominal viscera some surgeons would suture the wound of the diaphragm by way of the thorax. If there are indications of injury of abdominal viscera the abdomen must be opened. Personally, I prefer to open the abdomen in every chest wound implicating the diaphragm, even when symptoms of injury to abdominal viscera are not as yet manifest.

Chest Wounds in War.—In many recent engagements chest wounds represent 1 in 40 of the wounded. Our knowledge of these wounds is gathered from the immense experience of many military surgeons (Moynihan, Hull, Gray, Anderson, Duval, Depage, Rouvihois, Henry, Elliot and many others). A missile may perforate the chest, making a wound of entrance and a wound of exit (perforating wound). It may penetrate the chest and lodge, in which case there is a wound of entrance but no wound of exit (penetrating wound). A tangential wound may do as much damage as though the missile entered the chest, the damage being caused by bone-fragments. H. M. W. Gray ("N. Y. Med. Jour.," June 8, 1918) divides chest wounds clinically in the following useful manner:

1. No operation required.
2. Operation required at the earliest possible moment.
3. Question as to immediate operation doubtful.
4. Moribund and useless to operate.

We consider here wounds of the lungs and pleura. For heart wounds see page 464.

Sir Berkeley Moynihan ("American Addresses") discusses the mortality of chest wounds and shows that it differs greatly "at various parts of the line of communication." At the first-aid stations it is from 25 to 30 per cent. At the casualty clearing stations it is 18 to 20 per cent. In the base hospitals it is 10 per cent. "At the aid post, where the mortality is 25 per cent., there will remain alive, of 100 patients, 75. At the ambulance, of these 75, 20 per cent. will die and there will remain 60 patients. At the base of these 60, 10 per cent. will die, so that finally 54 cases will survive."

Moynihan (Ibid.) points out that the mortality is influenced by the nature of the projectile. A rifle bullet makes a very dangerous wound if it divides a large vessel. It makes a comparatively benign wound if the lung is wounded but no large vessel is damaged. Wounds from shell fragments are torn and irregular and bits of skin and portions of clothing are apt to be carried in. Such wounds are very grave because of the great probability of infection. It is well known that many cases of perforating bullet wounds recover easily. A rifle-bullet lodged in the lung may cause no symptoms and become encapsuled. Large shell fragments are always dangerous and should be removed.

Little or nothing can be done for chest wounds at the first-aid station. When such cases reach the evacuation hospital station they are usually gravely shocked. They require stimulants and if there is an open wound which sucks air it should be sutured or plugged to make it air-tight. Usually in a couple of hours alarming symptoms have largely subsided (Gray, Ibid.). It is desirable, if circumstances admit, to perform any urgently necessary operation in the evacuation hospital. Some cases are kept for several days and then sent to the base. There may be a lodged bullet. A rifle ball may have perforated. A rib or ribs may be broken. So may the scapula. A shell fragment may have broken ribs and driven them in, may have crushed the chest in or may have torn away a part of the wall of the thorax. A hail of bone-fragments may have been driven into the lung or pleura.

The bronchi usually escape injury. It is seldom that fissures or tears radiate in the lung from the track of the missile (Moynihan, Ibid.). Distant

parts of the lung or pleura may be damaged due to the force of the impact or by the alteration in air pressure produced by the explosion of the shell. "There may be hemorrhages by "contrecoup" in the upper lobe if the lower is wounded, or in the lower if the upper is injured, or in both if the projectile has passed near the base of the lung." There may be hemorrhages in the other lung or beneath its pleura, bronchopneumonia may arise in it or septic matter may be inhaled from the trachea ("American Addresses," by Sir Berkeley Moynihan). In some cases hemothorax is slight in some a quart or more of blood gathers. Inflammation soon arises and exudate is added to the blood. As hemothorax increases the lung collapses and collapse lessens and perhaps arrests bleeding. It was formerly taught that blood in the pleural sac did not tend to clot. We now know that it does clot. Hemothorax, if infection does not occur, will seldom be fatal but infection will occur in two-fifths of the cases (Moynihan, Ibid.). Moynihan points out the important fact that the upper portion of the fluid may be uninfected when the lower is infected, hence a tap may give deluding results.

Duval points out that in nearly half of all infections the infecting agents are anaërobic bacteria. Such infection arises from the wound (bacillus of gas gangrene, *Bacillus sporogenes*). Aërobic infection may come from the respiratory tract (pneumococci, staphylococci, etc.) or from the wound (streptococci or colon bacilli).

Treatment.—We have spoken previously of the reactive treatment necessary when the patient is brought into the evacuation hospital. Immediate operation is necessary when there is great dyspnea due to hemothorax or hemopericardium; to a foreign body in the diaphragm or to rapidly increasing infection especially by bacteria which form gas; severe and lasting pain (due probably to irritation of pleura or pericardium by a sharp-edged foreign body or a rib fragment) (H. M. W. Gray, Ibid.). Many cases with a wound of entrance and a wound of exit have very little hemothorax and soon recover from shock. "If the hemothorax does not reach higher than the nipple line, shows no sign of increasing, and if there is no evidence of infection, such cases may be sent to the base without danger in the course of three to six days" (H. M. W. Gray, Ibid.). In non-infected, closed hemothorax the pulse, respiration and temperature should become practically normal in twenty-four hours, if they do not do so an exploratory puncture should be made and the fluid obtained should be subjected to a bacteriological study. If the fluid has a foul odor, if the froth in the syringe has a "crimson purple color" no further proof of anaërobic infection is necessary (H. M. W. Gray, Ibid.). This test should be made every day until the situation has become clear. "The test is by no means infallible. Sepsis may develop in islands or areas of the clot or fluid which are not tapped by the needle. Increase of pneumothorax or development of resonant patches in previously dull areas should make one suspicious of gas infection. If, then, other symptoms pointing to infection are sufficiently prominent operation should be undertaken without waiting for bacteriological confirmation" (H. M. W. Gray, Ibid.).

A small, non-infected hemothorax does not require aspiration; usually the fluid will be absorbed rapidly, but if it lingers, diagnostic puncture and a bacteriologic examination of the fluid are called for. Gray (Ibid.) says that a mild infection may be cured by repeated aspiration.

If a hemothorax is large it will not do to send the patient to a base sooner than from three to six days. If during the wait respiration becomes difficult a slow aspiration is indicated, and the withdrawal of fluid is to cease as soon as respiration is relieved. Rapid aspiration may cause the hemorrhage to start again (Gray, Ibid.). If after relief by aspiration urgent symptoms arise again, operate. The operation consists in evacuating blood, clots and exudate, arresting the bleeding and closing the wound in the chest-wall. In many chest wounds we are in doubt what to do. If we do not operate sepsis may arise. The operation is dangerous. On one side is a danger which is problematical. On the other

is an operation which might give relief and save from sepsis but which is dangerous. Gray (Ibid.) says that in many of these cases operations followed by complete closure of the chest wound have been highly successful, and that the use of the blood transfusion in early stages would secure better results and give strength for a radical operation. If there is a severe open wound and the patient is not moribund, operate at once. If the wound is large and lacerated and a shell fragment is lodged, clothing and other infected matter has in all probability been carried in. There may be a sucking wound, a tangential wound. Take an *x*-ray picture. Give nitrous oxide and oxygen in preference to ether. Excise the damaged tissue. In some cases use this wound as the door of entrance for our work. In others close it at once and remove the fifth rib to permit of necessary procedures. Liquid blood is to be drawn off or poured out, clot is to be spooned and mopped out, the lung is grasped and drawn out of the wound. The missile is located, cut down upon and removed. The lung wound is excised, is sutured with catgut, the lung is wiped off with ether, sutured with catgut and restored to place. The wound in the chest-wall is sutured and sealed hermetically. The pleural sac is aspirated. As air is withdrawn the lung expands.

Occluding Pulmonary Embolism.—By this term we mean an embolism which completely blocks the pulmonary artery or some of its chief branches. Such cases occasionally follow a surgical operation, especially an abdominal operation. They are more frequent than used to be thought. The clot is derived from a vein. The calamity is most apt to occur between the second and fourth weeks after an operation (Bartlett and Thompson, in "Annals of Surgery," May, 1908). Pulmonary embolism may arise from fractures, inflamed veins anywhere, and during or after pneumonia, erysipelas, typhoid fever, and any acute infection. In malignant endocarditis and mitral stenosis small emboli are common. If the pulmonary artery is completely blocked death occurs at once. If one branch only is blocked the patient may recover if the heart is sound and strong. If the artery proper is partly blocked the patient has a period of suffering and dyspnea before death, but death is sure to occur from subsequent complete blocking.

Bartlett and Thompson (Ibid.) report 22 cases of occlusive pulmonary embolism, 20 of which were fatal. The greatest cause in a surgical operation seems to be varicose veins, especially about an abdominal or pelvic tumor. I am convinced that most sudden deaths in infected cases are due to pulmonary embolism. I have seen pulmonary embolism after an operation for varicocele, for hydrocele, for duodenal ulcer, and for appendicits.

I found myself wondering if more care in hemostasis might not lessen the liability to the accident. If vessels ooze and a clot gathers, the clot projects into the lumen of open vessels and muscular effort or even slight infection may loosen it (see page 207).

The **symptoms** of a mild case of embolism are rapid pulse, dyspnea, after some hours dulness of the base and impaired breath sounds, and, perhaps later, spitting of blood. In a real occluding embolism there are sudden collapse, cyanosis or pallor with livid lips, the pulse at the wrist is absent or very rapid, and irregular. There are pain in the chest, intense dyspnea, dilated pupils, and early unconsciousness. The right side of the heart distends greatly and the second sound is accentuated in the pulmonary area.

Schumacher in discussing these cases says there are three classes of them: Those in which almost immediate death occurs; those in which death occurs in a few minutes, and those which last much longer. In the last mentioned cases a main branch becomes blocked and total obstruction is gradual (Willy Meyer, in "Annals of Surgery," August, 1913). These cases only are suitable for operation. The surgeon must bear in mind the danger of embolism and endeavor to prevent it in operations by handling and exposing viscera as little as possible, by applying ligatures above all clots in veins and all varicosities, and removing

the affected structures. Quénu proposed to lessen the danger of postoperative thrombosis by administering citric acid before operation. This agent lessens the coagulability of the blood. Tuffier fears this remedy, believing that it makes an existing thrombus more apt to break up and form emboli ("Presse Médicale," April 20, 1910).

Treatment.—In small, non-occluding emboli, in which condition the only symptoms are dyspnea, pain, rapidity of pulse, and, after some hours, dulness at the base and impaired breath sounds, give stimulants, dry cup the chest, and administer morphin if there is no cyanosis. In a very severe case death is rapid and there is nothing to do medically.

Trendelenburg, of Leipzig, suggests surgical treatment (German Congress of Surgery, 1908). He points out that death is not always sudden (in 7 cases out of 9 the victim lived from ten minutes to one hour), and advises opening of the pulmonary artery and removal of the embolus. The first patient operated on died before the completion of the operation. "Since then it was done, twelve times in all, at the Leipzig clinic, without one permanent recovery (Willy Meyer in "Annals of Surgery," August, 1913). One patient lived four days; 1 died on the table; 1 died in fifteen hours from cardiac failure; 1 lived for thirty-seven hours and died of reactionary bleeding from the internal mammary artery. Kruger did one operation for embolism. The early result was apparently successful, but the patient died of infection on the eighteenth day ("Zentral. für Chir.," May 22, 1909). In Sauerbruch's clinic at Zurich the operation has been performed four times without a recovery (Willy Meyer, Loc. cit.). Of 15 recorded cases not one recovered, though one lived until the fourth day.

Trendelenburg thinks that the surgeon has about fifteen minutes in which to work. The operation is done under differential pressure. The pleura is opened, then the pericardium. A rubber tube is passed through the transverse sinus of the pericardium and the aorta and pulmonary artery are constricted. This constriction must be released within forty-five seconds. The artery is opened, the clot removed, the arterial wound clamped, and the elastic constriction released. The arterial wound is then sutured.

Abscess of the lung may follow ordinary pneumonia. It is more apt to follow aspiration-pneumonia. Wessler states that 28 per cent. of all cases of lung suppuration examined in the *x*-ray department of Mt. Sinai Hospital, N. Y., arose after operation upon the mouth, tonsils or pharynx (Lilienthal in "Annals of Surgery," 1916, lxiv). It is usually caused by streptococci or staphylococci, but it may result from pneumococci or colon bacilli. These germs may reach the pulmonary tissue by direct entrance from adjacent organs, by way of the blood, or by way of the bronchi and alveoli. Osler[1] tells us that pulmonary abscess may result from the aspiration of septic particles after "wounds of the neck, operations upon the throat," and suppurative lesions of the nose, larynx, or ear. Aspiration-pneumonia may develop when there is difficulty in swallowing from any cause, when there is profound exhaustion, and when there is palsy or incoördination of any of the muscles of deglutition. Cancer of the esophagus may be a cause; so may perforation of the lung by an abscess, wound of the lung, impaction of a foreign body in the lung, suppuration about a focus of tuberculosis or a metastatic abscess. A pulmonary abscess may be of trivial size or it may be very large, involving an entire lobe. There may be one abscess, several, or many. When suppuration results from aspiration-pneumonia or blood-infection, there are usually multiple abscesses.

Symptoms.—The expectoration is not frequent, but is profuse, and during a paroxysm mouthfuls are coughed up in rapid succession. The expectorated matter is sour or very offensive in odor and contains fragments or shreds of pulmonary tissue, which can be identified as such by the microscope. The

[1] "Practice of Medicine."

patient lies upon the diseased side in order to keep the pus from running into the bronchi and causing cough. When the cavity fills and pus reaches the bronchi, violent cough and expectoration begin, continue until the cavity is partly or entirely emptied, and then subside, perhaps for several hours. If the abscess-cavity is large and full of pus, an area of dulness on percussion can be mapped out. When the pus is coughed out and the air enters, physical signs of a cavity are clear. The *x*-rays often show the situation of such a cavity.

The course of abscess of the lung is usually acute. There are fever of the hectic type, rapid loss of weight, weakness and rapidity of circulation, dyspnea, pallor, sleeplessness, and great weakness. Gangrene may arise; empyema or pyopneumothorax may develop; very rarely the abscess breaks through the chest wall; recovery may follow spontaneous evacuation or drainage by coughing up pus; death may result from exhaustion or secondary septic lesions. If operation is performed, from 70 to 80 per cent. of the patients will recover. In an abscess which opens into a tube, it may be possible to collapse the lung and hence the abscess by filling the pleura with nitrogen gas. This can only be done in cases free from pleural adhesions. (Greer, in "Jour. Am. Med. Assoc.," April 1, 1916 and Tewksbury, in "Jour. Am. Med. Assoc.," March 10, 1917).

The **treatment** in most cases is purely surgical (*pneumotomy*). Make an incision over the cavity. Resect a portion of one or more ribs. Expose the pleura. If the two layers of the pleura are not adherent, suture them together and either wait two days, or surround the area to be incised by a coffer-dam of gauze and then operate. If they are adherent, always proceed at once. Search for the abscess with an aspirating needle. When the cavity is found, open into it with the actual cautery and insert a drainage-tube (see page 1040). The direct mortality is about 20 per cent.

Gangrene of the Lung.—This term means the putrefaction of a devitalized portion of pulmonary tissue. The tissue is devitalized by the action of pyogenic micro-organisms. Gangrene may follow abscess, bronchitis, or pneumonia, or may be due to diabetes, to embolism of a branch of the pulmonary artery, bronchiectasis, tuberculosis, malignant disease, wounds, or the lodgement of foreign bodies. Gangrene may be circumscribed or diffused. There may be one cavity, small or large, or multiple cavities may form. The gangrenous area putrefies, softens, and the softened matter may be expectorated, a gangrenous cavity being formed. In the rare cases which undergo spontaneous cure the cavity is, after a time, surrounded by fibrous tissue and obliterated by granulations. The mortality from operation is about 30 per cent.

Symptoms.—Expectoration occurs only now and then, but at each seizure a great quantity of matter is brought up and this matter is horribly offensive. Occasionally there is no expectoration. The patient, as in lung abscess, lies upon the diseased side. The expectorated matter is mucopurulent, contains particles or shreds of pulmonary tissue, bacteria, and altered blood. The fetor of the pus is much greater than is the fetor of the pus of an abscess. The breath is very foul. Physical signs may indicate either consolidation or a cavity. There are hectic fever, great exhaustion, deathly pallor, and diarrhea. Pulmonary hemorrhage is not unusual, and complications spoken of in the article upon Abscess may occur (see page 1028). Recovery sometimes ensues, the cavity closing by granulation. Death may take place in a few days. Often the patient lives for weeks, being sometimes better and sometimes worse, dying finally from exhaustion or from the effects of a complication.

The **treatment** is to operate as for pulmonary abscess.

Bronchiectasis.—This term means dilatation of the bronchial tubes. The dilatation may be fusiform, saccular or trabecular. The first form, or true bronchiectasis, is great dilatation of a tube caused by strain. It is most common in children and in them is a result of coughing. The other two forms occur in

adults and result from chronic inflammation. There may be one or more cavities. Not only are the bronchi dilated but fibrous tissue has formed about them. The condition may result from bronchial inflammation, from pulmonary sclerosis, or from the presence of a foreign body. Surgeons sometimes see bronchiectasis following tonsillectomy or operation for adenoids (Lilienthal, in "Annals of Surgery," 1916, lxiv). In bronchiectasis there are parosysms of violent cough with intervals of hours between them. The expectoration is profuse, mucopurulent and fetid. If very purulent it is like the matter coughed up by a victim of pulmonary abscess. Hemoptysis may occur. The physical signs are uncertain. Fever is seldom present unless purulent matter is long retained. The *x*-rays and the bronchoscope are very useful in diagnosis. The fingers may become clubbed. Most cases are treated medically. Drugs may be directly introduced through the bronchoscope. If medical and local treatment fails surgery must be considered. Pneumotomy does not cure the case. Radical operation is only to be considered in a unilateral lesion which is not very extensive and in which in spite of medical and local treatment the patient grows progressively worse. Radical operation consists in extirpation of the diseased lobe. Lilienthal (Ibid.) cured 4 cases out of 7.

The operation of lobar resection has a large but not a prohibitory mortality. Samuel Robinson reports five complete resections of the lower lobe of a lung with one death (Surgery, Gynecology and Obstetrics, Feb., 1917).

Torek's interpleural pneumolysia may be considered for the treatment of bronchiectasis (page 1032).

Surgical Treatment of Pulmonary Tuberculosis.—For a number of years past surgical thought has been actively directed toward placing on a scientific footing operations for pulmonary phthisis. The matter is still in a transition stage, and operations at present have a very limited field of application, although Sonnenberg and others have reported cures. Baglivi, in 1643, endeavored to tap and inject tuberculous cavities. Hastings and Stuckè did the same thing in the eighteenth century. Mosler, a number of years ago, attempted to treat cavities by introducing a trocar into the cavity and injecting permanganate of potassium solution through the cannula. Patients were not benefited by this procedure. The plan was revived by Pepper in 1874. The results are bad and the operation is dangerous. Hillier tried injection of corrosive sublimate into the lung parenchyma, but the effect of the injections was disastrous. Vidal advocates counterirritation by the actual cautery and maintains that congestion improves nutrition. When the strength of the patient is well preserved and the pulmonary lesion is circumscribed and slowly progressive, it may, in some few cases, be justifiable to perform an operation, open the cavity, and treat it directly (*pneumotomy*). That pneumotomy might be performed successfully was suggested to surgeons by observing that some patients recovered after sword-thrusts into the lung. Fowler said it is not justifiable to operate if the disease has come "to a standstill." The same surgeon stated that the only accessible region is bounded above by the clavicle, to the inner side by the manubrium, to the outer side by the lesser pectoral muscle, and below by the second rib.[1] This operation does not cure any one, but it may cause distinct improvement when there is hectic fever from an ill-drained cavity containing the products of a mixed infection. In an advanced case there is usually more than one cavity, and if there is, the operation is contraindicated. Before attempting it, be sure the case is advanced and not incipient and that the cavity is single. Locate the cavity by auscultation, percussion, and the *x*-rays. Tuffier collected 45 cases and only 1 was a success.

Mauclaise[2] says that pneumotomy is justifiable only in circumscribed

[1] See the very full and thoughtful article by George Ryerson Fowler on "The Surgery of Intrathoracic Tuberculosis," "Annals of Surgery," Nov., 1896.

[2] "La Tribune médicale," Sept. 21, 1893.

tuberculous cavities without peripheral infiltration and in pulmonary abscesses. Bronchiectatic cavities are usually multiple; they are exceedingly difficult to locate, and treatment by pneumotomy should not be attempted. In the treatment of pulmonary tuberculosis resection of the diseased area was proposed by Ruggi (*pneumectomy*). Tuffier successfully performed this operation. Surgeons, as a rule, do not believe in pneumectomy. Reclus[1] voices the general opinion when he says the operation is not required if the area of disease is very limited, as such a condition is frequently curable by medicinal means, and it does no good if the area of disease is extensive.

Only two methods of surgical treatment seem to have won a distinct place: one is the artificial production of pneumothorax; the other, some form of plastic operation upon the thorax to collapse and immobilize the lung.

Artificial Pneumothorax.—It has long been known that pneumothorax might benefit a tuberculous lung. Carson, of Edinburgh, in 1843, tried to create artificial pneumothorax by making a puncture in the visceral pleura to allow the passage of air into the pleural sac. Farlanini suggested the introduction of a gas into the pleural sac and reported a successful case in 1894. In 1898 Murphy began the use of nitrogen. In 1912 there were on record about 400 cases (Mary E. Lapham, in "Am. Jour. Med. Sciences," April, 1912). Since then many cases have been recorded. The method should only be used in unilateral cases which are not far advanced. It is used when the patient continues to grow worse in spite of medical treatment. The method is useless if there are adhesions, and is contraindicated if diabetes exists or if there is uncompensated valvular disease of the heart (Lapham, Ibid.). Adhesions forbid because they prevent pulmonary collapse. If adhesions exist the surgeon may consider Torek's operation to permit pulmonary collapse (page 1032). It is maintained that the operation occludes the lymph-channels, lessens the absorption of toxins (shown by the abatement of fever), prevents bleeding, compresses the lung, arrests its mobility, approximates the walls of cavities, squeezes masses of bacteria out of the tubes, favors the development of fibrous tissue, and leads to healing of cavities.

Certainly it seems that the once widely condemned therapeutic pneumothorax is of real value in proper cases and causes not only improvement but sometimes cure (Burnand, in "Rev. méd. de la Suisse Rom.," 1915, xxxv). Nitrogen is the best gas to use. It is non-irritant and remains long in the pleural cavity. Our aim is to keep the lung compressed for one year. The nitrogen is introduced by means of a special apparatus. At first injections are made daily, then every other day, then twice a week, then twice a month. The injection is made "over an area where the breath sounds and resonance are best" (Lapham, Ibid.). There is little danger in the method, but trouble may follow. There may be shock, dyspnea, or spasm of the glottis from pleural reflex. Other dangers are: gas embolism, convulsions, edema of the lung, empyema, pulmonary abscess (if the lung is stuck), cerebral embolism, and emphysema of the chest wall. A danger is an unfavorable influence on the other lung. In 18 cases out of 46 subjected by Mayer to the formation of an artificial pneumothorax exudate formed. In eight of the cases the exudate contained tubercle bacilli, in two staphylococci, and in one pneumococci (Boit, in Beitrag. z. klin. Chir., 1914, xciii).

Plastic Operations on the Chest Wall (Mobilization of the Thorax).—Freund and others asserted that a rigid thorax is a cause of phthisis. Allis[2] suggested that in extensive unilateral tuberculosis of the lung resection of a number of ribs would favor cure by permitting retraction of the chest wall. This operation is founded on the belief that the chief element in effecting a cure is the formation and contraction of fibrous tissue. Pulmonary collapse and

[1] "Revue de Chirurgie," Nov. 11, 1895.
[2] To State Med. Soc. of Penna., in 1891.

abolition of movements favor the formation of fibrous tissue. In this operation the pleura is not opened. Quincke, Landerer, and others remove portions of ribs with periosteum along the axillary line. Some surgeons remove portions of ribs and periosteum from directly over the lesion. In tuberculosis of the apex in a person with a narrow and rigid chest the followers of Freund remove the first rib. Freeman removes portions of ribs without periosteum and applies a truss to push in the chest wall ("Annals of Surgery," July, 1909). Friedrich, of Marburg, removes all the ribs from the second to the tenth inclusive and mobilizes the first rib (*thoracicoplastic pleuropneumolysis* with *subcostal apicolysis*). The pleura is not opened. He used to remove the periosteum, but does so no longer. He now leaves the periosteum so that after a time enough bone will re-form to prevent lung bulging on coughing. Sauerbruch, Wilms, and others have individual operations. When pneumothorax induction would be indicated were it not for adhesions Torek performs what he calls *interpleural pneumolysis.*

A long incision is made in the sixth or seventh intercostal space, the pleura is opened, the head is lowered, the ribs are held apart, the adhesions are separated by the fingers and later the hand is carried into the pleural cavity. When adhesions have been well separated the lung collapses. The wound is then closed (Surgery, Gynecology and Obstetrics, 1914, xix). The results of none of the above operations seem very encouraging.

Operations on Pleura and Lungs

Intrathoracic Operations Under Positive or Negative Air-pressure.—(This subject has been fully and judicially discussed by Jopson in "Annals of Surgery," May, 1911.) When under ordinary conditions the chest wall is widely opened the lung often rapidly collapses and the patient is placed in deadly peril (see Acute Traumatic Pneumothorax on page 1020). The reality of the danger has to a great extent retarded progress in the surgery of the heart, lungs, and lower portion of the esophagus. Of late, however, methods have been devised for maintaining normal respiratory movements and preventing pulmonary collapse during operations which open the pleura. There are two forms of pressure apparatus and each form finds warm advocates. Negative pressure is the form that is advocated by Sauerbruch. In Sauerbruch's negative pressure chamber the lung is kept from collapse by suction exerted upon its exposed surface. Positive pressure is advocated by Brauer. Positive pressure keeps the lung from collapsing by distending it from within. The two methods act similarly in many respects. Clinical observations and numerous experiments seem to prove that "emphysema, persistent pneumothorax, difficulty of narcosis, and infection of the pleura are not dangers associated with the use of positive pressure as such" (Samuel Robinson and George Adams Leland, in "Surg., Gynecol., and Obstet.," March, 1909).

The Sauerbruch Chamber (Fig. 654).—This is an air-tight cabinet. The sides are of boards covered with tin, the corners being soldered. The roof is of glass. The sides contain air-tight windows. There is one air-tight door.

The room is lighted by electricity and contains a telephone. The larger chambers have a communicating room. Instruments which are wanted can be placed in this room so that the surgeon may reach them. The patient's head projects outside of the cabinet and a tightly fitting rubber collar is placed around the neck. The body and legs are surrounded by a canvas-covered rubber sac the interior of which is in communication with the external air.

The chamber is sufficiently large to hold the patient, the surgeon, and the assistant. By means of an electric suction air pump, the valve of which is in the wall, negative pressure is obtained and is continuously maintained in the cabinet. The patient's thorax is exposed to the suction of negative pressure,

but the bronchioles are subjected to ordinary atmospheric pressure, hence, even when a wide opening is made in the chest wall, the lung does not collapse. The operator does not suffer from the negative pressure.

The Positive Pressure Apparatus.—Numerous apparatuses have been devised. Positive pressure used to be obtained by the Fell-O'Dwyer apparatus (see Fig. 653). The larynx was intubated and bellows were used. It can be obtained with this, but the apparatus is uncertain and difficult to use. Positive pressure can be obtained by the pulmotor and by the lungmotor.

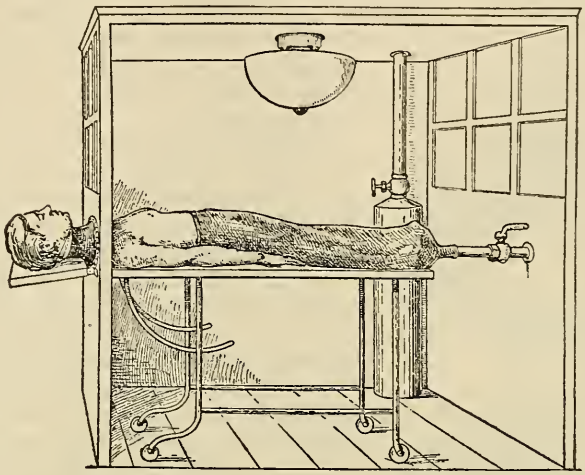

Fig. 654.—Sauerbruch's cabinet: Position of patient in chamber ready for operation under negative pressure.

Brauer advocated the following plan: When the patient has been anesthetized and the surgeon is ready to open the pleura, a glass case is placed over the patient's face and the air in the case is condensed by means of an apparatus.

Bauer subsequently modified the head chamber so that the hands and wrists of the anesthetist are admitted within it. Some surgeons have given compressed air by the nose, the mouth being sealed. Some give it by intubation from the mouth. The trouble with this method in man is that no com-

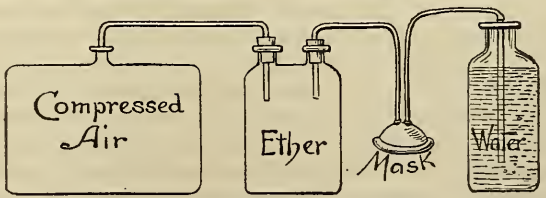

Fig. 655.—Scheme of apparatus for the maintenance of distention of the lung by positive pressure (Robinson and Leland).

pletely satisfactory tube has yet been made. As a general thing the best way to give it is by a well-fitting face mask. A small motor runs a rotary air pump and thus we dispense with the trouble and uncertainty of clumsy reservoirs. Robinson and Leland (Ibid.) state that any positive pressure apparatus consists of four elements: (1) A supply of compressed air; (2) an anesthetizing segment; (3) a device for introducing air and ether into the respiratory tract; (4) a means of varying the resistance of exhaled air (Fig. 655).

Intratracheal Insufflation (Method of Meltzer and Auer).—This method is highly valuable. It can be used to maintain respiration and, at the same

time, to give ether. The patient is first anesthetized by the ordinary method. A flexible and elastic tube is then carried through the larynx well into the trachea. In order to get it into the larynx use a tube director (Cotton and Boothby), or use Chevalier Jackson's direct laryngoscope, as do Elsberg and Peck. The tube usually enters the right bronchus before it blocks. When it blocks it should be drawn back 5 or 6 cm. (Meltzer, in "Keen's Surgery," vol. vi). The tube is an English catheter or, as Elsberg prefers, a woven silk catheter. The eye should be at the end. It is always decidedly less in diameter than the trachea. Meltzer says the largest size used should not exceed 8 mm. in diameter. The tube is attached to the insufflation apparatus. This forces the air, the air and ether, or the oxygen and ether into the lungs, and the vapor returns between the tube and the tracheal wall.

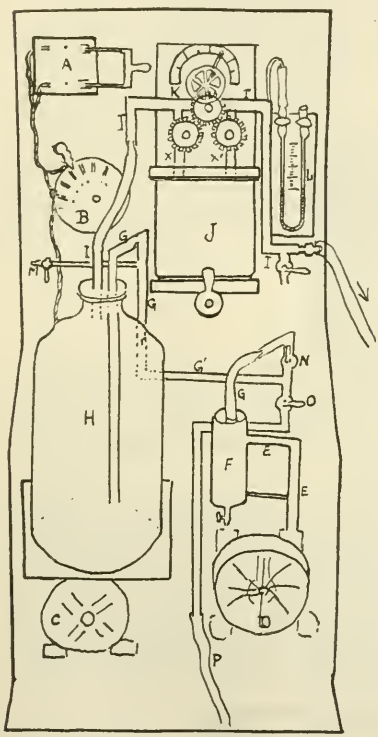

FIG. 656.—Diagram of Elsberg's apparatus showing essential parts.

Elsberg's apparatus is shown in Fig. 656. An electric current is turned on at the switch A. It is carried by wire to the motor C. This motor drives blower D. The air passes through a tube E, an oil filter F, and a tube G, into a bottle H, containing hot water. The air is then forced through the tube I to a rubber tube connected to the tracheal catheter. The tube I is also connected to the ether jar J. The tube P is joined to a foot bellows. This is a "safety device," for use if the motor or blower fails or if electricity is not available.

Exploratory Puncture of the Pleural Sac.—Puncture often gives valuable information as to the existence of fluid in the pleural sac and as to the nature of the fluid. The operation must be performed with aseptic care, otherwise a serous effusion might be converted into a purulent effusion, and either a serous or a purulent effusion might be rendered putrid. A large hypodermatic syringe with a long and strong needle is used for exploratory puncture. A slender needle breaks easily and is unsafe. In order to prevent breaking the needle, impress upon the patient the absolute necessity of keeping quiet and avoiding any violent respiratory or general movement during the operation. It is not desirable to stick the lung, although harm rarely results from such an accident. If no fluid is found in the pleura on one trial, several other punctures should be made. What is known as a dry tap may be due to the entire absence of fluid, to encapsulation of fluid in a region not invaded by the needle, to the lodgment of the point of the needle in thickened pleura or in an adhesion, or to blocking of the lumen of the needle with coagula. Fowler[1] points out that if a person has been recumbent for a long time the upper layer of fluid may be clear, while the lower layer is purulent. The fluid should be collected in a sterile glass tube and subjected to a careful bacteriological study.

Paracentesis Thoracis.—The operation of tapping with a trocar and allowing the fluid to flow out through the cannula is no longer practised except in an emergency, when an aspirator cannot be obtained, or in an

[1] "Annals of Surgery," November, 1896.

early stage of non-traumatic pneumothorax. An aspirator is a much better instrument.

Aspiration consists in the introduction into the pleural sac of the tip of a hollow needle, the other end of which is attached by means of a rubber tube to a bottle from which the air has been exhausted. The fluid does not run out, but is sucked out, air is excluded, and bacteria do not enter the pleural sac. Fig. 492 shows a pneumatic aspirator. No anesthetic is required. The patient's skin, the instruments, and the surgeon's hands must be thoroughly asepticized. The patient is given a little whisky, and, unless he is very weak, he assumes a semi-erect attitude, with the arm hanging by the side. The trocar is introduced in the fifth interspace, just in front of the angle of the scapula. The surgeon marks the upper border of the sixth rib with the index-finger, and plunges in the trocar just above the finger, thus avoiding the intercostal artery, which lies along the lower border of the rib above. He guards the needle with the index-finger to prevent its going in too far. The fluid is withdrawn rather slowly in order that the patient may escape syncope and violent cough. If the patient becomes very faint the operation should be abandoned. All the fluid present should not be removed at one sitting—complete removal of a large effusion is not safe. The operation can be repeated if necessary. After withdrawing the cannula place iodoform collodion over the opening in the chest. In an early stage of non-traumatic pneumothorax perform paracentesis without suction. In non-purulent pleuritic effusion, if the lungs will not expand after tappings, perform thoracotomy. In some cases aspiration is followed by pulmonary embolism or embolism at a distance. Syncope is a not unusual result. Convulsions occasionally occur. In rare cases the sudden withdrawal of a large effusion is followed by *albuminous expectoration,* as was pointed out by Pinault in 1853. It usually begins from a few minutes to half an hour after aspiration. When this complication arises the pulse is very weak, there are severe dyspnea, cyanosis, cough, and the expectoration of quantities of a yellow, frothy fluid. Riesman ("Amer. Jour. Med. Sciences," April, 1902) demonstrates that the condition is due to pulmonary edema and not to puncture of the lung. The sudden withdrawal of fluid by aspiration relieves the pressure which was compressing the lung, the lung becomes congested with blood (*congestion by recoil,* Riesman calls it), the blood distends weakened vessels, and profuse transudation takes place into the air-cells. Most cases recover in a few hours or a day or two. Severe cases die from asphyxia. Terrilon collected 23 cases, with 2 deaths. If albuminous expectoration arises, dry cup the chest and counterirritate with mustard plasters. Perform venesection. Give oxygen by inhalation. Administer atropin hypodermatically. Employ artificial respiration if necessary.

The Operation for Creating Artificial Pneumothorax.—Murphy's apparatus as modified by Brauer is shown in Fig. 657. The manometer is on the left-hand side of the figure. The jar for nitrogen (*A*) contains a solution of corrosive sublimate through which the gas flows. The water jar (*B*) is lowered and the nitrogen tube is opened, and as the stream of nitrogen passes along the glass tube it goes through a filter of sterile cotton. The tube from the jar of nitrogen joins a three-way stopcock (*C*). The nitrogen may be made to flow through the needle (*H*), or deliver the intrapleural pressure to a water manometer and a mercury manometer. After determining that the functional capacity of the other lung is sufficient to sustain the demands about to be put upon it, proceed with the operation. Follow Brauer's plan because it is the safest. Select a spot where the healthy sounds and resonance are best heard (Mary E. Lapham, "Amer. Jour. Med. Sciences," April, 1912). Expose the pleura by an incision. If adhesions are absent, puncture by a blunt instrument and explore by a catheter to be sure there is a pleural cavity. If a cavity exists attach the needle to the apparatus and inject the nitrogen. After in-

jection suture the wound. Subsequent injections are made by the needle alone, no incision being required.

Thoracotomy is an incision into the cavity of the pleura. It may be merely an intercostal incision, or may be an opening into the chest after resecting a portion of a rib. Often in a child with empyema good drainage can be obtained by an intercostal incision, but in most children and in all adults a rib should be resected.

If there is very little dyspnea, ether may be given. If there is considerable dyspnea, chloroform should be given. If there is severe dyspnea, no general anesthetic is admissible. In severe dyspnea the patient is using certain voluntary muscles to aid him in obtaining air. A general anesthetic abolishes the activity of the voluntary muscles of respiration, and so may cause suffocation. In such cases the operation can be done with fair satisfaction after

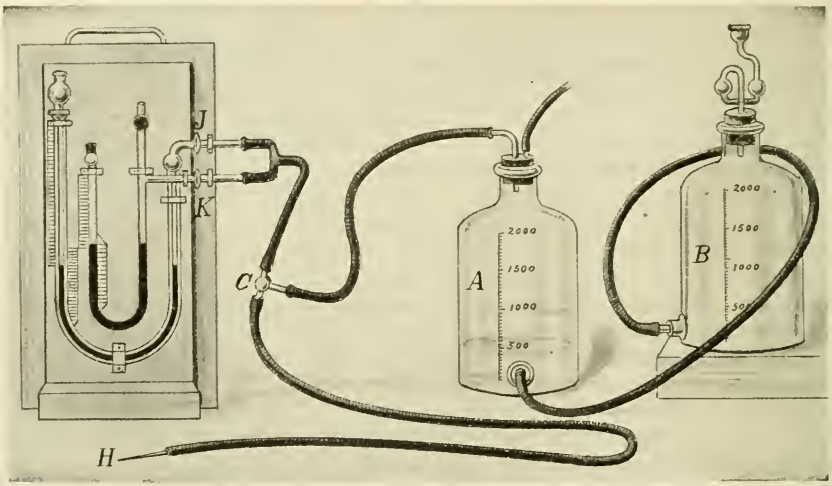

FIG. 657.—Brauer and Spengler's modification of Murphy's apparatus for nitrogen injections.

the injection of eucain or after infiltrating the superficial tissues of the chest wall with Schleich's fluid, or, what is better, preliminary aspiration can be performed. Aspiration will permit of the subsequent administration of a general anesthetic. The patient on whom thoracotomy is to be performed is placed supine, the diseased side being at or over the edge of the table. He must never be placed on the sound side, because he breathes with that side only, and pressure on it may be dangerous.

The arm of the diseased side should be elevated to a right angle with the body. If the surgeon desires to obtain intercostal drainage only, he should make a longitudinal incision about 3 inches in length at the upper border of the sixth or seventh rib, and the middle of this incision should correspond to the midaxillary line. This incision is carried, layer by layer, to the pleura. If, as will usually be the case, he wishes to remove a portion of a rib, he will make an incision about 3 inches in length directly upon the outer surface of the rib he wishes to remove, and the middle of this incision should correspond to the midaxillary line. Some surgeons resect a portion of the fifth rib, some remove a bit of the eighth rib, and Munro[1] shows that at the level of the eighth rib there is no danger of injuring the diaphragm. By many operators a portion of the seventh or eighth rib is removed in front of the line of the posterior axillary fold.

[1] "Medical News," Sept. 2, 1899.

I agree with Hutton that a portion of the sixth rib in the midaxillary line should be removed.[1] The reasons given by Hutton for the selection of this rib are: (1) It is over the portion of the lung which expands last. An empyema is drained only partly by gravity, and most of the fluid is really forced out and the cavity is obliterated by lung expansion. If an incision is made anterior or posterior to this point the expanding lung will block the drainage opening, and a pus-cavity without drainage will remain in the midaxillary line. (2) Such an incision permits a patient to lie on his back without making pressure on the drainage-tube.

The periosteum of the outer surface of the rib must be divided in the same direction as the superficial incision. The exposed rib is stripped of periosteum front and back by means of a periosteal separator, and with the periosteum at the lower border of the rib the intercostal artery is lifted out of harm's way. The rib can be divided by means of cutting forceps or a Gigli saw. The usual method is to push a periosteal separator under the rib and saw the bone in two places by means of a metacarpal saw (Fig. 658). I prefer a costotome, as it accomplishes the section most rapidly. An inch or more of the rib should be removed. The intercostal artery is ligated at each end of the incision, the periosteum is removed, and the pleura is opened. The object of removing the periosteum is to prevent the rapid formation of bone which might narrow the opening and interfere with drainage. The actual opening of the pleura is carried out in the same way in intercostal incision and after rib resection. A grooved director is pushed into the pleural sac, and the opening is enlarged by means of the forceps and the finger.

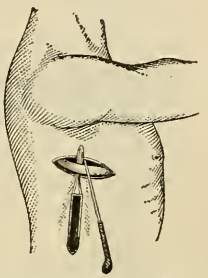

Fig. 658.—Resection of a rib (Esmarch and Kowalzig).

The finger removes all masses of tuberculous material or aplastic lymph within reach. If the finger finds the lung firmly bound down by dense adhesions so that it cannot expand, simple rib-resection will not cure the patient. If the adhesions between the parietal and visceral pleura can be separated by the finger the lung may expand. In order to accomplish this separation a piece of more than one rib must be removed, because it is necessary to insert more than two fingers (Samuel Lloyd, quoted by Lund, in "Jour. Am. Med. Assoc.," August 26, 1911). If adhesions cannot be separated so that the lung can expand, Estlander's, Schede's, or Fowler's operation should be done. Some surgeons advocate immediate irrigation after opening an acute empyema, but this procedure has long been thought unsafe. It is true that in most cases flushing does no harm, but in no case will a single flushing sterilize the cavity, and in some cases it is very dangerous. The pleura is very susceptible to the action of irritants. This is especially true of young children. It happens occasionally that the injection of the blandest fluid is followed by intense dyspnea, great shock, disturbances of respiration and circulation, convulsions, and even death (Quénu). The convulsions which occasionally follow pleural irrigation were called by de Cerenville *pleural epilepsy*. In putrid empyema I have always irrigated. Irrigation will remove part of the actively poisonous putrid matter, and the retention of putrid matter is a greater danger than irrigation. I now irrigate all empyemata gently every two hours with Dakin's fluid. This combats foulness, fever, and suppuration, and favors healing. It is much safer than flushing by means of a large and forcible stream but even this process sometimes produces pleural epilepsy (see page 1018). Some believe that pleural epilepsy is a reflex phenomenon. Others, especially Breuer, maintain that it is due to embolism. In favor of the reflex theory is the fact that a preliminary injection of morphia prevents it. I regard the method as

[1] See W. Menzies Hutton on "Empyema," in "Brit. Med. Jour.," Oct. 29, 1898.

an immense improvement in practice. It saves many lives in spite of its occasional danger. The balance is strongly in its favor. It was formerly a common custom to make a counteropening by cutting down upon the long probe pushed against the chest wall after being introduced through the incision, but a counteropening is of no particular use. A drainage-tube about 2 inches in length, carrying a Carrel tube fastened upon it, is introduced and stitched in place. The tube must not be long enough to touch the lung. A safety-pin is clamped upon the tube to keep it from slipping into the chest. A tape should be fastened to each side of the tube and tied about the chest to prevent it from slipping out. Arrest bleeding, suture the skin, dress with gauze and a binder, and have the dressings changed as soon as they become soaked at one point. The Carrel tube is kept blocked except when we irrigate. Then the drainage tube is blocked and the fluid is permitted to flow in. When sufficient has entered the Carrel tube is blocked and the drainage tube is opened. This process is repeated until the fluid runs out clear. Several times a day change the patient's position. At each change of dressings direct him to lie on the diseased side with the foot of the bed raised for half an hour. Healing takes place by ascent of the diaphragm, expansion of the lung, and retraction of the chest wall. Expansion of the lung is favored by expiratory acts; hence cause the patient several times a day to blow through a rubber tube into a 1-gallon Wolff bottle filled with water. The water is blown into another bottle attached to the first by a tube. Remove the drainage-tube when the discharge becomes thin and scanty (about the eighth or tenth day, as a rule). If an empyema ceases to improve and remains stationary for months after it has been drained, firm adhesions exist. If after one year has passed a cavity still exists and there is a flow of pus, the surgeon must perform the operation of Schede, Estlander, Fowler, or Ransohoff.

Thoracoplasty (**Estlander's operation**) was first proposed by Warren Stone, an American surgeon, but was set forth in detail by Estlander, of Helsingfors, in 1879. It is employed in old cases of empyema in which drainage has failed and in cases with retracted chest wall, collapsed lung, thickened pleura, and cavities whose rigid walls will not collapse. The procedure recognizes the fact that after pus is evacuated, if the lung is adherent, it cannot expand to fill the space once occupied by fluid, and that the rigid chest wall cannot fall in as a substitute for the lung. It seeks to destroy the rigidity of the chest wall and to permit it to collapse and thus obliterate the cavity of the empyema. In this operation a piece is removed from every rib which overlies the cavity. When the surgeon resects a rib and finds a cavity with uncollapsible walls, or a lung bound down with firm adhesions, he should perform thoracoplasty. This operation causes the obliteration of the cavity by collapsing that portion of the chest wall overlying it. The cavity is usually in the upper or central part of the pleural space. The instruments required are the same as those for resection of a rib. The position is the same as that for rib resection. The length of the incision depends on the size of the cavity. The surgeon usually removes portions of the second, third, fourth, fifth, sixth, and seventh ribs. Make a transverse incision along the center of an intercostal space, and through this incision remove the ribs above and below by the method set forth on page 1036 (the removal of six ribs will require three incisions). Instead of this incision, we can make a vertical incision or a U-shaped flap. Always take away the periosteum in order to prevent reproduction of the ribs. In cavities which are surrounded by firm adhesions, and in old cases in which the pleura is greatly thickened, irrigation is safe. If the cavity is small, it should be packed with iodoform gauze and allowed to granulate; if large, it should be drained by a large tube, the skin being sutured by silkworm-gut.

Schede's Operation.—Schede, of Hamburg, showed that when the pleura is much thickened, even Estlander's operation will not permit the chest wall to

collapse and fill the cavity once occupied by the fluid. The instruments used are the same as for Estlander's operation. A U-shaped flap is made from the level of the axilla in front to the level of the second rib and between the scapula and spine behind. The lowest level of this incision corresponds to the lowest limit of the pleura (Fig. 659). The flap is loosened and raised and the scapula is lifted with it. The ribs from the second rib down and from the costal cartilages to the tubercles are removed, along with the intercostal muscles and the pleura. This is accomplished by cutting with bone-shears and scissors. Hemorrhage is arrested. The pleura is curetted. A drainage-tube or a piece of iodoform gauze is introduced, and the raw flap is laid against the visceral layer of the pleura. The superficial incision is sutured, except at the point where the tube or the gauze emerges. The average mortality from Schede's operation is from 15 to 20 per cent. The operation is far more often necessary in adults, but the results are much better in children.

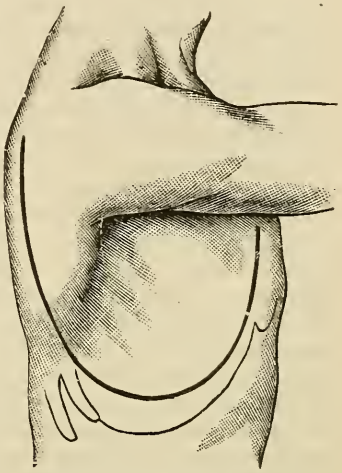

Fig. 659.—Incision for Schede's operation of thoracoplasty (Esmarch and Kowalzig).

Total Pleurectomy or Pulmonary Decortication (Fowler's Operation).—In the spring of 1893 de Lorme, of the Val de Grace, performed some experiments on dogs looking to the development of the operation. In October, 1893, the late George Ryerson Fowler, of Brooklyn, having no knowledge of de Lorme's investigation, operated on a man and cured a chronic empyema. The French surgeon's first operation was months later. De Lorme sought to do without the great mutilation of the Schede operation. His idea was to make an opening in the chest wall large enough to work through (but not nearly so large as that caused by Schede's operation), incise the dense fibrous membrane which binds down the lung, and allow the lung to expand and fill the cavity. De Lorme makes a trap-door incision. Fowler resected ribs extensively to obtain room. The thickened fibrous membrane is removed from the chest wall, lung, pericardium, and diaphragm, any sinus is extirpated, and all granulation tissue is taken away. The shrunken lung expands to fill the cavity.

Lund describes the operation as follows ("Jour. Am. Med. Assoc.," August 26, 1911): "In regard to the technic of the operation, the method of the resection of 1½ inches of five or six ribs, through an incision running upward an forward from the anterior end of the old drainage incision, has proved, to my mind, very satisfactory. In slitting up the thickened pleura beneath the ribs I have had, in one or two cases, to grab the intercostal artery, but have been very much surprised to find how little trouble there has been from bleeding. The visceral pleura, which is about ¼ inch thick and which is more like the sole of an old rubber shoe than anything else, is carefully incised with a knife over the lower part of the lung. The finger is inserted through the incision and, as soon as the soft surface of the lung is felt, is swept to an fro with the pulp of the finger toward the pleura and pressing outward so as to cause the least possible damage to the lung. Then a pair of blunt-pointed scissors is inserted and the membrane slit clear up to the top of the chest, and cleared off from the lung with the finger. A wound of one or two of the air-cells resulted in 2 or 3 of my cases, allowing the escape of bubbles of air on exploration, but so small an area of the lung was affected that, apparently, no harm resulted. In regard to the after-treatment, it is probable that after the patient is put to bed the lung

does retract to a certain extent, but the occasional coughing keeps up the expansion. The thick, pus-soaked dressing, if tightly applied, to my mind, acts as a more efficient valve than any mechanical valve which one could employ."

Fowler made a report of 30 cases. Eleven cases were completely cured. In 17 cases the empyema was cured, but 6 of them had tuberculosis. There were 3 deaths. The combined statistics of Fowler, de Lorme, and Cestan show 35.7 per cent. cured, 19.7 per cent. improved, 33.9 per cent. not cured, and 10 per cent. died (Kurpjweit, in "Beiträge fur klinischen Chirurgie," Bd. xxxiii, H. 3).

Discission of the Pulmonary Pleura (Ransohoff's Operation).—This operation was devised by Ransohoff, of Cincinnati. It can be employed when decortication is impossible, and it may be used as a substitute for decortication in certain cases. It permits the shrunken lung to expand. It is founded on the observation that if the thickened pleura over a shrunken lung is incised the cut widens with each respiration and quickly becomes a groove (Ransohoff, in "Annals of Surgery," April, 1906). The pulmonary pleura is divided by numerous parallel incisions ¼ inch apart, and then similar incisions are made to cross these. An incision is also carried through the costal side of the angle of reflection of the pulmonary and costal pleura.

Pneumotomy for Abscess and Gangrene of the Lung.—Pneumotomy is employed for abscess, gangrene, and bronchiectasis. Give chloroform or use a local anesthetic. Place the patient recumbent with the shoulders a little raised. Make a U-shaped flap over the seat of disease. Resect a portion of a rib. If it is found that adhesions do not exist between the pulmonary and costal layers of the pleura, stitch these layers together with catgut, and either postpone further operation for forty-eight hours or surround the area by gauze and operate at once. If adhesions exist, proceed at once. Chloroform can be put aside when the pleura is exposed. Fowler called attention to the fact that lung tissue is so insensitive that the administration of an anesthetic can be suspended as soon as the pleura has been opened. Incise the agglutinated layers of the pleura, and pass an aspirating needle into the lung in various directions. When the abscess is located, open it by the cautery. Carry the Paquelin cautery slowly into the lung in the direction of the abscess-cavity. The cautery knife should be at a dull-red heat.

When the cautery opens the cavity of the abscess, withdraw the instrument and insert a drainage-tube, and suture the flap of superficial tissue. If the abscess is not found after one or two punctures by the aspirating needle, abandon the attempt.

Tuffier explores for an abscess by what he calls *décollement of the parietal pleura*. He exposes the parietal layer of the pleura, passes his hand between this layer and the chest wall, strips the pleura off over a considerable area, and is able to feel the lung beneath and thus determine its condition.

Hartmann ("Presse Médicale," April 27, 1912) states that Garré collected 96 cases of abscess, with 19 deaths, and 122 cases of gangrene, with 42 deaths. In bronchiectasis pneumotomy may be employed. Hartmann (Ibid.) combines the cases of Körte and Sauerbruch, and states that in 149 cases there were 46 cures. In Sauerbruch's 133 cases there were 40 cures, 43 deaths, and 7 were improved.

XXVII. DISEASES AND INJURIES OF THE UPPER DIGESTIVE TRACT

Injuries and Diseases of the Face, Nose, Mouth, Salivary Glands, Tongue, Jaws, and Esophagus. Closure of the Jaws.—This condition may be caused by tetanus, by the irritation of a non-erupted wisdom tooth, carious teeth, by cancer of the mouth, sarcoma of the jaws, alveolar abscess, cicatricial contractions due to burns or noma, and temporomaxillary ankylosis. In many

cases of old wounds and scars constriction is due to rapidly developing muscular contracture. It seldom arises if the jaw is fractured. It is a condition of hysterical hypermyotonia, and is analogous to contractures of the limb. The jaws can always be opened widely by the gradual use of a dilator. Treatment of contracture is by repeated gradual dilatation and by suggestion. The condition is curable.

Temporomaxillary Ankylosis.—Ankylosis of the temporomaxillary joint may result from gonorrheal arthritis, rheumatoid arthritis, or fracture of the condyle. Even when one joint is completely ankylosed, the jaws upon the sound side can be somewhat separated because of the elasticity of the mandible. The constriction may be fibrous, the result of peri-arthritis of the articulation. It may be bony.

Treatment.—Gradual dilatation by means of box-wood screws is useless even for fibrous constriction. Violent separation is without value. After either method the condition always recurs rapidly. Esmarch removed a wedge-shaped piece of bone from the angle of the jaw in order to form a false joint. Other operators do a like operation on the ramus. A simple osteotomy is certain to fail because bony union will occur. That is the trouble with Swain's operation (sawing the body at the angle). Bony union may be prevented by resecting the zygoma and putting a flap of temporal muscle between the fragments (Helferich). The masseter may be used. Removal of the condyle and a portion of the neck is usually efficient. In double ankylosis both condyles should be resected. Verneuil, in 1860, suggested mobilizing the joint and interposing an attached flap of temporal muscle between the condyle and the socket. Such an operation may give a gratifying result. Murphy divided the neck of the mandible and removed sufficient tissue to permit of the interposition of a flap of fat and fascia. He fixed the lower border of the flap to the upper border of the zygoma and sutured the flap in place between the bones.

Alveolar Abscess.—This condition is caused by a decayed tooth. A superficial abscess is known as a *gum-boil.* The process may spread to the jaw-bone, causing necrosis. From the maxilla the suppuration may enter the antrum. From the lower jaw pus may track into the neck.

Treatment.—Early and free incision; usually, but not always, the extraction of the offending tooth, and drainage.

Necrosis of the Jaw.—Extensive necrosis is much more common in the lower than in the upper jaw. Necrosis of the alveolar process of either jaw may be due to suppurative periostitis, the result of carious teeth. In suppurative periostitis of this form an alveolar abscess arises which is followed perhaps by circumscribed necrosis. In rare cases widespread suppurative periostitis occurs which may result in extensive necrosis.

Syphilis produces periostitis and osteomyelitis, but more commonly causes caries than necrosis. Tuberculous periostitis may result in limited necrosis. Its most common site is the orbital margin of the maxilla.

Actinomycosis is a rare cause of necrosis. In mercurial salivation extensive necrosis is prone to occur. A child suffering during dentition from an exanthematous fever or other virulent infection is liable to a violently acute suppurative periostitis and osteomyelitis with evidence of severe general infection. In the lower jaw particularly extensive and usually symmetrical necrosis follows.

Treatment.—In an acute suppurative periostitis, if there is a carious tooth, extract it, and incise the gum to the bone; if osteomyelitis exists open the outer plate of the bone, and order frequent cleansing of the mouth by antiseptic washes. In syphilitic caries place the patient on antisyphilitic treatment and use a curet to remove carious bone. In tuberculous caries use a curet and employ antituberculous treatment.

When necrosis occurs it is usual to wait until the sequestrum loosens before removing it, but early sequestrectomy is a better plan. The sequestrum is

usually removed through the mouth or nose. If there is profuse suppuration, remove the dead bone by subperiosteal resection (Tillmanns's "Text-Book of Surgery").

Phosphorus Necrosis.—This condition was first observed by Lorinser, of Vienna, in 1838 and was fully described by Bibra and Geist in 1847. It is seen among those who mix, box and dip in factories in which matches are made from yellow phosphorus. Recent legislation against the use of yellow phosphorus is wiping out the affliction. The condition is most common in the lower jaw, but it may occur in either jaw, or in both jaws. Most sufferers have decayed teeth but Lewin of Berlin claims that decayed teeth do not exist in all cases.

It is supposed that the fumes dissolve in saliva and the fluid enters the cavities in the diseased teeth. We know that fumes are not the sole cause. If a worker eats food without washing his hands he may come to trouble. In some cases the condition does not manifest itself for a year or even two years after a man has ceased working in a match factory. There may be serious impairment of the general health when the necrosis begins (albuminuria, pallor and dyspnea).

Oliver points out that in phosphorus workers there is a decided tendency to fracture of the long bones.

The first lesion is periostitis. The gums and jaw swell and become painful, salivation occurs, pus forms eventually even if there is ossifying periostitis. In that case the pus gathers between the periosteum and new bone or between the new bone and old bone. The jaw enlarges enormously and the bone is slowly destroyed. Eventually extensive necrosis takes place, sinuses form and the patient may become toxic from swallowing quantities of foul pus. Dead bone may be cast off. The entire lower jaw may be lost. The bones of the base of the skull may be destroyed and meningitis may arise.

Most of the victims of phosphorus necrosis get many teeth pulled but even wholesale extraction does not cure the pain.

Tillmanns (quoting Maas, Binz and others) states that arsenic and pyrogallic acid act like phosphorus, and tend to produce ossifying periostitis.

If yellow phosphorus is used the paste should be mixed in closed vessels by a machine. Dipping and boxing are sources of danger from fumes and should be done only in very well-ventilated places.

Phosphorous workers should always wash their hands before eating, should never eat in the factory and should take the best of care of the teeth. The treatment of necrosis consists in the removal of the victim from the fumes, making him live in the open air and frequently use antiseptic mouth-washes. If pus forms incisions are required. Early subperiosteal sequestrectomy by means of a chisel and mallet is indicated.

Wounds of the Salivary Glands.—An aseptic wound usually heals and rarely results in a salivary fistula, although after healing it is not unusual for an encysted collection of saliva to gather under the skin. Such a collection of saliva, if it does not disappear spontaneously, can usually be caused to disappear by continued pressure. When a wound of a salivary gland is infected a single fistula or multiple fistula may be left as a legacy. A salivary fistula is very annoying, because the saliva flows constantly. A fistula of a gland usually heals spontaneously after a long time, but healing may be quickly brought about by touching the orifice with the Paquelin cautery.

Wound of Steno's duct is apt to cause a fistula, and the condition is often difficult to cure. In this condition, if the duct has been cut across, the central end grows fast to the cutaneous surface. Fistula of Steno's duct may also be caused by obstruction and rupture of the duct and by suppurative or gangrenous processes.

In wounds of the duct the ends should be brought as near together as possible by catgut sutures which do not enter the lumen of the duct. If the mucous membrane is not already opened an incision should be made through

it to permit drainage of saliva into the mouth, and the skin should be sutured. In some cases the central end of the duct may be carried into the mouth and sutured to the mucous membrane. If, after any injury of Steno's duct, saliva gathers under the skin, make an incision through the mucous membrane to give a route for the saliva to enter the mouth, and apply pressure externally. When an external fistula forms, it may perhaps be cured by the cautery and pressure, but, if the peripheral portion of the duct is obliterated (which can be determined by a sound) a cutting operation must be performed. Tillmanns advocates cutting out the external portion of the fistula by two elliptical incisions. A trocar is passed through the bottom of the wound in two places, about ½ cm. apart; a piece of stout silk is drawn through the holes and tied tightly and the superficial incision is closed. The silk cuts through and makes an internal fistula. Another method is to make an incision, find and isolate the central end of the duct, open the mucous membrane, suture the duct to it, and close the superficial wound.

De Guise's operation is shown in Fig. 660. He threads a piece of silk through two needles and carries the needles into the mouth so that the silk will embrace a bit of tissue ½ cm. in length. The silk is tied tightly within the mouth, the ends are cut off, and the margins of the fistula at the surface are freshened and sutured. I prefer silver wire to silk.

Fig. 660.—De Guise's operation for salivary fistula (Esmarch and Kowalzig).

Parotitis.—Mumps, or epidemic parotitis, is treated by the physician. In this condition the submaxillary and sublingual glands are usually involved as well as the parotid. In pyemia, metastatic abscesses may form in the parotid gland. If such abscesses form great swelling arises, respiration is often embarrassed, and early incision is necessary. Parotid inflammation other than mumps is usually due to the passage of bacteria up Steno's duct, the source of the microbes being a foul condition of the mouth, particularly noma or stomatitis. Hence such inflammation is most common during the existence of acute infectious diseases and sepsis. Suppuration or even gangrene may occur. As a rule, only one gland is attacked, but both may be. It is a well-known fact that occasionally, though very rarely, after an abdominal operation inflammation of the parotid gland occurs (*sympathetic parotitis*). The condition is more common in adults than in children. This form of parotitis may, of course, be due to septic metastasis and may be produced by trauma, but I am satisfied that most cases result from foul mouths, the infection ascending from the mouth along the duct. Oral cleanliness tends strongly to prevent the so-called sympathetic parotitis. In about one-third of the cases the condition is not to be distinguished from mumps and is recovered from in seven to eight days. Mild cases seldom suppurate, and if they do, the pus may flow down the duct into the mouth. In nearly one-half of the cases, according to Marchetti ("Epitome of Surgery," in "Brit. Med. Jour.," March 6, 1909), there is phlegmonous inflammation with necrosis and suppuration of the tissues and formation of a salivary fistula. In non-suppurative parotitis there are pain, tenderness, obvious swelling, and hyperemia of the skin, and it is difficult to open the mouth or swallow. When suppuration occurs, all of the above symptoms are intensified, the discoloration becomes dusky, the skin becomes shiny and edematous, the constitutional symptoms of pus formation exist, and there is usually delirium.

Treatment.—In the non-suppurative form apply heat. Wash the mouth

out frequently with an antiseptic wash and apply ichthyol and lanolin to the swollen region. In the suppurative form make several openings by Hilton's method, seeking for points of softening; apply hot antiseptic fomentations, wash the mouth frequently with an antiseptic fluid, and combat sepsis by appropriate constitutional treatment.

Salivary Concretions (Sialolithiasis).—The saliva contains in solution certain salts which may be deposited. Deposited on the teeth they constitute tartar. Deposited in a salivary duct or the acini of a gland they constitute a calculus. The salts deposited are carbonate and phosphate of lime. A calculus may consist purely of these two salts or there may be a foreign-body nucleus. A calculus is a possible result of an inflammation which blocks, constricts, or roughens a duct or acinus and decomposes saliva. Inflammation of a duct is known as *sialodochitis*. Small concretions are often passed. Concretions the size of a bean are retained. A concretion may attain the size of an English walnut. A concretion does not block a duct continuously, but does so now and then, causing swelling and tenderness of the gland. A retained calculus can be palpated by a finger in the mouth and a finger externally. Whenever a salivary gland enlarges an attempt should be made to probe the duct. In some cases the stone can be touched. In others the duct is found to be blocked. The *x*-rays demonstrate the stone. Salivary calculus is more common in adults than in children but is not very rare in children. The duct of the parotid, of the sublingual, or of the submaxillary, may contain a calculus, but it is unusual to find a stone in Wharton's duct.

Fig. 661.—Ranula.

Treatment.—A calculus in a duct is extracted by making an incision through the mucous membrane. If a very large calculus forms in the submaxillary gland, the gland should be removed through an external incision.

Ranula is a retention-cyst of the duct of the submaxillary or the duct of the sublingual gland. A ranula when first formed contains saliva, but after a time the saliva undergoes a change, and then resembles mucus. *Mucous cysts* occur in the floor of the mouth, resulting from obstruction of the ducts of the *mucous glands of Nuhn and Blandin*. These glands lie on each side of the frenum of the tongue. Such a cyst is often spoken of as a ranula. A *cyst of the incisive gland* forms just back of the lower jaw and lifts up the frenum. A true ranula appears upon the floor of the mouth on one side and pushes the tongue toward the opposite side (Fig. 661). The *treatment* of a mucous cyst is by excision of a portion of the cyst wall and cauterization of the interior with pure carbolic acid; or by cutting a flap from the cyst wall and stitching it aside so as to keep a permanent opening. Such an operation may cure a genuine ranula, but will often fail. In true ranula it is usually advisable to make an external incision, and through this remove both the cyst and the gland. This plan is recommended by Mintz.[1]

Lymphomata of the Salivary and Lachrymal Glands (Mikulicz's Disease).—Mikulicz, of Breslau, described this condition in 1888 (see Billroth's Festschrift for 1892). It is a chronic brawny, and non-inflammatory swelling, painless though sometimes tender, perhaps fluctuating in size and unconnected with any known systemic condition. In Mikulicz's early cases the lachrymal, parotid, and submaxillary salivary glands of both sides were enlarged, hence

[1] "Zeitschrift für Chirurgie," March, 1899.

he regarded it as symmetrical. We now know that non-symmetrical cases occur, in fact, only one gland may be enlarged, although, of course, such cases may eventually develop growths on the other side. In some cases the sublinguals have been involved, in some the accessory lachrymals, in some the glands of Nuhn and Blandin. In a case of Osler's there was enlargement of the spleen, tonsils, and cervical lymph-glands. In a typical case the cheeks are much broader than natural, and the eyelids droop on the temporal side like "those of a bloodhound" (Zeigler, in "New York Med. Jour.," Dec. 11, 1909). The mouth is very dry because of deficiency of salivary secretion. The conjunctiva is dry for want of enough tears. Chronic inflammation in the nasopharynx is not unusual. In some cases the blood findings resemble those of lymphatic leukemia (Paton, in "Proc. Roy. Soc. Med.," 1915, viii).

The condition may occur at practically any age after three or four. A case four years of age has been reported. The glands may undergo regression during pneumonia, appendicitis, or some other infection. The cause is doubtful. Some think it is due to bacteria, but the tissue is not inflammatory, being merely hyperplastic lymph tissue. Others regard it as due to a toxic material in the blood. Ziegler believes that the causal toxic material comes from the nasal sinuses.

Treatment.—Arsenic internally will perhaps produce cure. The iodids are used by some and pilocarpin has been recommended. The *x*-rays should be applied. Operative removal has not been successful. All diseased conditions of the nasopharynx should be corrected, if possible. (See Ziegler's thorough study, in "New York Med. Jour.," Dec. 11, 1909.)

Harelip and Cleft-palate.—*Harelip* is a congenital cleft in the upper lip due to defective development. *Cleft-palate* is a congenital fissure in the soft palate or in both the hard and soft palates. In harelip the cleft is usually complete, through the entire lip into the nostril, but in rare cases it may show only as a furrow in the mucous edge or as a split from the nostril partly into the lip. It is most common on the left side. In double harelip the central portion of the lip is often adherent to the tip of the nose. Double harelip may be free from complication, but is often associated with a malformation of the alveolus and palate. The term "harelip" is a poor one, as the cleft in a hare's lip is the shape of the letter Y, the stem of the Y being median and an arm entering each nostril. Median harelip is exceedingly rare. Dupuytren said it never occurred, but at least 9 cases have been reported (Ransohoff, in "Lancet Clinic," Nov. 2, 1912). Ordinary or lateral harelip is due to failure of fusion of the lateral maxillary and frontal processes. Median harelip is due to "failure of union between the lateral tubercles of the frontonasal process which is placed on each side of the middle line" (Ransohoff, Ibid.). We recall His's teaching, that the central portion of the upper lip is formed from the lower portion of the frontonasal process by the fusion of its two buds (Ransohoff, Ibid.). In cleft-palate the septum of the nose is usually adherent to the palatine process opposite the side upon which the fissure exists. In those rare cases of cleft-palate double in front, the nasal septum is attached to the premaxillary bone only, and the premaxillary bone is not attached at all to the superior maxillary bone. In harelip there is frequently a cleft in the alveolus, and almost always flattening of the corresponding side of the nose. Harelip is often associated with cleft-palate, talipes, and other deformities. It is a great deformity, and interferes with sucking, swallowing, and articulation.

It was long taught that operation must not be done until the child is several years old. In 1868 Thomas Smith insisted that operation should be done before the child has learned to talk.

Operation for harelip uncomplicated by cleft-palate should be performed between the third and sixth months of life in a child in good health, free from stomach trouble, cough, or coryza, but operation is not advisable in the early

weeks of life. Always, if possible, operate before dentition begins (seventh month). If the child is in poor health, postpone the operation until restoration has so far advanced as to render operation safe. While waiting for operation be sure the child is getting enough food. If it cannot suck, feed it with a spoon. If a cleft exists in the palate, we sometimes operate first upon the lip, because the pressure of the parts after the edges of the gap are approximated aids in the closure of the bony cleft. In other cases we operate first on the palate. Cleft-palate interferes with sucking, deglutition, mastication, and articulation. In severe cases the food passes into the nose and excites inflammation. Loss of control of the palate muscles always exists, and liquids and solids are liable to pass into the wind-pipe. Clefts in the hard palate should not be operated on until the second year, but should be operated upon then, otherwise speech will be permanently affected. Some surgeons refuse to oper-

FIG. 662.—Dr. Teller's case of harelip and cleft-palate.

FIG. 663.—Dr. Teller's case of harelip and cleft-palate.

ate until the tenth or twelfth year, but operation done this late will not correct speech-defect. The patient at the period of operation should be well and free from cough. In many cases the passage of food and drink into the nose can largely be prevented by the use of a diaphragm.

Operation for Harelip.—Wrap the child in a sheet; place it in the Trendelenburg position, and rest the head upon a sand-pillow. The surgeon stands to the right side of the patient. Ether or chloroform is given. For *single harelip*, separate with the scissors the upper lip from the bone on each side of the cleft until approximation of the edges can be effected without tension. If the premaxillary bone of one side projects more than its fellow, grasp it with sequestrum forceps and bend it back (Jacobson and Treves). Clamp the upper lip at each angle of the mouth to prevent hemorrhage. If the edges are of equal or nearly equal length, and if the gap is not very wide, perform Malgaigne's operation. This is performed as follows: A flap is detached on each side, the detachment beginning at the upper angle of the gap; each flap is detached above, but remains attached below. The flaps are separated from the bone, and are drawn downward so as to form a prominence at the vermilion border (Fig. 664). If the edges are pared so that in closure the vermilion border is even, when the parts are healed a gutter will be visible at

the line of union. The edges are approximated by an assistant, and silkworm-gut sutures or silver wires are passed by means of a straight needle. Each suture goes down to the mucous membrane. The first suture is passed through the middle of the lip, ⅓ inch from the cleft. Three or four main sutures are passed through the thickness of the lip, and are tied and cut off. Two or three fine silk or catgut sutures are passed by a curved needle through the vermilion border of the lip and the mucous membrane of the mouth, and are tied and cut off. A small piece of gauze is placed over the lip and is held in place by straps of rubber plaster. After operation prevent the child

crying by feeding it often and giving it small doses of laudanum. Heath orders 2 drops of laudanum in 1 oz. of distilled water, a teaspoonful to be given every two or three hours. About the sixth day one-half the sutures are taken out, and on the eighth or ninth day the remaining ones are removed. In many cases no further procedure is necessary, but if after some weeks the prominence at the lip border does not shrink, it can be readily clipped away. Harelip-pins are not used at the present time, and are not needed if the lip is well separated from the bone. If the edges of the cleft are of unequal length, Edmund Owen's operation can be performed (see below, under Double Harelip), or we can perform Mirault's operation, as shown in Fig. 665.

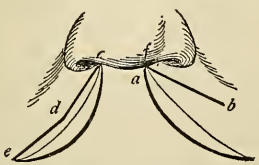

FIG. 667.—Double harelip, the prolabium and incisive bone having been removed (Owen).

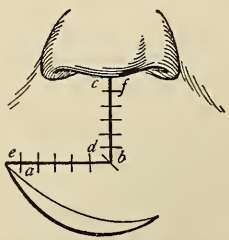

FIG. 668.—The two sides of the lip drawn together and secured by sutures (Owen).

In *double harelip* the operation is similar to that for single harelip. If the intervening piece is vertical and is covered with healthy skin, complete each operation as for single harelip, closing both fissures at once with silver wire in a strong, healthy child; closing them at intervals of three weeks in one not so lusty (Fig. 666). Excise the septum if it is deformed. The premaxillary bone should in most instances be removed, the skin over it being preserved. Sir William Fergusson was accustomed to incise the mucous membrane and shell out this bone. The premaxillary bone can be forced back into line, being held, if necessary, by catgut suture of the periosteum; but if saved, it is liable to necrose and its teeth soon decay. Heath removes this bone two weeks before operating on the lip. If there is much hemorrhage after removal of the bone, arrest it with a hot wire, the electric cautery, or with Horsley's wax. Figure 666 shows incisions for double harelip. Edmund Owen's operation is very useful (Figs. 667, 668). In this operation very thick flaps are cut. The prolabium and

incisive bone are removed. The flaps are cut as shown in Fig. 667, on one side by a line *a–b*, and on the other side the piece *c–d–e* is removed; *a* is brought to *e*, *b* is brought to *d*, *f* is brought to *c*, and sutures are applied (Fig. 668).

Operation for Cleft-palate.—Harelip was operated upon in the days of long ago. Operation for cleft-palate is much more modern. Chelius published his surgery in 1718. He states that openings in the palate cannot be healed by operation. It is usually said that Roux in 1819 did the first staphylorrhaphy but it seems to be proved that Le Monnier operated in 1764 and that von Graefe sewed and cured a soft palate cleft in 1816 (Blakeway, in "Practitioner," 1914, xcii). No man except Langenbeck did as much to perfect the operation as Sir William Fergusson. It is true that during the early years of its growth a cleft diminishes in size, and particularly if a harelip is closed, but to wait too long before we operate means permanent speech impairment. Bony clefts should be operated upon early in the second year. Clefts of the soft palate only may be operated upon during the first six months of life. If both the hard and soft palates are cleft, close both at one operation. In an ill-nourished child in which the covering of the bone is obviously thin it is best to postpone any operation upon a bony cleft until the end of the third year. I agree with Berry that operation is justifiable up to the age of twenty, but early operation is highly desirable. Edmund Owen put forth a convincing plea for early operation.[1] He said he was operating earlier and earlier, and quoted Chilton as the gentleman who led him to do so. Owen maintained that if speech were to be improved, operation must be done early, and he formulated some very valuable rules for preparation and care. I have never been convinced that operation in early infancy is sufficiently safe or has any notable advantages. When one comes to treat congenital clefts of the lip, the alveolar process, and the hard and soft palate, the necessities one should seek to obtain are the surgical closure of the clefts, the establishment of the function of the involved tissues, the correction of the congenital deformity, and the prevention of postoperative or acquired deformity. There are few if any cases of cleft-palate that cannot be successfully treated by surgical means; and it is a very unusual thing for a case really to need any mechanical appliance, such as the obturator and velum.

In deciding upon the time for operating and the nature of the operation, the safety of the patient should be the first consideration. One must carefully consider the physical condition, especially in respect to nutrition. An operative method that has a greater mortality than is incident to minor surgery ought not to be selected, and no operation should be performed until the condition of the patient justifies it. Having considered the physical condition of the patient and the relative safety of different operative plans, a careful study of the individual case should be made, and in this study each of the four requirements above set forth must be attentively regarded. If we succeed in closing the cleft without establishing the function of the tissues, without correcting congenital deformity and without preventing postoperative or acquired deformity, we leave the patient worse off than he was before, and perhaps render subsequent satisfactory treatment impossible.

We should attempt to secure closure of the cleft with the least possible formation of cicatricial tissue. The simplest technic is the best, and we should endeavor to avoid all unnecessary additional traumatism. One should refrain from passing additional approximation sutures, from bruising the tissues by overtension or by traction-forceps, and from using large needles and coarse suture materials, which make large suture-cicatrices. The amount of scar tissue bears directly upon the functional result. In addition, when dealing with the lip, and especially with the soft palate, one must seek to avoid incisions that involve muscles, and particularly the nerve-supply of muscles.

The periosteal-flap operation separates portions of the soft palate from the

[1] "Lancet," Jan. 4, 1896.

palatine bones. A large amount of cicatricial tissue is necessary to effect repair, and this mass of new tissue lessens the good functional results. In the periosteal-flap operation the repaired soft palate is anterior and inferior to the position secured by the osteoplastic method and, to that extent, interferes with the closure of the nasopharynx. Nevertheless, in my opinion, the operation which uses the soft tissues only is by far the safest and is the one I usually employ. In cases of complete cleft, associated congenital deformities are especially manifest in the nose, lips, premaxilla, and maxillæ.

To correct congenital deformities and to prevent postoperative or acquired deformities are the most neglected and the least understood phases of the subject, and it is a very complicated question to hope to make clear in a brief statement. The key to the difficulty is the normal contour of the face as established by the proper occulsion of the permanent teeth. In finding this out there is no better guide than the rules laid down by Dr. Angle in the latest edition of his "Orthodontia." He maintains that every tooth must be held in its proper relation and occlusion; and that if any teeth are lost they must be replaced in order to establish or restore the proper expression and contour of the face. To comply with the foregoing requirements one should avoid any operation that would not maintain or would fail to replace the normal position of the premaxilla and the maxillæ and their future complement of teeth. If the premaxilla is only slightly in advance of its normal position, the early closure of the cleft of the lip will help to replace it. If, however, the premaxilla is far in advance of its normal position, it is hopeless to expect the pressure of a reunited lip to restore it to position. In such a case sufficient of the nasal septum posterior to the premaxilla must be resected, and the premaxilla must be carried back and sutured in position; but this operation should be done after the closure of the cleft soft and hard palates, and seldom at the same operation. If the cleft is unilateral in relation to the premaxilla and that bone is swung to the opposite side, and anterior to its normal position, the pressure exerted by an early repaired lip will often correct the condition. Until the deciduous incisors have erupted it is difficult to determine how far the intermaxillary bone really protrudes; and it is often surprising to observe how little correction is needed in what had appeared to be marked protrusion of the premaxilla in a unilateral or bilateral cleft. If in doubt about this point it is better to wait until the eruption of the deciduous incisors, when one may decide with certainty whether there is enough anterior protrusion to warrant the closure of the lip before operation on the palate. Early closure of the cleft of the lip brings very considerable pressure to bear, especially in double cleft or the typical harelip, as the lateral portions are comparatively short and the lip is usually quite tense. Sometimes this pressure is quite efficient, when exerted upon these cases of protrusion of the premaxilla, which are frequent, and of lateral separation of the maxillæ, which are infrequent; but when such pressure is exerted upon cases without protrusion or separation, it produces an unfortunate postoperative deformity, and one that is too frequently encountered. It causes the alveolar arch to lose its parabolic curve, and what should be an arch is frequently V shaped or triangular, and not infrequently the cuspid teeth are closely approximated. One thus gets marked flattening of the anterior lateral region of the face or cheek, with loss of contour and position of the upper lip and apparent protrusion of the lower lip and chin. It is true that such a postoperative deformity can be corrected by modern orthodontic methods, but it is better to prevent it than to be obliged subsequently to correct it.

From the preceding remarks it is evident that it is to be regarded as advisable in many cases to close the cleft in the soft and hard palates before operating upon the lip. The best time for operating is just before the patient begins to employ articulate speech. In most cases the cleft in the alveolar

process, including the floor of one or both nares, should be repaired separately, and after the repair of the hard and soft palates. A comparatively short time after operating upon the palate the lip may be repaired, and the lip also should be repaired before the establisment of articulate speech. An advantage in operating with the harelip still unclosed is that one can see better and work better during the operation on the palate, and can give the palate better local care after the operation. Unfortunately, however, many children with cleft palates are never brought for advice until they have cultivated articulate speech. It is always very difficult and often impossible to correct the manner of speaking that they have taught themselves. Only long training and much perseverance is of any avail. The earlier the operation is performed, the better will be the result—not only from the functional standpoint, but also as regards the correction of existing deformity and the prevention of future deformity. So far as obtaining good surgical results go there is practically no set age limit.

I am not convinced that modern operators obtain results greatly superior to those obtained by some of their predecessors. Sir William Fergusson, "between 1828 and 1864" operated upon 400 cases of harelip with only 3 failures and 134 cases of cleft palate with only 5 failures (Garrison's "History of Medicine").

If operation is refused for cleft of the hard palate, if it offers no real hope, or if it is very dangerous, an obturator must be worn. An obturator is made by a dentist. In preparing a child for operation I follow Edmund Owen's rules, viz.: Have the child in the best condition, free from cough and stomach disorder. Operate in summer. Place the child under the charge of a nurse several days before the operation.

Operation for Suture of the Soft Palate (*Staphylorrhaphy*).—The operation of staphylorrhaphy, which is applied to clefts of the soft palate alone, is a comparatively easy procedure. In performing this operation the patient should be anesthetized and be placed in the Trendelenburg position, or else with the head hanging over the end of the operating table. The mouth is held open by Whitehead's gag, and an assistant holds an electric light and a reflector to illuminate the oral cavity. If the patient is not a young child, the operation may be done under cocain, with the subject sitting erect in a chair and the surgeon sitting directly in front of him.

The surgeon should have at hand several knives of different shapes. The double-edged, pointed knife is an excellent one for freshening the margins of the palate. Special forms of needle-holders have been devised for the purpose of carrying the needle. The heavy, curved, sharp-pointed bistoury is the best instrument for dividing the muscles of the palate; and a sharp hook should be at hand, in order to catch the edge of the cleft, if necessary.

The surgeon first of all separates the soft palate from the posterior edge of the palate bones and from the nasal mucous membrane. This step is necessary in order that the edges may meet in the middle line (Berry). One edge of the cleft uvula is now grasped with a pair of forceps or a sharp hook, and is pulled upon to make it tense. This edge is then pared from below upward, the piece being continuous from the base to the apex of the cleft. This piece is severed, and then the other margin of the cleft is pared in the same way. It is now advisable to free the margins of the wound from tension. These lateral incisions not only relieve tension, but temporarily paralyze the soft palate. Figures 669 and 670 show the incisions as recommended by Berry. These incisions divide the tendons of the levator palati and the palatopharyngeus muscles and temporarily paralyze the palate. The impairment of palate function is not permanent, as the nerves to the muscles are not cut.

The sutures are inserted by means of a special needle-holder, so arranged that the needle may be directed in many different positions when grasped.

The sutures are introduced from below upward, silkworm-gut being used for the uvula and the lower part of the velum, and silver wire for the balance of the cleft. Each suture, as it is passed, is tied or twisted, and it is not cut off until the next suture is inserted, and thus serves as a handle. If there is too much tension to allow of the sutures being tied as they are inserted, all the sutures are passed and lightly twisted before one is tied.

Closure of Clefts in the Hard Palate (*Uranoplasty*).—As previously stated, the best time to perform these operations is during the second year of life. In some few cases we postpone the operation until the end of the third year. If the child learns to talk with the palate cleft, articulation will never be very greatly improved, even by operation. One should, therefore, try to operate before the child learns to talk. Even after the closure of the cleft the speech does not become entirely normal; in fact, as Berry says, it never becomes even very good. One should exercise the greatest care in forming the soft palate,

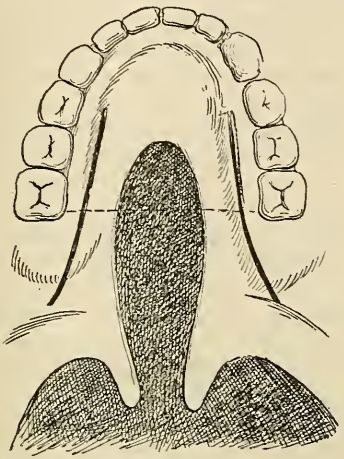

Fig. 669.

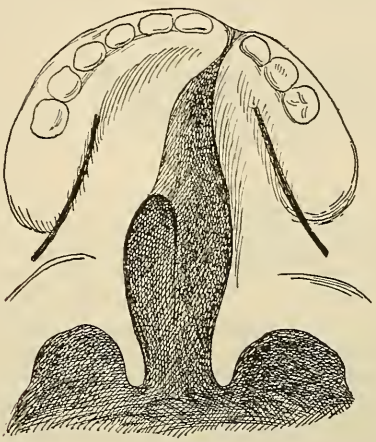

Fig. 670.

Fig. 669.—Cleft of soft and part of hard palate. Shows exact situation in which the lateral incisions should be made (Berry).

Fig. 670.—Semidiagrammatic view of complete left cleft palate. The septum nasi is attached to the palate on the (patient's) right side. The mucous membrane on the left side of the septum may be detached and brought down if necessary to help in the closure of the anterior half of the cleft. Shows exact situation in which the lateral incisions should be made (Berry).

because good articulation is largely dependent upon a well-formed soft palate (Berry, in "Brit. Med. Jour.," Oct. 7, 1905). The surgeon may be able to close the entire gap at one operation; or, owing to undue tension, he may be forced to close it but partly, completing the closure at some subsequent period.

The operation that to my mind is the best is one that uses the soft tissues alone—such a one as is advised by Berry. I have entirely abandoned the operation of wedging the bone over with a chisel. I am satisfied that it is far more dangerous than is the other method; it is more liable to fail; and, if it fails because of necrosis, it is difficult or impossible to cure the defect by a second operation. The essence of a successful operation, using the soft tissues alone, is, as Berry insists, the complete detachment of the soft palate from the posterior edge of the palate-bone (Fig. 671), because, if one fails to secure this, the edges of the gap will not approximate in the median line. One should also separate the soft palate from the mucous membrane of the nose (Fig. 671).

A second very important point is the imperative necessity of making incisions to the sides to relieve tension and to paralyze for a time the soft palate. The incisions, as recommended by Berry, are shown in Figs. 669, 670. The cut is close to the teeth, and is taken as far posterior as the middle of the soft palate, at the junction of that structure with the lateral pharyngeal wall. In this cut there is some risk of dividing the anterior palatine artery, but hemorrhage from this vessel can be arrested by pressure. Berry insists that the incision need not go forward more than the level of one or two premolar teeth; or, in older children, to the first or second molars. The edges of the fissure are pared on each side, from the tip of the uvula to the top of the gap. Strips of the mucoperiosteum are lifted up on each side of the gap and shifted toward the cleft, and at this stage the posterior border of the soft palate is separated from the posterior border of the hard palate (Fig. 671).

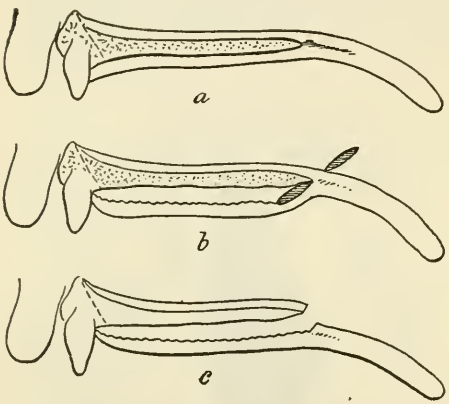

Fig. 671.—Longitudinal vertical section through the hard and soft palates: *a*, Before operation; *b*, palatine mucoperiosteum detached and brought down, blades of scissors introduced to cut attachment of soft palate to the bony palate and to the nasal mucous membrane; *c*, the same after the cut has been made and the soft palate thus brought down (Berry).

The parts are sutured with silver wire, following the advice of Edmund Owen to twist and cut each wire, leaving an end $\frac{1}{8}$ inch in length. This procedure causes the child to keep his tongue from the suture line.

For the first twenty-four hours water only is given. After this period the patient is fed with jelly and liquids. Only fluid or soft food is used for two or three weeks. Talking is forbidden. A day or two after the operation the child should be taken into the open air and kept in it all day. As Owen shows, this greatly stimulates vital resistance and lessens, to a considerable extent, the danger of sloughing of the suture line. The mouth is washed frequently, and always after taking food, with Condy's fluid. The sutures are allowed to remain between two and three weeks.

Sir William Fergusson's Operation.—In this operation the mucous edges are pared, the bones are drilled for wires, and the sutures are inserted, but not tied. An incision is made on each side of the cleft down to the bone, each incision being midway between the cleft and the corresponding alveolus. The bone is divided on each side, by means of a chisel, to the full length of the incision; and the chisel is used as a lever to force each half of the bone toward the gap. The sutures are tied, and each lateral incision is plugged with iodoform gauze.

Brophy's Operation.—This operation is employed particularly for children under three months of age, and cannot be used when the child is over six months. In this operation the palate is closed before the harelip is touched. Operating at this time the bones are soft, and by leaving the harelip untouched the surgeon has more room to work. The author of the operation believes that when it is performed at this early age the palate muscles do not atrophy, but develop, and that the patient does not form the evil habit of talking through the nose.

In performing this operation the very strong-handled needles of Brophy are necessary. The patient is anesthetized and put into the Trendelenburg position and a strong piece of silk is put through the tip of the tongue as a traction-suture. The edges of the cleft in the hard palate are pared, a little

of the bone being taken away with the paring. Then the edges of the cleft in the soft palate are pared. The needle is threaded with strong silk; the cheek is lifted, and the threaded needle is forced through the superior maxillary bone from without inward, starting just back of the malar process and just above the palate. As the needle shows in the cleft the thread is picked up with a pair of forceps, and the needle is pulled out, the loop of thread remaining in the cleft. Through a part of the opposite superior maxillary corresponding with this first point of entrance the needle is entered again and another loop is got into the cleft. The second loop is caught into the first loop, and when the former is pulled out it carries the latter with it. This thread now passes through both the superior maxillary bones and usually through the nasal septum as well. This thread is used to pull a piece of strong silver wire through. One other silver wire is introduced in the same manner more to the front. The silver wire ends are threaded through perforated lead plates, which fit the external outline of the bones on each side. The wires are tightened and twisted. For instance, on one side the end of the anterior wire is twisted to the end of the posterior wire, and so on. The thumbs are used to jam the two ends of the maxillary bones forcibly together, thus closing the cleft, and then the wires are twisted more firmly to hold the edges in contact. The cleft in the soft palate is then sutured, although the surgeon may deem it advisable to wait one day before doing so. After the palate heals the harelip is closed.

Carcinoma of the Lower Lip.—Cancer frequently arises in the lower lip, very rarely in the upper lip. Males suffer frequently, but females are not very often attacked. In some cases it seems to arise in smokers at the point on the lip where the pipe habitually rests. A short-stemmed clay pipe, which grows hot when it is smoked, is particularly apt to lead to the causal irritation. The region of the lip which is most liable to cancer is the junction of the skin and mucous membrane. The growth may begin in a fissure or abrasion, may start in an eczematous area or a wart, but most frequently arises as an indurated area which quickly ulcerates. After a cancer has existed for a variable time the submental, submaxillary, and cervical lymphatic glands become diseased. These glands are usually involved within three months after the beginning of the cancer but may remain free for seven or eight months. In a case of my own they were found to contain carcinoma cells in less than three months after the origin of the carcinoma of the lip. This involvement cannot be detected by external manipulation in the earliest stages, hence it is not proper to conclude that the glandular involvement is absent simply because it cannot be palpated. In many cases when glands cannot be detected by palpating beneath the jaw they will be discovered by placing one finger in the mouth back of the lower jaw and one finger beneath the chin. It occasionally happens that glands enlarge because of septic absorption, and this enlargement may even precede carcinomatous involvement. From an operative point of view the glands should always be regarded as carcinomatous. If cancer is not operated upon it destroys the lip, extensively involves the glands of the neck, the floor of the mouth, the periosteum and the lower jaw, and produces death in from three to five years. If the jaw is involved the prognosis is bad, and it is almost hopeless if the floor of the mouth is involved.

The *treatment* consists in the early and thorough removal of the growth by the knife, and also in the removal of the fatty tissue and glands from the submaxillry triangles, from the submental region, and down to the carotid bifurcation. The growth must be thoroughly removed, that is, the incision must be at least ½ inch wide of the disease. For many years a favorite operation was the V-shaped incision, the skin edges being sutured by silkworm-gut, the sutures being passed almost to the mucous membrane and being inserted so as to compress the vessels when tied, and the mucous membrane being sutured with fine

silk or catgut. The V-shaped incision should only be used for a very small and very recent growth. After the removal of the growth from the lip a vertical incision is made from the point of the V over the cricoid cartilage, and, from the origin of this incision incisions are made in each direction along the under surface of the body of the jaw. The glandular area is thus exposed, and after the removal of the fat and glands the wound is sutured with silkworm-gut. Far better than the V-shaped incision is the operation devised by W. W. Grant, of Denver.[1] In this operation the growth is removed and cheiloplasty is performed.

Grant's Operation for Cancer of the Lip.—This operation gives a useful mouth and a more natural-looking lip than does the ordinary operation, and there is decidedly less tension on the suture line. Furthermore, the suture line in a man is apt to be soon covered with a beard. The procedure has great advantages over the ordinary V-shaped operation, which greatly lessens the size of the mouth, making it what is known as a sucker-mouth, and the new lip is rigid and ugly.

In Grant's operation two vertical incisions are made, one on each side of the growth, and these are connected by a horizontal incision at the base (Figs. 672, 673). Thus, a quadrangular gap is formed, which must be filled

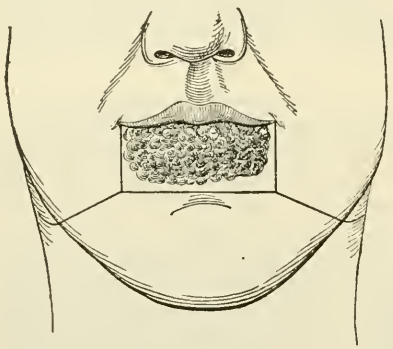

FIG. 672.—Grant's method for removal of carcinoma of the lower lip. The incision.

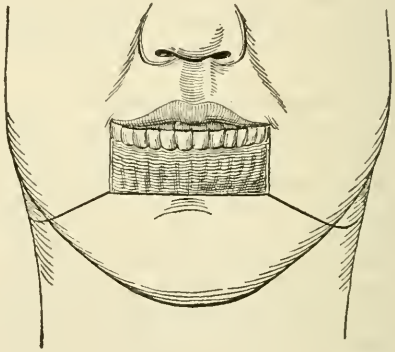

FIG. 673.—Grant's method for removal of carcinoma of the lower lip. Second step. The mass removed.

by flaps. An incision is made on each side from each inferior angle of the wound, obliquely downward and backward beneath the maxilla, on a line about midway between the angle of that bone and the apex of the chin (Fig. 672). Its further extension is determined by the amount of lip removed and by the degree of glandular involvement.

The submaxillary lymph-glands are removed through these incisions. The glands in the midline, however, beneath the chin may require a separate incision. If the lip is extensively involved, the cheek ought to be completely separated from the inferior maxillary bone to the middle of the masseter muscle (Fig. 674). When the glands have been removed, the triangular flaps are brought together and united, first of all, in the middle line (Fig. 675). If the tension is marked, owing to the amount of tissue excised, it is wise, to insert a traction suture, ¾ inch from the center line, and tie it over pads of gauze covered with muslin. One thus prevents undue tension upon the sutures in the center of the flap. The stitches that unite the cheek posteriorly are inserted and tied, and the entire thickness of the cheek must be included. Silkworm-gut sutures are used. A drainage-tube is inserted in the posterior angle of the wound on each side. It is very useful to use also a T-drainage-tube as advised by Grant. This tube is about the diameter of a lead pencil and

[1] "Medical Record," May 27, 1899.

the cross-piece rests behind the incisor teeth or symphysis and beneath the tip of the tongue. It drains away all of the mouth secretions, saves the lines of incision from being constantly bathed in them, and renders very frequent changes of dressing unnecessary.

I have employed this operation repeatedly, and regard it as the most useful method we have for the purpose. Thorough removal of the carcinoma of the lip and of the related glands will cure from 60 to 80 per cent. of cases.

The glands should be removed in all cases. If the lesions on the lip and the glands are removed and the glands show no metastasis Bloodgood obtains 95 per cent. of cures, setting the five-year limit as a cure ("Surgery, Gynecology, and Obstetrics," 1914, xviii). Bloodgood shows that when the lip lesion is removed but the glands are not there are 37 per cent. of recurrences in the glands. In this stage not over 20 per cent. of operations will secure a cure.

Operations for recurrence give but 10 per cent. of cures. If the bone is involved in cancer, cure is practically never obtained.

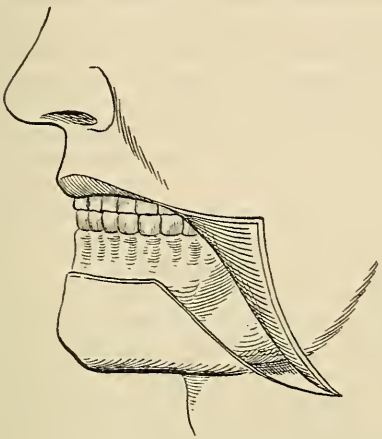

Fig. 674.—Grant's method for removal of carcinoma of the lower lip. Dissection preliminary to suturing.

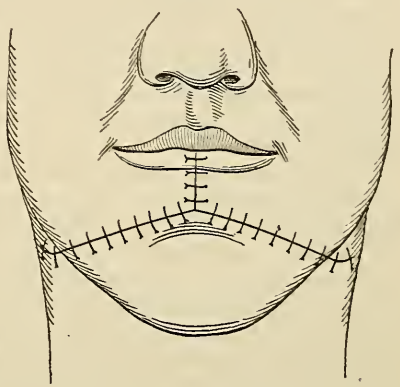

Fig. 675.—Grant's method for removal of carcinoma of the lower lip. The wound sutured.

Carbuncle of the Upper Lip.—In contrast to carbuncle in other regions of the body, facial and labial carbuncles are most common in young persons. Carbuncle of the lip is due to staphylococcus infection and begins as a papule. Numerous pustules appear, and sloughing usually takes place. There may or or may not be sêrious constitutional involvement. The condition is very dangerous, as thrombophlebitis may arise and track up into the cranium by way of the ophthalmic vein and cavernous sinus. I have known two persons to die from carbuncle of the lip.

Treatment.—Excise if possible. If excision is impossible, make a crucial incision, cutting away the skin corners and edges with scissors and dividing the venous connection with the cranium. Scrape out the carbuncle with a sharp and strong curet, swab with pure carbolic acid, pack with iodoform gauze, and dress with antiseptic poultices.

Tongue-tie (*congenital ankyloglossia* or *adherent tongue*) is congenital shortness of the frenum, the tip of the tongue adhering to the floor of the mouth. It is due to the projecting portion of the tongue being incompletely developed from the tuberculum impar. "In many of the slighter cases the development has merely lagged behind and will be completed as the child grows after birth" ("Diseases of the Tongue," by Henry T. Butlin, Second Edition). The tongue cannot be protruded beyond the incisor teeth. Swallowing is interfered with,

and later in life articulation is impeded. It is not very unusual in infants, but in the great majority of cases disappears as the child grows older. Persisting tongue-tie, Butlin says, is one of the rarest of conditions, and my experience is in absolute accord with his—in fact, I have never seen a single case. Many unnecessary or even harmful operations are done for a condition which, if let alone, will usually correct itself. Improper operation may result in fatal hemorrhage or in "swallowing of the tongue." The operation usually done is to tear up the frenum with a thumbnail. This is unsurgical and makes a lacerated wound. A better way is to raise the tip of the tongue to make the bands tense, and then snip with the scissors close to the mucous membrane of the lower jaw. The slit in the handle of the grooved director was placed there to catch the frenum in, but a short frenum will not enter it (Butlin).

Tuberculosis of the Tongue.—This is rather a rare trouble although Durante was able to collect 250 cases from literature and to report 5 cases ("Annals of Surgery," 1916, lxiii). The tongue, being a muscle, resists tuberculous infection as does all muscle and it is not easy for the bacilli to pass through the epithelial covering. The lesion is never found in infancy and is most common between the twentieth and fiftieth years, and met with far oftener in men than in women (Durante, Ibid.). It is predisposed to by irritation or injury of the mucous membrane. In the great majority of cases the lesion is secondary to distant tuberculosis, especially the pulmonary form, but primary tuberculosis is occasionally found. Durante (Ibid.) asserts that in a primary case the infection is hematogenous.

In one type of the disease, an elevated, gray, uninflamed induration forms in the mucous membrane. There may be multiple lesions (miliary tuberculosis of the tongue). Nodular tuberculosis arises in the tongue parenchyma.

Ulceration may be early or late. Its edges are irregular, reddish in color, and non-indurated and the floor is yellowish (Durante, Ibid.). I recently saw an indurated tuberculous ulcer which was thought to be cancer. Any part of the tongue may be attacked but the tip is most apt to suffer. The glands under the jaws on each side enlarge and become tender. Diagnosis is difficult. To mistake it for cancer is a grave misfortune as cancer calls usually for amputation of the organ. In very few cases can the bacilli be found. Always take a section and have it studied by the pathologist. In every doubtful case make the therapeutic test, which is the administration of salvarsan. Primary cases give a favorable, secondary cases an unfavorable, prognosis. The treatment is destruction by the high frequency current.

Thyrolingual or Thyroglossal Cysts and Sinuses.—In early embryonal life the thyroid gland has a duct which passes from the thyroid isthmus to the foramen cæcum of the dorsum of the tongue. The duct may be lined with one layer, two layers, or several layers of epithelium, and there are mucous glands and lymph-follicles in its walls, these structures being derived from the mucous membrane of the tongue. The wall of the duct presents numerous irregularly placed and irregularly shaped diverticula. It is known as the thyroglossal or thyrolingual duct. The duct runs from the base of the tongue down the midline of the neck. It is connected with the body of the hyoid bone, with the periosteum in front of the bone, and with the thyrohyoid bursa behind the bone. It passes to the upper portion of the front surface of the trachea, where it bifurcates, each branch passing to a lateral lobe of the thyroid gland. This fetal structure under normal conditions begins to atrophy in the fifth week and closes by the eighth week, the foramen cæcum marking its old orifice on the dorsum of the tongue. When the duct is obliterated, it becomes a cord of epithelium. In more than 30 per cent. of bodies the remains of this primitive passage can be found (Weglowski, in "Zentralb. f. Chir.," 1908, xxxv, 289). The duct may persist between the foramen cæcum and the hyoid bone, developing, it may be, into a *sublingual dermoid*. The portion behind and below the

hyoid may remain and develop into a *subhyoid cyst.* The part inferior to the hyoid may persist, give origin to a cyst which ruptures, and constitute an *incomplete median cervical fistula.* The duct may remain open from the mouth and make, by bursting an opening into the neck, a *complete median cervical fistula.* A patent duct may exist for years and announce its existence by some acute inflammatory process. The small diameter of a cervical fistula renders probing to any depth impossible. Some have told us to determine if a fistula is complete by injecting quassia solution into the lower end. The patient will perhaps experience a bitter taste. If we inject a colored fluid we may see it if it runs from the mouth. I have never succeeded in doing either. Tumors may spring from the duct.

Treatment.—If a thyroglossal cyst or tumor arises on the dorsum of the tongue, and if it is increasing in size and interferes with swallowing and speech, it must be removed through the mouth. A general anesthetic should be given. In some cases preliminary tracheotomy is necessary.

A cyst, tumor, or fistula about the hyoid bone requires excision, the patient being under the influence of a general anesthetic. A portion of the cyst wall adheres strongly to the posterior surface of the hyoid bone and must be carefully removed even if it be necessary to split the bone to accomplish it. In treating fistula the surgeon injects the tract with methylene-blue and makes an elliptical incision of the skin about its orifice so as to free the fistula from the subcutaneous tissue. When traction is made upon the cutaneous end of the duct it will stand out clearly and can be dissected out (M. S. Seelig, in "Surg., Gynec., and Obstet.," May, 1907). It is useless to try to cure a fistula by cauterization. A fistula requires the complete removal of its epithelial-lined walls. No lesser operation will cure. In 1 case I operated four times before securing success. In another case I divided the hyoid bone, removed the fistula, sutured the bone by chromic gut, and obtained a cure.

Carcinoma of the Tongue.—This is one of the most dreadful forms of cancer. It is quite a common disease. For a time it may grow slowly but sooner or later it takes on very rapid growth. In most of the cases I see it is far advanced when first brought to the hospital. Almost without exception cancer of the tongue is composed of squamous-cells but columnar-cell growths have been reported. It is much more common in men than in women. It is a disease of adult life and is very rare before the age of thirty-five. The period of greatest liability is between the age of forty and sixty. Only 30 cases are recorded in those of less than thirty years of age ("Collective Review in Internat. Abstract of Surgery," Feb., 1916, by Vilray Papin Blair.) It begins, as a rule, near the tip, on the side or at the base of the anterior two-thirds of the tongue, as a warty growth, as an ulcer having at first a papillary structure, as a fissure which indurates, or as an indurated area which ulcerates. The cause of the growth may sometimes be traced to the irritation of a jagged tooth or an ill-fitting plate, or to the smoking of a pipe, or to holding nails in the mouth, as is done by those who nail laths. Abbe states the case against tobacco very strongly and claims that 90 per cent. of cases of cancer of the tongue result from the use of tobacco and only 10 per cent. from a jagged tooth ("N. Y. Med. Jour.," July 3, 1915). Cancer may follow a chronic inflammation—leukoplakia, for instance. Chronic ulcers are liable to become cancerous and any indurated ulcer has potentialities of deadly peril and should be promptly removed. Syphilis predisposes to cancer especially if leukoplakia arises. It is highly probable that leukoplakia is due to syphilis. Fournier regards syphilis as an influential cause, and states that in 184 cases of cancer of the mouth or tongue 155 had had syphilis. There has been no such proportion of syphilitics in my personal cases. In Whitehead's 104 cases only 7 had had syphilis. In most cases the disease spreads rapidly; produces early and extensive glandular involvement; disease of the floor of the mouth; dribbling of saliva; difficulty in masticating, swallowing, and

talking; foulness of the breath; severe pain which is apt to radiate toward the ear and is certain to if the base of the tongue is involved. Fatal septic trouble may arise at any time. Cases not operated upon usually die in much less than two years. Wölfer described a very rare form of carcinoma, which grows very slowly or even remains latent for years.

One reason why cancer of the tongue grows so rapidly has been pointed out by Heidenhain, of Greifswald. The lingual muscles are contracting almost constantly and as a result cancer-cells are forced along the lymph-spaces to healthy areas. In advanced cases the diagnosis is easy. In early cases it may be very difficult. Early cases are the only curable cases and in them correct diagnosis is imperative. The diagnosis from tuberculosis is set forth on page 1056. A positive Wassermann test does not prove that the ulcer is syphilitic. It is well known that cancer may arise from syphilitic lesions. It is necessary in every doubtful case to take a section for examination and to apply the therapeutic test (salvarsan or mercury and the iodids).

The superficial ulcer of a broken-down gumma affects the mucous membrane. It is small, indurated, has perpendicular edges and is covered by a white and adherent slough. It is most common on the edge or tip of the tongue. Such sores may be multiple and are usually at least bilateral. A parenchymatous gumma begins beneath the mucous membrane. When it ruptures it exposes a cavity, lined by slough and surrounded by induration.

The results of operation have improved much of late, probably because cases are brought earlier and operations are more thorough. Up to very recent years surgeons were able to obtain only 10 to 15 per cent. of recoveries (cases which passed three years without recurrence). Johns Hopkins Hospital now reports 50 per cent. cured.

Treatment.—A cancer of the tongue should be removed radically at the earliest possible moment. Specific treatment for diagnostic purposes should not be continued beyond a very few weeks. In doubtful cases a Wassermann test is made, and if it is positive, salvarsan is given intravenously. If still in doubt as to the nature of the growth, remove it and have a pathologist at hand to study it immediately by frozen sections (Warren, in "Annals of Surgery," Oct., 1908). Have permission beforehand to proceed at once to radical operation if conditions demand it. The study of a small section is always of somewhat uncertain value, hence, if the growth is small or of moderate size remove it for study. If the growth is larger take a considerable piece for study. This piece must include a part of the floor and the edge of ulcer and of apparently sound tissue beyond the ulcer. An ulcerating, warty or indurating lesion of the tongue requires removal. If it is not cancer it will be apt to become cancerous. Before any operation is undertaken all stumps of teeth should be extracted and a dentist should clean tartar from the teeth. During several days preceding an operation the teeth should be scrubbed twice a day with a brush and soap and the mouth rinsed with hydrogen peroxid. The nares and nasopharynx should be sprayed with peroxid of hydrogen and then with boric acid solution every second or third hour when the patient is awake.

In some cases the entire tongue is removed; in some, half of it; in some, only a piece of it. Not only the diseased tongue, but also the adjacent lymphatic glands must be removed. Cancer of the tip of the tongue, as a rule, involves the submental and sublingual groups of glands early. Cancer of the anterior two-thirds of the dorsum of the tongue first involves the lingual and submaxillary lymph-nodes. Cancer of the under surface of the tip of the tongue, first involves the submaxillary glands. Sooner or later the superior deep cervical glands about the carotid bifurcation become involved as a result of cancer of the tip or edges of the anterior portion of the tongue. In cancer of the dorsum the deep cervical glands become involved as well as the superficial nodes. The

lymphatic system of the base of the tongue is distinct from that of the balance of the organ. It drains into the deep cervical groups.

It was formerly my belief that in a very recent and limited case only the glands on the diseased side required removal, but that in an advanced case the glands must be removed from *both sides* of the neck. Experience has convinced me that in any case the glands on both sides should be removed. Kuttner, of Tübingen, has demonstrated that lymph from one side of the tongue may flow to glands on the same side of the neck, but some also may flow to the opposite side of the tongue. Remove the obviously involved glands by the *block dissection* of Crile. In a bad case everything is removed but the carotid arteries. The sternocleidomastoid muscle, the omohyoid, the jugular vein, even the pneumogastric and phrenic nerves of one side may be taken away. After a week or two the other side of the neck should be operated upon. It seldom requires a wide removal of structures. If the pneumogastric or phrenic were cut on one side it must be preserved on the other. The jugular vein can be removed after a collateral circulation has been established subsequent to removing the jugular of one side. Two operations are to be considered: partial removal and complete removal.

Partial Removal of the Tongue.—This operation is restricted to recent cases in which one side only of the anterior portion of the tongue is involved. The operation does not offer as good a chance of cure as complete excision, because lymph containing cancer-cells may have reached the opposite side of the tongue. Even in partial removal the glands should be removed from both sides. Intratracheal anesthesia is employed.

In performing the operation of partial excision introduce a mouth-gag, pass a silk ligature through each half of the tip of the tongue, and draw the organ out of the mouth. Place the patient recumbent with the head a little raised. Split the tongue back in the middle line by the scissors, and loosen the cancerous side from the floor and side of the mouth. Pass a stout silk ligature through the base of the tongue posterior to the cancer. Draw the organ out and cut off the diseased side in front of the ligature, but well back of the disease. Tie the vessels, remove the traction threads, and treat subsequently as in cases of complete removal.

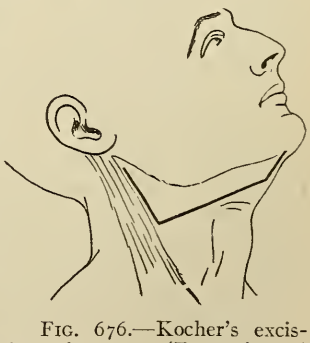

Fig. 676.—Kocher's excision of tongue (Esmarch and Kowalzig).

Complete Removal of the Tongue (Kocher's Method).—Kocher recommends a preliminary tracheotomy in tongue excision, but the Trendelenburg position renders this procedure unnecessary so far as fear of the passage of blood into the larynx and trachea is concerned. I operated many times with the patient in that position. At present I operate with the head a little raised and the patient taking ether by intratracheal insufflation. Because of the insufflation there is no respiratory difficulty and the stream of escaping air and ether keeps blood out of the bronchial tubes. The method is most satisfactory. The surgeon stands to the side. Ether is given by intratracheal insufflation (see page 1340). Ligate the lingual artery on the side opposite to the one where the main incision is to be made. Remove the glands on that side and suture the wound. An incision is then made on the side opposite to that on which the artery was ligated. This incision passes from behind the lobe of the ear, along the anterior edge of the sternocleidomastoid to about the middle of the margin of this muscle. From this point the incision is carried to the level of the hyoid bone and then to the symphysis menti, along the anterior belly of the digastric muscle (Fig. 676). The flap is dissected and turned up;

the facial and lingual arteries are ligated; "the submaxillary fossa is evacuated" (Treves); the sublingual and submaxillary glands are removed; the mylohyoid muscle is divided; the mucous membrane is incised close to the jaw, and the tongue, caught by tenaculum forceps, is drawn through the opening. The tongue is split in the middle by scissors, and the near half is removed, bleeding is arrested, the remaining half of the tongue is cut through, and the vessels are tied. Stitch the mucous membrane of the stump to the mucous membrane of the floor of the mouth with catgut sutures. Kocher does not suture the skin wound. I prefer to suture it and employ drainage-tubes. I follow the suggestions of Treves as to after-treatment. Some hours after the operation, when oozing has ceased, dust the mouth wound with iodoform. The patient, as soon as possible, is propped up in bed, and he must not swallow the discharges if it can be avoided. The mouth, every half-hour, is sprayed with peroxid of hydrogen and washed with a carbolic solution (1 : 60). Every three hours, after washing the floor of the mouth and the stump, the parts should be dried with absorbent cotton and dusted with iodoform. For twenty-four hours after the operation nothing is given by the mouth except a little cracked ice, the patient being fed by rectum. At the end of twenty-four or forty-eight hours some liquid food is given from a feeding-cup. The patient will soon learn to swallow; but if he cannot swallow easily, he is fed by a tube. Treves, in his clear and positive directions for after-treatment, states that nutrient enemata are to be continued until sufficient nourishment is taken by the mouth; that the mouth should be flushed by irrigation, and must be washed immediately after taking food; that morphin is to be avoided, and that the patient can usually leave the hospital in from seven to ten days.

Whitehead's Operation.—Whitehead removes one-half of or the entire tongue from within the mouth by the use of scissors. He passes a ligature through the tip, cuts the frenum, draws the tongue strongly forward, and separates by a series of clips with the scissors. The lingual arteries are tied as cut. "The stump should be kept under control, as regards hemorrhage, by a stout silk ligature passed through the remains of the glosso-epiglottidean fold and retained for twenty-four hours."[1]

Heath has shown that if the forefinger be passed to the epiglottis and used to "hook forward" the hyoid bone, the lingual arteries are stretched and portions of the tongue can be removed almost without bleeding. It is rarely desirable in Whitehead's operation to remove the glands and the tongue at one séance. To do so increases shock and the danger of death. The rule of procedure set forth by W. Watson Cheyne[2] is eminently wise. This rule is as follows: If glandular involvement is trivial or not detectable, it is perfectly proper to remove the tongue first, and after a week or so remove the glands. If the glandular involvement is marked, growth in the glands will be much more rapid than growth in the tongue. In such a case the glands should be removed before the tongue, because, if the tongue is removed before the triangles are cleared, in the week or two of waiting the case may become inoperable. In the majority of cases clear out the triangle before removing the tongue, doing the other operation in one or two weeks when the wound in the neck is healed. If the disease in the mouth is far advanced, do both operations at one séance.

Examination of the Esophagus.—The *x*-rays are of great value not only in detecting foreign bodies, but in finding carcinoma, pouches, and constrictions. As Waggett ("Brit. Med. Jour.," Oct. 19, 1912) says, by means of the *x*-rays we may learn that there is a stricture (or are strictures), where it is (or they are), how narrow it is (or they are), and whether or not there is extrinsic pressure. In this examination the patient first swallows material through which the rays pass with difficulty. A salt of bismuth is generally used. The

[1] "American Text-Book of Surgery."
[2] "The Practitioner," April, 1899.

carbonate of bismuth is a safe and satisfactory salt. It is given in glutoid capsules (Kohler, in "Brit. Med. Jour.," Oct. 19, 1912). Barium sulphate may be used instead of a bismuth salt.

Esophageal Sounds and Bougies.—These instruments were long our only mechanical means of diagnosis. They are used far less than formerly. They possess certain dangers. For instance, if an aneurysm exists and we are misled in believing that the condition is stricture, the rigid sound and even the flexible bougie may penetrate the sac of the aneurysm and cause death. I have personal knowledge of such a case. If a person has ever brought up blood, neither a sound nor bougie should be used. Again, neither the bougie nor sound can prove the existence of a slight stricture. They give no information at all as to the nature of a stricture. I find their greatest diagnostic use is to locate the situation of a constriction before passing the esophagoscope. In view of the fact that such an examination may cause bleeding, and that blood interferes with an examination by the esophagoscope, the bougie or sound, if used at all, should be employed the day before the introduction of the esophagoscope.

The olive tip flexible bougie is made from elastic web. It is a safer instrument than the sound with a hard bulbous tip (see Fig. 683, E). The latter has a series of removable ivory or metal tips which vary in size. Used diagnostically, the olive tip bougie is to impart information as it enters; the bulbous sound, as it enters and as it is withdrawn. On withdrawing the bulbous sound it may catch upon the lower border of a constriction which it passed on entering.

Before being passed the bougie or sound should be warmed and greased with glycerin. The patient sits in a chair and throws the head well back against the breast of an assistant. The mouth is opened widely and is held open by a large cork or by a gag. The patient is directed to breathe deeply and regularly while the instrument is being passed. Depress the tongue with the finger and carry the instrument beyond the glottis. As it reaches the back of the pharynx the patient will gag and choke. Tell him to swallow and breathe regularly. The fact that he can breathe regularly shows that the instrument is not within the larynx. It may then be gently urged along the gullet. All maneuvers are to be conducted with the utmost gentleness. Force means danger.

Remember that in an adult the esophageal orifice is 5 or 6 inches from the incisor teeth, that the esophagus has a length of from 9 to 10 inches, hence, that the cardiac orifice of the stomach is from 14 to 16 inches from the incisor teeth (Maylard's "Surgery of the Alimentary Canal"). It is further important to remember that the normal esophagus is of smaller caliber in some regions than in others. There are four points of physiological narrowing, viz.: On a level with the cricoid cartilage, where it is crossed by the aorta, where it is crossed by the left bronchus, and where the tube passes through the diaphragm.

Auscultation may enable the surgeon to hear the food bolus rub against a stenosis and to note delay in the passage of liquid. Fluid normally passes in four seconds.

The Esophagoscope.—This instrument is of the highest value, a value just beginning to be properly appreciated. It is not altogether free from danger. Deaths have occurred from it. The mandrel does the harm, and should not be used at all or should be withdrawn as soon as the tube has passed the cricoid constriction. The rest of the way the instrument is carried along while the surgeon is looking through it and seeing what is ahead. It is not carried into a constriction; it is not carried by an ulcer or a pulsating lump. It enables us to make diagnoses otherwise impossible, to diagnosticate cancer in an early stage, to treat local conditions, and to remove a fragment of tissue for examination. I prefer to pass the instrument without general anesthesia even in children, and highly nervous people, unless there is very severe spasm. Until I watched Jackson work it was my custom to apply cocain to the back of the tongue, pillars of the fauces, epiglottis, and pharynx and to place the patient on the right side with the head thrown back. This is known as *Starck's position*, and,

as Gottstein shows, it relaxes the diaphragmatic crura. An assistant supports the head and follows every movement of the surgeon. The patient is cautioned to breathe tranquilly, and is told if the pain or annoyance becomes intolerable to raise his left arm, when the surgeon will cease for a time. The surgeon must, of course, keep his word on this point. Artificial teeth are removed. The instrument is kept in the midline and is inserted as is a sound or bougie. As soon as it passes the cricoid narrowing the mandrel is withdrawn, and the instrument is passed slowly and gently along while the surgeon is looking through and ahead of it. For Chevalier Jackson's method of esophagoscopy see page 1005. His work is a masterpiece which combines knowledge, dexterity, gentleness and psychical control of the patient.

The cervical esophagus is closed and seems to unroll before the instrument. The thoracic esophagus is open, and while the esophagoscope enters into the upper part of this region, if the gullet is normal, the surgeon can see all the way down to the diaphragm. At the diaphragm the esophagus bends forward and to the left and this point must not be mistaken for the cardia (Kohler, in "Brit. Med. Jour.," Oct. 19, 1912).

The cardia may be found closed or may be seen to open and close with respiration. This instrument is of great value in the extraction of foreign bodies, in the diagnosis and treatment of many esophageal diseases, and in the diagnosis of certain peri-esophageal conditions. Every surgeon should be able to use the esophagoscope. (See Gottstein, in "Keen's Surgery," vols. iii and vi; Waggett, in "Brit. Med. Jour.," Oct. 19, 1912; Kohler, in "Brit. Med. Jour.," Oct. 19, 1912; "Reports of Eightieth Meeting of the British Medical Assoc.," July, 1912; Lewisohn, in "Annals of Surgery," Jan., 1913.) For Chevalier Jackson's directions as to the use of the esophagoscope see page 1005.

Stricture of the Esophagus.—*Fibrous* or *cicatricial* stricture or scar of the esophagus is due to the healing of an ulcer, and results from traumatism, chronic inflammation, scarlet fever, syphilis, tuberculosis, chronic ulcer, prolonged vomiting, variola, gout, or to swallowing a corrosive substance or a boiling liquid. In about 15 per cent. of cases of scarlet fever there is inflammation of the esophagus and larynx and stricture may result. Fibrous stricture is commonest in the young, and is apt to be situated opposite the cricoid cartilage, at the tracheal bifurcation or near the cardiac end. Cicatricial strictures, except when due to boiling or corrosive liquid, are usually single, but may be multiple. A cicatrix may be of irregular shape, may be cylindrical, may be annular, may be narrow, or may be broad. Stricture following impaction of a foreign body is located at the seat of impaction unless the tube has been injured by efforts at extraction, in which case multiple strictures may exist (Maylard). Strictures which result from swallowing boiling fluid or corrosive liquid are usually very extensive, may be multiple, and give early symptoms. In some cases they are slight and may not give symptoms for years after the injury. Syphilitic stenosis is due to the healing of a gummatous ulceration, but there is nothing characteristic in this kind of stenosis. Tuberculous stenosis is extremely rare. The esophagus above an extensive scar is usually dilated.

Symptoms of Cicatricial Stenosis.—The condition is most common in youth, but may begin at any age. The chief symptom is difficulty in swallowing, at first slight, but becoming more and more pronounced until swallowing is almost or quite impossible. The dysphagia is first manifested to dry solids, then to all solids, and finally to liquids. In some cases vomiting occurs after swallowing. If the stricture is high up, the vomiting is almost immediate; if it is low down, the vomiting is delayed, especially if the canal is dilated above the stricture. From time to time the patient vomits independently of taking food, the ejected matter containing no gastric juice, only saliva and mucus which gathered in the dilated gullet about the scar. The vomited matter is not bloody. The

patient feels weak, hungry, and thirsty, becomes exhausted and emaciated, and suffers from flatulence, gastralgia, and constipation.

There is occasionally slight uneasiness or even pain in the region of the stricture, possibly "about the epigastrium or between the shoulder-blades" ("The Surgery of the Alimentary Canal," by Maylard). If there is certainly no aneurysm and if blood has never been brought up, the flexible bougie may be used first and then the solid tipped sound, in order to find a stricture. The stricture may be located by auscultation over the spine on a line with the supposed obstruction. While a patient is swallowing water, the arrest of the fluid at the seat of stricture may be audible. Even if the fluid passes, it will be delayed for a time and the duration of deglutition is thus prolonged. In order to determine the time of deglutition put the ear just below the angle

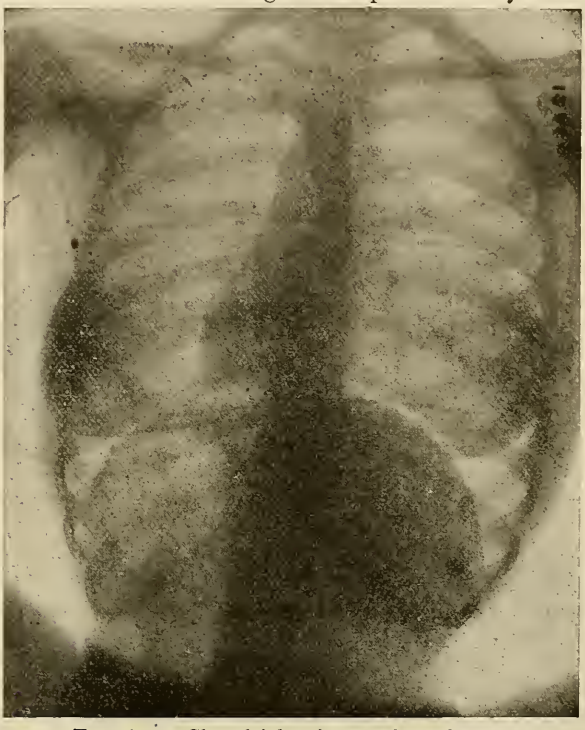

FIG. 677.—Cicatricial stricture of esophagus.

of the left scapula, or else between the left sternocostal margin and the xiphoid cartilage, place a finger on the patient's Adam's apple, and hold a watch in the other hand. Have the patient take a drink of water. Count the time from the moment the Adam's apple begins to rise until the fluid is heard to gurgle into the stomach (Ogston's method). It ordinarily requires four seconds for fluid to pass from the mouth into the stomach (Maylard, Ibid.). The *x*-rays are used to diagnosticate stricture and to locate it. They are valuable in diagnosis. An emulsion of bismuth or barium sulphate is swallowed and a skiagraph is taken. The metallic salt is seen on the plate as a black mass extending above the seat of constriction (Fig. 677). A fluoroscopic examination shows the bismuth or barium through a constriction. A bougie can be passed until it reaches the block and a skiagraph may be taken with bougie in position.

In a case reported by Seelig ("Surgery, Gynecology, and Obstetrics," Sept., 1908) the patient was directed to swallow a fine gold chain as thick as ordinary wrapping twine. The chain was about 2 feet long. If a diverticulum exists

the chain will fill the sac and a skiagraph will show the position of the diverticulum. If no diverticulum exists the plate will show the chain nearly in the middle line of the body. The esophagoscope should be used (see page 1061).

The history of the case is of much importance in diagnosis. The surgeon must inquire about impaction of a foreign body, or swallowing of acids, alkalis, or boiling fluids; and must examine for evidence of syphilis. If there is no history of injury, syphilis, tuberculosis, scarlatina, variola, or prolonged vomiting, and the patient is over forty years of age, the indications point to cancer rather than to cicatricial stenosis. The easy passage of a bougie when the patient is anesthetized shows that spasm is the cause, and not organic disease. Narrowing due to external pressure (*compression stenosis*) is marked by positive symptoms of the causative disease.[1] Compression stenosis may arise in goiter, vetebral growths, enlargement of the heart, glandular enlargement, peri-esophageal abscess, aneurysm, lordosis, and mediastinal tumor (Kohler, in "Brit. Med. Jour.," Oct. 19, 1912).

Treatment.—Thiosinamin is given by some physicians, but I have never seen it accomplish the slightest good. Telleky[2] recommends it in old scars without inflammation. He makes a 15 per cent. alcoholic solution and injects from ½ to 1 syringeful at a dose, throwing the fluid beneath the skin be-

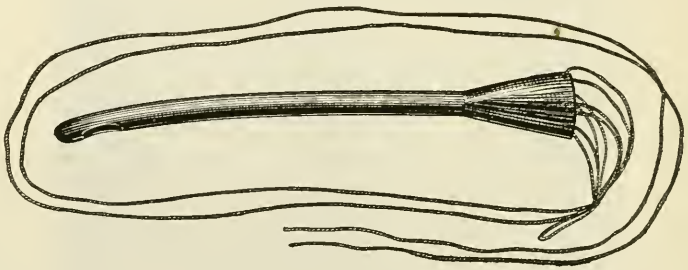

Fig. 678.—Symonds's short tube for intubation of the esophagus (Morrow).

tween the scapulæ. He uses twenty doses in the course of two weeks. *Gradual dilatation* through the mouth is a method employed for at least a time in almost every case. It is the method of choice when it can be carried out, and usually it can be carried out. Begin with the largest flexible bougie which will easily pass. Warm the bougie, oil it, pass it gently, and hold it in position for several minutes, prolonging the time of retention of the bougie as treatment progresses. Pass an instrument every second or third day, gradually increasing the size. Chevalier Jackson is impressed with the danger of blind dilatation. He inaugurates dilatation by using instruments through the tube of the esophagoscope. Plummer ("Northwestern Lancet," Jan. 15, 1912) dwells on the danger of using bougies, especially in cancerous constriction, and advocates the use of the string guide of Mixter in tight or tortuous stenoses. Mixter's plan is to have a patient put a piece of silk on the back of the tongue and swallow it while drinking water. The string may thus be floated through the stricture. Plummer proceeds as follows: He takes a spool of buttonhole twist and inserts a safety-pin so as to make a reel. He unwinds the thread, marks it with black ink at intervals of 1 yard, rewinds it, takes a few inches of the free end of the thread, moistens it, places it on the back of the patient's tongue, and gives the patient a swallow of water. The patient is directed to swallow 2 or 3 yards before bedtime, "and an equal amount at the rate of a foot an hour the following forenoon." The first portion, in a state of snarl, enters the intestine during the night. By afternoon the thread may be rendered taut by pulling upon it;

[1] See the valuable article in Maylard's "Surgery of the Alimentary Canal."
[2] "Wien. klin. Woch.," Feb. 20, 1902.

yet it will not be pulled out. The thread may remain in place for some time, dilating the stricture. It may be used as a guide to direct a bougie through a tight or tortuous constriction, the eyed bougie being threaded upon the strand (Plummer, in "Collected Papers of the Mayo Staff in Rochester," 1911). If the stenosis involves a considerable portion of the esophagus, gradual dilatation will almost certainly fail to cure.

Symonds advocates the insertion of a tube through the stricture and leaving it in place until there is decided dilatation, and then replacing the tube with a larger instrument. The patient is fed through the tube (Fig. 678). In some cases in which it is impossible to pass a bougie through the stricture by the ordinary plan it is possible to pass one when viewing the opening through the stricture by means of the esophagoscope. Whalebone or olive-tipped instruments may be passed in increasing sizes. Strands of silkworm-gut may

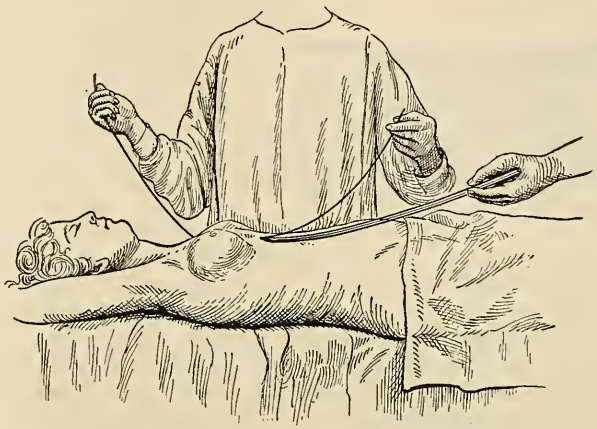

Fig. 679.—Abbe's method of cutting esophageal strictures.

be passed. If they are, they can be left in place a few hours, when a larger bundle of gut or perhaps an instrument can be passed. Surgeons have divulsed strictures and performed internal esophagotomy through an esophagoscope. Either of these plans is preferable to forcible dilatation or internal esophagotomy by a special instrument, but without the esophagoscope.

Electrolysis has been advocated by Fort and others. Gradual dilatation from below has been practised in cases in which a bougie could not be passed from the mouth. A gastrostomy is performed, and after the fistula has become sound the patient is made to swallow "a shot to which is attached a silk thread" (Maylard). The silk thread is brought out through the fistulous orifice and is attached to a bougie, and the dilating instrument is pulled up through the esophagus. *Forcible dilatation* can be employed through a gastrotomy opening, by means of bougies, tents, or divulsing instruments. A fibrous stenosis in the region of the cricoid cartilage which is not cured by gradual dilatation should be treated by the operation of *external esophagotomy.* In this operation the stricture is divided by a longitudinal incision; "funnel-shaped retraction of the cut portion is caused by adhesion to the external tissues divided, and it lessens future contraction."[1] If dilatation fails in the case of a stenosis anywhere above the line of the aortic arch, the esophagus may be opened above the stricture (external esophagotomy). If the stricture is below the wound a tenotome may be introduced through the wound, and the stricture cut and well dilated by the passage of instruments. This operation is known as Gussenbauer's combined esophagotomy.

[1] W. J. Mayo, "Jour. Amer. Med. Assoc.," July 29, 1899.

If a stricture is impassable from above, the stomach should be opened and retrograde dilatation be carried out. Billroth showed years ago that a stricture impassable from above may be passable from below. This is because the esophagus above the stricture is basin shaped and immediately below the stricture is funnel shaped (Abbe). If a fine bougie is carried from the stomach to the mouth it is used to carry a piece of string through the same route, and this string is used to pull bougie after bougie through the stricture. A firm, non-dilatable stricture in the thoracic portion of the esophagus can be treated by Abbe's method (Figs. 679, 680). He performs a gastrotomy, sutures the stomach to the abdominal wound to prevent contamination of the peritoneum, and seeks for the esophageal opening by two fingers passed within the stomach. Abbe points out that finding the orifice would seem much more easy than it is. In a recent case I found it only after a prolonged search, the entire esophageal region feeling smooth to the touch. Abbe says that "this surface is maintained by the circular sphincter muscle layers, and it is not until a moment's pressure of the finger at the right place causes them to yield that it slips upward into the esophagus" ("Med. Record," Nov. 30, 1907). Abbe then passes a long filiform whalebone bougie from the stomach into the mouth, ties a piece of braided silk to the bougie, withdraws the instrument, and leaves the silk in place. One end of the silk emerges from the mouth and the other end from the gastrotomy wound. In some cases he opens the stomach and also opens the esophagus above the stricture; one end of the string comes out of the esophagotomy wound and the other end out of the gastrotomy wound. A large dilating bougie is then passed from the stomach into the esophagus and pushed as forcibly as is safe into the lumen of the stricture. The string is used as a string- or bow-saw, and the stricture is divided, the dilating bougie being pushed firmly upward while the saw is being used. If this is not done the saw will not cut. Only stretched tissue will be divided. When the stricture has been divided the silk is withdrawn and full-sized bougies are passed. The surgeon usually makes a temporary gastrostomy and then sutures the wound in the neck.

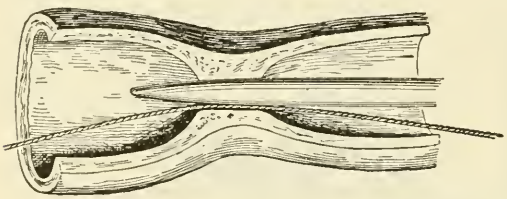

FIG. 680.—The bougie engaged in the stricture while the string-saw is being used.

An operation devised by A. J. Ochsner is thus described by Mayo:[1] "The anterior wall of the stomach is drawn out of a left oblique incision through the abdominal coverings; a small opening is made into the stomach sufficient in size to introduce the finger. A whalebone probe, to the tip of which a silk string guide has been tied, is now passed through the esophagus either from above or retrograde, as in the Abbe method. With this guide a loop of silk is drawn out of the gastric incision in such manner as to leave the guide as a third string. Into this loop a small soft-rubber drainage-tube 3 feet or more in length is caught in the middle by traction on the ends of the doubled thread through the mouth; this loop of rubber tube is drawn through the stomach and made to engage in the stricture.

"The greater the amount of traction, the smaller the stretched rubber tube, until it is sufficiently reduced in size to enter the stenosed portion; by alternating the direction of the pull the tube is drawn out by its free ends and in by the silk loop. Increasing sizes of tubes can be employed, and if necessary the third string can be used as a string-saw, after the Abbe plan of procedure." In a very severe case of stenosis gastrostomy is performed to keep the patient

[1] "Jour. Amer. Med. Assoc.," July 29, 1899.

from starving. In a case of fibrous stenosis in charge of the author it was found impossible to insert any instrument from above or from below. Gastrostomy was performed by Kader's method. The patient was fed through the artificial opening and the esophagus was thus put at rest. Two weeks after the operation it became possible to pass a bougie from the mouth. The gullet was gradually dilated to its normal caliber and the gastrostomy wound was closed. This case demonstrates that a stricture of the esophagus, like a stricture of the urethra, may become temporarily impassable from inflammation, edema, and spasm; but, after the part is put at rest, may again permit the passage of an instrument.

In some cases of incurable stricture *cervical esophagostomy* is performed below the stenosis, and the patient is fed permanently through the opening. The operation is performed like esophagotomy, except that the mucous membrane is sutured to the skin.

Carcinoma of the Esophagus.—Cancer causes obstruction of the esophagus. It arises in those beyond middle life, and is far more common in men than in women. The disease may begin at any portion of the gullet, but is least often met with in the central portion (Maylard, Butlin). Epithelioma is the usual form, but scirrhus or encephaloid may occur. Cancer soon ulcerates, involves adjacent parts, and affects the deep cervical and posterior mediastinal glands. In at least 75 per cent. of cases of chronic obstruction of the esophagus cancer is the cause.

Symptoms of Cancerous Stenosis.—The patient is over forty years of age, is usually a male, and presents the same difficulty of swallowing met with in cicatricial stenosis. Regurgitation is common. The regurgitated matter is alkaline and is apt to contain blood. There is generally decided pain and very rapid and great emaciation occurs. The seat of obstruction may be located by the very gentle use of a soft or semisolid bougie, but it is wiser to use no bougie and to rely on the *x*-rays and the esophagoscope. In a very recent case diagnosis is possible only by esophagoscopy. The stomach is the seat of pain; the mouth is dry, and there is often great thirst. As the disease infiltrates, the involvement of adjacent regions produces other symptoms. Dyspnea may result from tracheal pressure. Pleuritis, pericarditis, or pneumonia may arise. There may be paralysis of the sympathetic or recurrent laryngeal nerves.

In suspected cases of cancer never try to pass unguided bougies or sounds through the constriction. In a cancer case dilating instruments are weapons rather than tools. If a bougie is used to locate the constriction it will probably start bleeding and be bloody when withdrawn. A solid instrument might perforate the esophagus. If it does, death will follow. The *x*-rays should first be used and then the esophagoscope.

Treatment.—The disease is, of necessity, fatal, and treatment is only palliative. Complete excision of the cancer is scarcely feasible even in the cervical region. I know of but one successful resection of the thoracic esophagus, which was the case reported by Torek ("Surgery, Gynecology, and Obstetrics," June, 1913). The operation was intrathoracic and through the pleura. At present the justifiability of such an operation has not yet been conclusively demonstrated. Zaaijer of Leyden successfully resected a carcinoma of the cardia, going through the pleura to accomplish it (Hirschmann and Frohse, in "Beiträg. z. klin. Chir.," 1915, xcv). Arch, Voelcker, Kümmel and Sauerbruch also obtained recovery after such an operation (Meyer, in "Trans. of Am. Surg. Assoc.," 1915). The patient should be put upon a soft, bland diet, small quantities being given frequently. When trouble is experienced in swallowing even the bland and soft food, pass a soft bougie every third or fourth day. When the patient becomes entirely unable to swallow soft food, we may insert a Symonds tube (see Fig. 678) or do an esophagostomy (if this can be performed below the stricture), or perform gastrostomy. In every doubtful case of esophageal

stricture give salvarsan. This might clear up a gumma. In these days of esophagoscopy the chance of diagnostic error is far less than formerly.

Spasmodic Stricture of the Esophagus (*Esophagismus; Hysterical Stricture*).—By this term is meant a spasm of the circular muscular fibers of the gullet, which is most common near the larynx or the cardia. This condition not unusually arises in a hysterical individual, in whom it will be associated with the stigmata of hysteria, especially globus hystericus. In some cases evidence of hysteria are wanting, although the patient is neurotic and ill-nourished, the condition being due to a reflex irritation. A spasm of the muscular fibers of the esophagus may be clonic or may be tonic. A clonic spasm may arise during vomiting or from some reflex cause; it may affect one part of the tube for a time and then shift to another, or may develop in one particular region only. Globus is a spasm which moves upward. Tonic spasm is in one fixed place. Most reflex spasms are tonic and result from cancer of the liver, cancer of the stomach, tonsillitis, glossitis, pharyngitis, gall-stones, cholecystitis, or inflammation of the epiglottis (A. L. Benedict, in "Am. Jour. Med. Sci.," Aug., 1904). It occasionally occurs in tetanus; sometimes in epilepsy. Spasmodic stricture may also arise during pregnancy and as a result of laryngeal ulceration. I have seen several instances due to cancer of the stomach. In 1 of these cases the esophageal spasm entirely disappeared after the performance of pylorectomy.

Symptoms of Spasmodic Stenosis.—It arises suddenly in a hysterical or neurotic individual. It may last for a time and suddenly pass away, or may persist for a considerable time. The difficulty in swallowing is irregular, rarely interfering seriously with nourishment. Usually fluids are taken more easily than solids, but sometimes solids are taken more readily than fluids.

There may be regurgitation; but in recent cases, if it occurs, it does so at once on swallowing food. Examination with a bougie detects the obstruction. If the bougie is held firmly against it, in most cases the spasm will, after a time, relax suddenly or gradually and let the instrument pass. A medium-sized instrument or a large one may not pass until the patient has been anesthetized, but in every case a bougie can be passed after an anesthetic has been given.

Treatment of Spasmodic Stenosis Above the Cardia.—The systematic passage of bougies. Occasionally the passage of an instrument but once will cure a case. The general health must be improved, and in persistent cases it may be necessary to use electricity within the esophagus, employ cold locally, and administer the bromids.

Cardiospasm (Abdominal Esophagismus).—When the cardiac sphincter contracts the condition is known as cardiospasm. It may or may not be associated with cancer, ulcer, or some other disease of the stomach, with gall-bladder disease or cancer of the liver. The attacks are periodic, with a variable time between them, but sooner or later diffuse dilatation occurs. Before dilatation takes place the patient has periodic attacks of difficulty in swallowing, being perfectly well between the attacks. One of Plummer's cases had periodical attacks of dysphagia lasting from three to fourteen days, and during these attacks it was impossible to swallow either solids or liquids. In many cases the attacks are neither so severe nor prolonged. They usually begin suddenly while swallowing, but may begin at a time when no food is being taken. The attack is a feeling of choking or obstruction felt in the cardiac region and the back. Soon after these attacks originate the patient begins to suffer very soon after eating from regurgitation into the mouth. As the esophagus dilates the regurgitation is postponed longer and longer after eating, until finally the gullet is never completely empty (Plummer, "Northwestern Lancet," Oct. 1, 1906). The matter which is regurgitated is not sour, because it contains no gastric elements. Plummer points out that a stomach-tube cannot be passed, but a large-sized sound can be passed easily. The fact that a large sound can be

passed proves that there is no organic stricture. When external causes of pressure are excluded the diagnosis rests between diverticulum and dilatation of the esophagus (Plummer, Ibid.). The *x*-rays aid in diagnosis. Plummer gives methods in detail (Ibid.).

Treatment.—Russell's plan is to dilate the cardia with a silk-covered balloon of rubber. Plummer describes how to construct it ("Collected Papers of the Staff of St. Mary's Hospital, Mayo Clinic, 1905–1909"). The distention is to be gradual, and at once suspended if there is violent pain indicating laceration. Mikulicz and others have performed gastrotomy and dilated the cardia. Willy Meyer ("Am. Jour. Surg.," June, 1912) has opened the thorax under positive pressure, plicated the dilated portion of the esophagus into two longitudinal double folds, and separated the pneumogastric nerves, tearing off the minute esophageal branches (*esophagoplication* and *vagolysis*). This patient was cured. This operation was attempted on 2 other patients. One was improved. The other turned out to have organic stricture. In another case Wendel performed cardioplasty in the same manner as pyloroplasty is done. He did it by the abdominal route. Meyer suggests that it may be done transthoracically.

Diverticula of the Esophagus.—Rokitansky in 1849 described traction diverticula and pressure diverticula. Maylard tells us that these pouches may be due to one of four causes: they may be congenital; may be due to stricture; may be caused by pressure from within upon a weak spot of the wall; may be due to traction from without by the healing and contraction of an area of inflammation. To these another cause should be added, muscular weakness resulting in dilatation. The usual situation for such a pouch is on the posterior wall of the gullet on a level with the cricoid cartilage. At this point there is a space devoid or nearly devoid of muscle, called the *Lannier-Hackerman area* (Charles H. Mayo, "Jour. Am. Med. Assoc.," July 22, 1912). As the pouch enlarges the fundus comes toward the side, usually the left side. Pouches are rare in the thoracic esophagus.

Symptoms.—In spite of the statement that a diverticulum may be congenital, we encounter the condition clinically in adults only. The first symptom is difficulty in swallowing, like that in cancer. There may be cough from nerve irritation and dyspnea from pressure on the trachea (Chas. H. Mayo, "Annals of Surgery," June, 1910). Regurgitation may occur, the regurgitated matter being free from gastric juice. As the opening of the sac is usually a prolongation of the esophageal canal a sound or bougie tends to enter the sac. When the diverticulum is in the neck a lump forms during deglutition, and this lump may be obliterated by pressure. Food will pass into the stomach only when the diverticulum is full. A bougie can seldom be passed unless the pouch is full of food, at which time it may pass or may not. Sometimes it enters the pouch. This striking symptom, the variability in the passage of the bougie, is evidence suggesting the diagnosis of intrathoracic diverticulum. By listening through a stethoscope fluid may be heard to pass into the pouch. The diverticulum causes obstruction. "The depth of the obstruction can be measured with a stomach-tube, bougie, or acorn probe, but, as a matter of fact, these procedures do not differentiate between diverticula and strictures which are pervious to liquids and yet impassable to sounds" (Charles H. Mayo, "Annals of Surgery," June, 1910). After a patient swallows an emulsion of bismuth or barium or food mixed with one of these salts a diverticulum may be skiagraphed. When a bougie is passed as far as it will go a skiagraph should be taken with the bougie in position. The plate may show that the instrument is so much deviated to the side that it must be in a pouch. If a fine gold chain is swallowed it may fill up the pouch, and if it does, a skiagraph will indicate the diverticulum. The opening of the pouch may be seen by means of an esophagoscope. Plummer's test is valuable. He has the patient swallow a string guide, as described on page 1064. The protruding end of the thread is passed

through the eye of an olive tip set on a whalebone stem. The instrument is passed onward until it meets an obstruction. "Should the trouble be due to stricture the tip will not change its level when the thread is tightened, but if there is a diverticulum the probe will be elevated to the level of the opening in the lower esophagus, proving at once the existence of a pocket and also its depth by the amount of elevation of the probe upon tightening the thread" (Charles H. Mayo, Ibid.).

Treatment.—In very early cases dilatation may cure. In advanced cases in the cervical esophagus we must perform extirpation and suture, as done by von Bergmann, Hearn, the author, and others. For five days after operation no food is given by the mouth. No attempt should be made to extirpate a pouch in the thoracic esophagus. In such a case gastrostomy may be necessary.

Injuries of the Esophagus from Within.—Injuries of the internal surface are more common than injuries from without. Burns and scalds are among these injuries. Wounds may be inflicted by foreign bodies. Injuries of the gullet cause pain on swallowing, and a wound induces bleeding, the blood being both coughed up and vomited. A severe wound may involve a large vessel and cause violent or even fatal hemorrhage. If the bronchus or trachea is involved, there will be "cough and expectoration of blood, mucus, and food" (Maylard). The pleural or pericardiac sacs may be perforated.

Treatment.—Freed by the rectum only. Give morphin hypodermatically. Do not feed by the mouth for ten days, and even then give only fluid food, olive oil and jelly. Symptoms are met as they arise. After burns by caustic, administer the antidote; give large drafts of water and wash out the stomach. From two to four weeks after a caustic has been swallowed and after a burn or scald the use of sounds should be begun (provided there is no raw surface), and sounding should be persisted in for a considerable time to prevent contraction.

Injuries of the Esophagus from Without, Other Structures Not Being Involved Seriously.—Such injuries are rare. Esophageal injuries, as a rule, are associated with serious damage to adjacent structures. Injuries may be due to stabs or to bullets. Besides the obvious external signs of the injury there will be difficulty in swallowing, cough, bloody expectoration, or vomiting; and mucus or the contents of the stomach may run out of the wound.

Treatment.—Suture the wound, and feed by the rectum for ten days.

Spontaneous Rupture of the Esophagus.—By this we mean rupture of an apparently healthy gullet. It is a very rare accident. Most recorded cases of rupture have been in those in whom the esophagus was ulcerated or cicatricial. Vomiting is the cause of rupture. Alcoholism predisposes. Rupture may occur when the wall undergoes auto digestion, as it may do in protracted vomiting. The symptoms are the sudden onset of violent pain, vomiting, collapse and not unusually emphysema above the clavicle. If a diagnosis is made operation is indicated provided the case is seen early enough. Without operation death is certain.

Foreign Bodies Lodged in the Esophagus.—These accidents occur especially in children and lunatics, and women are more apt to suffer from them than men. A list of various bodies which have been swallowed will be found in Poulet's elaborate treatise. There are three regions where a foreign body is especially apt to lodge—viz., opposite the cricoid cartilage, at the level of the diaphragm, and at the point where the left bronchus crosses the gullet. Small and sharp bodies may lodge anywhere.

The *symptoms* are variable; if the body is large, there will be pain and difficulty in swallowing, and, in many cases, dyspnea from pressure upon the trachea or bronchus. Occasionally the dyspnea is such a prominent feature that it misleads the physician into the belief that the foreign body is lodged in the air-passages. Death may actually result from asphyxia. In some other cases the symptoms are very slight. If the body is sharp, there

will be hemorrhage and severe pain. The blood may be hawked up, or may be swallowed and vomited. In rare cases a patient grows accustomed to a foreign body and ceases to notice it; but, more often, the foreign body produces inflammation. It may even ulcerate into the wind-pipe, the pleura, the pericardium, or the aorta. In many cases of impaction a patient makes violent efforts to hawk up the foreign body and so produces aphonia. There may be violent retching. Even after a foreign body has been removed by swal-

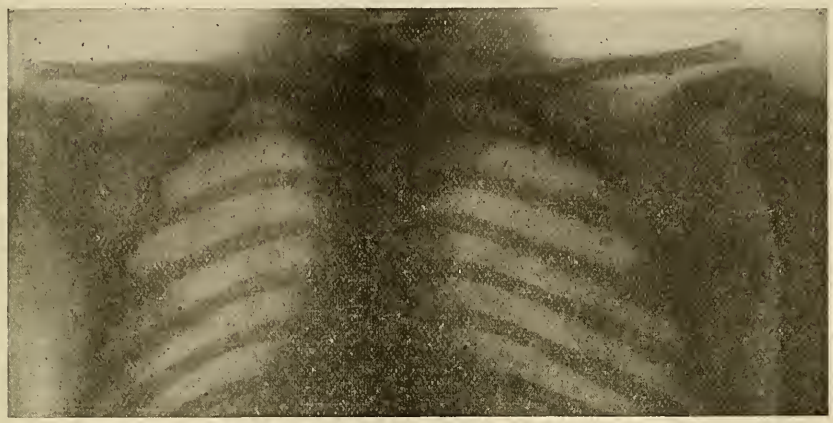

Fig. 681.—Author's case of whistle in esophagus, removed by external esophagotomy.

lowing, by vomiting, or by surgical extraction a sensation is apt to remain as if the body were still lodged. The diagnosis is made by the history, the detection of the body by external manipulation, by feeling it with an esophageal bougie, by esophagoscopy, and, if bone or metal, by seeing it with the fluoroscope or obtaining a skiagraph.

Treatment.—The surgeon should learn, if possible, the size, shape, weight, and nature of the foreign body, and should locate its point of impaction. The

Fig. 682.—Author's case of jackstone in esophagus, removed by external esophagotomy.

exact point of lodgment of bone or a metallic body is determined by the *x*-rays. An anesthetic is given before manipulating a child, a nervous woman, or a lunatic, and is *sometimes* necessary for a man. If the foreign body is soft, external manipulation may succeed in altering its shape, so that it may be swallowed or ejected. If the foreign body is hard, external manipulation may shift its position. It is usually impossible to reach the foreign body through the mouth by means of the fingers (when the body is in the rear of the pharynx it may be pulled forward or pushed down). Sharp foreign bodies may be en-

tangled and carried down when the patient eats mush, bread, or boiled potatoes. The administration of emetics is an old plan which occasionally succeeds, but which is too unsafe to be employed. The esophagoscope is of immense value. By means of it a surgeon, skilled in its use, may remove many foreign bodies which, otherwise, would demand the performance of grave operations (see page 1073). Nevertheless I believe, with E. Fletcher Ingalls, that the esophagoscope "cannot entirely supplant the older methods" ("Amer. Jour. of Surg.," Jan., 1912). The instrument is not always at hand, and to use it successfully and safely one must be well trained in its management. Maylard says that when a mass of food is impacted it is occasionally possible to soften and disintegrate the mass by administering a mixture containing pepsin. The bristle probang (Fig. 683, C) is a very useful instrument for the removal of fish-bones, pins, and other small objects. It may be used to push a body downward into the stomach, or to catch the body and pull it up. When this instrument is withdrawn it opens like an umbrella. It has been shown that in an adult the cardiac opening is from 14 to 16 inches from the incisor teeth, a point to be remembered in deciding whether to push down or pull up the impacted article. Esophageal forceps (Fig. 683 A, B) are valuable in some cases. The coin-catcher (Fig. 683 D) is a useful instrument. Créquy's plan of removal is to take a tangled mass of threads, tie a stout piece of string about the middle of it, coat it with sugar, and have the patient swallow it. It may pass the foreign body; if it does so, on withdrawal it may entangle the object and extract it. To remove a fish-hook with line attached the following plan may prove successful; stick the line which projects from the mouth into a metal catheter, carry the catheter down to the hook, and push the hook out. It is not proper to allow a foreign body to remain in the esophagus until it causes ulceration. Neither is it proper to make prolonged efforts to extract it through the mouth. Such efforts may do great harm, and if one careful and consistent effort fails, and the esophagoscope is not suited to the case, fails, or is unobtainable, or if there is no skilled man to use it, an operation should be performed. If the body is lodged anywhere above the lower third of the esophagus, *external esophagotomy* is performed, and usually on the left side. Through this wound the foreign body is extracted. The cut is made on the left side, between the trachea and larynx in front and the carotid sheath behind, the center of the incision being opposite the cricoid cartilage. After the foreign body has been extracted the mucous membrane is sutured with chromicized catgut, and the superficial structures are closed with silkworm-gut after a drainage-tube has been inserted. The patient is fed by the rectum for eight or ten days. When a foreign body is lodged in the lower portion of the tube the stomach is opened and the body extracted by this route. In White's case of jackstone in the gullet gastrotomy was performed. A string was tied about some rolls of gauze, the string was passed by means of a

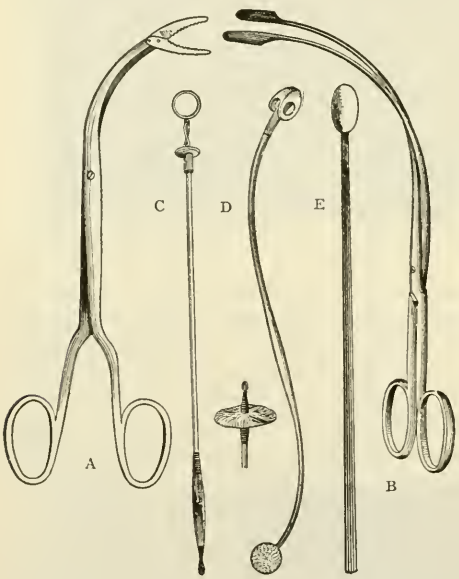

FIG. 683.—Esophageal instruments: A, B, Forceps; C, Gross's bristle probang; D, coin-catcher; E, bulbous esophageal sound.

whalebone from the stomach into the mouth, and the body was entangled and drawn out.

Surgical Invasion of the Mediastinum.—The posterior mediastinum has been entered in order to remove a foreign body from the bronchus and to extract a set of false teeth wedged in the esophagus. The same method can be followed to reach suppurative processes in the mediastinum, abscesses of the lung otherwise inaccessible, and diverticula and carcinomata of the lower end of the gullet. Nassilov resects ribs close to the spine. The portion of the esophagus above the aortic arch can be reached after partial resection of the third, fourth, fifth, and sixth ribs of the left side. Willy Meyer has made four heroic attempts to resect cancers of the esophagus. All the patients perished. He does it under positive pressure ("Surg., Gynec., and Obstet.," Dec., 1912). Out of 35 known operations 1 recovered and 1 lived two weeks after operation. Torek's case was successful (page 1067). The anterior mediastinum may be entered to remove a bullet, to drain an abscess, to reach a wound of the heart or lung, and to explore for the cause of obscure and dangerous symptoms. I explored the anterior mediastinum after rib resection, found a bullet embedded in the aorta, and allowed it to remain. The patient recovered. M. H. Milton[1] splits the sternum and separates the two pieces.

Invasion of the mediastinum is much safer if the operation is performed in the Sauerbruch chamber or with the aid of positive pressure within the bronchi. Either of these plans will prevent pulmonary collapse if the pleura is opened.

XXVIII. DISEASES AND INJURIES OF THE ABDOMEN

Diagnosis of Intra-abdominal Emergencies.—The exact diagnosis is always difficult and in many cases is impossible. What a surgeon must try to determine, and what he usually can determine, is whether he is dealing with a trivial and temporary derangement for the relief of which an operation is entirely unnecessary, or whether he is confronted by a grave calamity which imperatively demands immediate surgical aid. We can decide that a calamity exists, but the exact nature of the lesion is often doubtful until operation is performed. Every operation in such a case is exploratory. Before the diagnosis of a calamity is made morphin should not be given, because it allays the pain, relieves the anxiety, causes the disappearance of rigidity, lowers the pulse, abates mental shock, and hence veils the real situation, so that the most discerning surgeon will probably be misled. If shock is profound, diagnosis is usually impossible, unless shock is due to hemorrhage, and immediate operation during shock is not to be thought of except for a perforation or to arrest bleeding. If excessive and continued hemorrhage is suspected, immediate operation is indicated. If it is not suspected, the patient should be covered with blankets and surrounded with hot-water bags, atropin should be given hypodermatically, and hot salt solution should be administered by rectum, subcutaneously or intravenously. When the patient reacts, and he usually will react, an attempt is made to make a diagnosis. An ice-bag should not be used. Truly it allays pain, but it abates rigidity and masks other symptoms as would a dose of morphia. Morphia is not given until the diagnosis has been made; unless removal is necessary when morphia may be required. If a patient must be moved to a hospital it is perfectly proper to give a single hypodermatic injection of morphin (⅓ gr.) after the effort has been made to diagnosticate the condition. The danger of deluding the surgeon is past, and the drug abates pain, lessens peristalsis, relieves mental anxiety, and is distinctly beneficial. Before the morphin was given the surgeon had come to a conclusion as to the

[1] "Lancet," March 27, 1897.

necessity for operation. After the morphin has been given, if an operation is indicated, it is performed as promptly as circumstances admit. Whenever it is consistent with safety, the patient ought to be removed to a hospital for operation.

Foreign Bodies in the Abdomen.—Now and then a sponge, a pad, or an instrument is left in the abdominal cavity during an operation—left, not because of the surgeon's carelessness, but in spite of the most painstaking precautions. Instruments and sponges are counted before and after the operation. A miscount means calamity. The surgeon does not and cannot make the count himself. He has not time. He is doing a more difficult thing which he is trained to do and which the patient expects him to do, that is, operating, closing the wound, and dressing it. The surgeon must delegate the duty of counting pads, sponges and instruments, and he delegates it to assistants or nurses, who do it with as much accuracy as he. At least *two* people count sponges, pads, and instruments and at least *twice* before and *twice* after the operation. If the count is short, and the missing instrument or material is not discovered on the floor, in a bucket, on or under the table, the abdomen must be opened and the lost object sought for and found.

A great safeguard is to use no small sponge or pad unless it has a bit of tape sewed to it. The tapes stick out of the wound and on each one a forceps is clamped. Another precaution is to refrain from cutting a pad in two after the operation has been begun. The safest way of all is to use rolls of gauze (Halsted's packs or rolls). To do so means a long broad end sticking out of the wound so that the pack cannot be lost in the belly.

If a septic body of any sort is left in the abdomen it at once produces acute disturbances.

If an aseptic gauze pad or sponge is left it may become encapsuled and cause no trouble for months or years. Sooner or later it will cause trouble or even death. The sufferer may become a chronic invalid. The object may make its way into the intestine or into the bladder. It may even passs out through the rectum. Usually a piece of retained aseptic gauze or an aseptic instrument produces abdominal pain and a tendency to intestinal obstruction. Sooner or later an abscess forms and the symptoms of an acute septic condition arise.

Schachner says the mortality in reported cases is about 50 per cent. Many fatal cases have not been reported. If we suspect the presence of a metal instrument the *x*-rays will show it.

Treatment.—Laparotomy (which is often exploratory) and removal of the offending material.

Simple Contusion of the Abdominal Wall Without Injury of Viscera.—In some cases of contusion of the abdominal wall, only the parietes are damaged; in other cases the viscera or the abdominal tissues are injured. Contusion may involve the skin alone, or may involve the skin, muscles, and peritoneum. In *simple contusion* there is considerable shock if the injury be severe. There is pain, increased by respiration, motion, pressure, and attempts at urination or defecation. When tenderness is not found soon after the accident but appears some days later there is usually deep-seated injury. Extensive ecchymosis may appear. Even after a severe contusing force has been applied there may be no discoloration, and it may happen that after a slight force there is much discoloration. There is great ecchymosis in anemic persons, victims of hemiplegia, obese individuals, opium-eaters, and drunkards. In severe cases the tissues are pulpified and sloughing inevitably ensues. Abscess occasionally follows contusion. The prognosis after abdominal contusion is always uncertain.

Treatment of Simple Contusion.—In treating simple contusion place the patient at rest in a supine position, with the thighs flexed over a pillow. Obtain

reaction from the shock. If pain be severe, and we are certain there is no visceral injury and no internal hemorrhage, give morphin. After shock has passed off it is advisable to place an ice-bag over the seat of injury. If much blood is extravasated into the abdominal wall, aspirate and apply a binder. After twenty-four hours apply local heat by means of the hot-water bag, employ an ointment of ichthyol, and move the bowels, if necessary, by salines. Regard every contusion as serious, and watch carefully for the development of signs of internal hemorrhage or visceral injury.

Muscular Rupture from Contusion.—In this injury there are severe shock, and pain (increased by respiration and movement). Separation between the fibers of the muscle is distinct at first, but it is soon masked by effusion of blood. Such injuries may cause death or may lead to hernia. The rectus is the muscle most apt to rupture. The rupture is due to sudden contraction rather than to the direct effect of a blow.

The *treatment* is the same as for simple contusion. Always apply a binder. If a hernia exists it is returned and a compress is applied over the opening through which it emerged. Later operation is performed. If strangulation occurs, operate at once.

Injuries with Damage to the Peritoneum or the Viscera. Rupture of the Peritoneum.—The peritoneum may be involved in an abdominal contusion. It may rupture even when there is no visceral injury or muscular contusion. The uterine peritoneum, the parietal peritoneum, the visceral peritoneum, or the mesentery may rupture. Rupture of the peritoneum causes intra-abdominal hemorrhage.

The *treatment* consists in opening the abdomen, arresting the hemorrhage, and bringing about reaction.

An injury to the peritoneum creates a point of least resistance, and at such a point peritonitis may develop. The peritonitis is usually local, but may become general. After any severe intra-abdominal injury the symptoms of *peritoneal shock* appear (*peritonism*), and the patient may rapidly die. In the condition of peritoneal shock the temperature is subnormal; the extremities are cold; the face is pallid and sunken; the pulse is small, weak, and very frequent; the respiration is shallow and sighing; there is great thirst; the patient is restless and turns uneasily, and there is rigidity and distention. Vomiting almost always occurs. In some cases there is regurgitation rather than vomiting. The abdomen is the seat of a violent, persistent pain. The patient is fearful of impending death. As the symptoms develop in a grave case they will point to one of two conditions—hemorrhage or peritonitis.

In *intra-abdominal hemorrhage* the subnormal temperature and other evidences of shock persist. Vomiting ceases, but nausea exists. The patient is uncontrollably restless and tosses about in bed. The thirst is great. The abdomen is rarely rigid. Fainting-spells occur. Blood examination shows a marked fall in the percentage of hemoglobin. Percussion demonstrates the existence of an effusion which alters its position as the patient's position is altered, and which gradually increases in amount. Dulness is first met with in the loins. Digital examination of the rectum or vagina may aid in diagnosis, because in hemorrhage blood gathers in the rectovesical or in Douglas's pouch. If peritonitis develops, the vomiting is aggravated, the pain is intensified, and the abdomen grows rigid and distended.

Rupture of the Stomach Without External Wound.—The usual course of rupture is a violent blow, although the accident may happen while washing out the stomach. Rupture is more apt to occur when the stomach is distended with food than when it is empty. The rupture may be partial, the peritoneal coat not being torn. The rupture may be complete. Either the anterior or the posterior wall may suffer. The region of the pylorus is most apt to be lacerated. The symptoms of rupture are collapse, severe pain over the entire

abdomen, great thirst, excessive tenderness, especially over the epigastric region, occasionally vomiting, the vomited matter being usually, but not invariably, bloody; tympanitic distention and muscular rigidity coming on after a few hours. Austin Flint pointed out years ago that after complete rupture or perforation gas may enter the abdominal cavity and cause the diminution or disappearance of liver-dulness, but the area of liver-dulness can be lessened by great intestinal distention, and I have seen cases of perforation of the stomach and intestine in which liver-dulness was not lessened at all. (See article on Perforating Ulcer of the Stomach.) The flatter the abdomen the greater the significance of the sign. After *incomplete* rupture local peritonitis is frequent; in *complete* rupture the escape of stomach contents into the peritoneal cavity causes general peritonitis. The contents of the stomach are not so liable to escape after rupture of that viscus as are the contents of the intestine after rupture of the gut, because of the thickness of the stomach wall and the tendency of the mucous membrane to evert and block the opening. Perforations of the anterior wall are most apt to lead to extravasation and general peritonitis. Posterior laceration may cause subphrenic abscess. To diagnosticate between complete and incomplete rupture, Senn favored distending the viscus with hydrogen gas. In incomplete rupture the contour of the dilated stomach can be made out upon the surface; in complete rupture the viscus cannot be distended, and the gas passes into the peritoneal cavity, producing the physical signs of tympanites. This maneuver is open to the objection that it may increase extravasation in a complete rupture.

The **treatment** for complete rupture is immediate operation. Treatment for shock is at once instituted and an intravenous infusion of salt solution is given before or during operation. In doubtful cases endeavor to bring about reaction and explore. Open the abdomen. Note if gas emerges from the wound or if stomach fluid appears. Search for the rupture in the same manner as we would search for the opening of a perforated ulcer. When the rupture is discovered, flush out the stomach and the peritoneal cavity with hot salt solution; sew up the stomach wound with a double row of silk sutures, the first row being buried and including the muscular coat and mucous coat, the second row being Halsted sutures; drain the abdomen; close the wound in the parietes; place the patient in Fowler's position; let salt water at low pressure flow continuously into the rectum; feed by the rectum for four days, and then begin the administration of a very little food by the mouth. In incomplete rupture the danger is perforation. The patient is put to bed, and after reaction has taken place is fed by the rectum for several days. Cases of complete rupture not operated upon occasionally recover, adhesions arising and perigastric suppuration taking place. The mortality is extremely large. In 1896 Petry collected 23 cases in which operation was not performed. The mortality was 59 per cent. This mortality is not so large as one would anticipate. It is quite possible that some of the cases were not genuine instances of rupture. Many fatal cases have not been reported. Nevertheless, the lesion, for reasons previously stated, is not nearly so dangerous as rupture of the intestine. Another reason for the greater danger of intestinal rupture is that fecal matter is much more poisonous than the gastric contents. Laparotomy has lessened the mortality of rupture of the stomach. Petry and also Eisendrath mass together operations for rupture of the stomach and rupture of the intestine. Petry finds the group mortality to be 52.3 per cent., and Eisendrath finds it to be 52.5 per cent. Statistics referring to the stomach alone should show a much lower death-rate.

Rupture of the Intestine Without External Wound.—In the great majority of cases the damage is produced by direct violence. In some few cases the force is indirect (falls on the feet or buttocks, blows on the back or loin). The injury may result from *oscillation* or from *compression* (the

younger Senn). The common cause is undoubtedly compression of the gut against the pelvis or vertebral column, but it is certain that a gut containing fluid may be ruptured purely by violent shaking or oscillation. If oscillation produces the damage, the rupture is of the portion of gut furthest from the mesentery; if compression be the cause, any part of the bowel may suffer. Rupture is most apt to occur if the belly is relaxed. It is predisposed to by adhesions, disease of the wall of the bowel, and irreducible hernia. Most ruptures are complete. In a very few cases the tear extends through one or two of the coats only and the rupture is incomplete. A contusion of the gut may be followed by rupture several days after the injury. A complete rupture usually permits leaking of feces, but in very rare cases a small opening is closely plugged by pouting mucous membrane. Leaking from a rupture may be delayed because intra-abdominal pressure may for a time keep the opening pressed against a section of sound gut (the younger Senn). The amount of damage to the belly wall does not convey any notion of the extent of visceral injury. The belly wall may be severely injured and the viscera escape. With only slight contusion of the wall there may be extensive visceral injury. Homer Gage[1] collected 85 cases; in 75 the injury was due to direct force, and in 32 of these the force was inflicted by the kick of a horse or of a man. In 1 of my cases it was due to the kick of a horse, in 1 to the kick of a man, and in 1 to a crush inflicted by a cart-wheel. The victims in the majority of reported cases were young men, probably because young men are most apt to be exposed to violence. In 78 collected cases (Gage) the situation of the injury was specified: The duodenum, 10; jejunum, 20; ileum, 42; large intestine, 6. Curtis found the large intestine injured in 4 cases out of 113, and Poland, in 5 cases out of 64. In many cases there is more than one tear, and sometimes many tears exist. Both the large and small intestines may suffer. Chavasse collected 106 cases in which the ileum or jejunum suffered, 19 in which the large intestine did, 7 in which the duodenum did, 7 in which both the large and small intestine were involved, and 1 case in which the rectum was ruptured (quoted by the younger Senn, in "Am. Jour. Med. Sciences," June, 1904). As Makins points out, the portion of gut most apt to be injured is a portion hanging low in the pelvis, because a loop in this situation is most easily squeezed against bone by a blow on the belly. The mesentery may be lacerated (it is in 7 per cent. of cases, according to Gage; in 16 per cent., according to Curtis). Now and then we read of a death resulting from someone introducing into the anus of an unfortunate person the nozzle of a hose carrying compressed air. The victim of this perversion, cruelty, or morbid sense of humor whichever it may be, usually dies from multiple ruptures of the intestine. Bendixen and Blything report a case in which operation was followed by recovery ("Surgery, Gynecology, and Obstetrics," 1914, xviii). They call the condition *pneumatic rupture*. In their case there were 9 lacerations in the large gut and 1 in the small gut. The lacerations were from 2 to 7 inches in length. There was also a tear in the mesentery. The symptoms of rupture of the intestine are profound shock, tympanites, abdominal pain, and rigidity, rapidly followed by peritonitis if the patient survives. In some cases pain is referred to the back. Vomiting comes on soon after the accident, the vomited matter being possibly at first bloody and later stercoraceous. The respiration is costal, dyspnea exists, the tongue is dry, and great thirst exists. The pulse, which may be slow at first but seldom is, soon becomes small, rapid, and of high tension. Blood in the stools rarely appears early enough to be of diagnostic value, and there may be diarrhea or constipation. There may be no marked symptoms for an hour or two or for many hours. Cases are on record of people with ruptured intestine returning to work perhaps for hours. One of my cases walked over two miles to reach the hospital. Holland's patient had no symptoms for twenty-four

[1] "Annals of Surgery," March, 1902.

hours, although the jejunum had been ruptured. Poland's patient ruptured the duodenum, but walked one mile in spite of it. The escape of gas into the peritoneal cavity may cause the diminution or disappearance of liver dulness. After anesthetizing the patient, hydrogen gas insufflated into the rectum will come from the mouth if there is no perforation in the stomach or the intestine; if a perforation exists, tympanites is much increased and the area of liver dulness may disappear. To apply *rectal insufflation of hydrogen*, generate the gas in a bottle by means of zinc and sulphuric acid, catch the gas in a large rubber bag, and attach the tube from the gas reservoir to a tip which is inserted in the rectum. Give the patient ether to relax the abdominal muscles, direct an assistant to press the anal margins against the rectal tip, and when the patient is unconscious turn on the stopcock and press upon the reservoir (the elder Senn).

It has been suggested that ether vapor, mixed with air, can be used instead of hydrogen gas.[1] In this method a little ether is poured into the bottle of an aspirator, the valves are opened, one tube is carried into the rectum, the other tube is attached to a bicycle pump, and by working the pump the ether vapor is driven into the bowel. If there be perforation, tympanites is notably increased. Most surgeons regard the rectal insufflation test as unsatisfactory and often dangerous. Personally, I am not inclined to use it. Its application requires considerable time; it must, of necessity, increase fecal extravasation. If we operate after insufflation the gaseous distention is an embarrassment to the surgeon; as Le Conte[2] says, it "so distends the intestines that it may be impossible to return them to the abdominal cavity until they have been emptied of gas."

Treatment for Rupture of Intestine.—After an abdominal injury, if symptoms point to dangerous hemorrhage, and in any case in which the patient does not seem to be reacting, but is rather getting worse, operate at once. If in doubt as to whether or not rupture exists, make every endeavor to bring about reaction and explore. Reaction is brought about as previously directed. Asepticize and anesthetize. Perform a laparotomy, making the incision in the middle line and below the umbilicus; observe if gas escapes when the peritoneum is opened or if fecal material or an inflammatory exudate flows out; check hemorrhage; start at a fixed point and conduct a careful search to find the rent. When the rent is found, it should be closed by Halsted sutures if possible, but only a small rupture can be so treated. A large tear makes resection necessary Because of the frequency of multiple lesions the surgeon must not be sure he has finished his work when he finds and closes one tear, but he must determine by careful search that no other tears exist. The surgeon notes if there is injury of the mesentery and if the circulation of any portion of the bowel is interferred with. If there is serious impairment of circulation in any part of the bowel wall, perform intestinal resection, followed by end-to-end approximation or lateral anastomosis. In some cases of rupture the patient is so severely shocked that it is impossible to do a resection with any hope of his living. In such a case stitch the ruptured portion of gut to the belly wall. The opening in the gut becomes a fecal fistula, and if the patient survives, can be subsequently closed. The same procedure is proper if the bowel is distended and paralyzed. After closing the opening in the bowel or resecting, flush the abdominal cavity with hot saline solution, and wipe the peritoneal fossæ and the space between the liver and diaphragm with gauze. Finney eviscerates, wipes out the abdominal cavity, and wipes the intestines as he restores them. This is justifiable if the operation is done soon after the rupture, but not in later cases, in which the lymph has gathered on the bowel. Whatever method is used to cleanse the abdomen, remember that infectious material is apt to accumulate between the liver and diaphragm

[1] Emerson M. Sutton, of Geneva, in "Jour. Am. Med. Assoc.," July 23, 1898.
[2] "Jour. Am. Med. Sciences," Dec., 1901.

and in Douglas's pouch. Drainage is to be used. Suprapubic drainage is most advantageous. Place the patient semi-erect and employ continuous proctoclysis of normal salt solution as directed for peritonitis. The value of operation for intestinal rupture is conclusively demonstrated. Curtis collected 116 cases which occurred before 1887. Not a case was operated upon, and every patient died. Homer Gage collected 85 cases since 1887: 45 were not operated upon and every one died; 40 were operated upon and 17 recovered. Eisendrath collected 40 cases operated upon: 19 recovered and 21 died (52.5 per cent.). The mortality of cases not operated upon is, according to Eisendrath, at least 93 per cent. The sooner after the injury operation is performed, the greater the chance for success. The younger Senn points out that in operations done within four hours the mortality is 15.2 per cent.; in those done between five and eight hours it is 44.4 per cent.; in those done between nine and twelve hours it is 63.6 per cent., and in those done later it is 70 per cent.

Identification of the Small Intestine and of the Large Intestine.—"In abdominal operations it is frequently imperatively necessary that the large intestine be recognized with certainty or the small bowel be positively identified. The size of the tube will not always aid in this recognition, as a small intestine may be distended enormously, and a large intestine may be contracted to the size of a finger because of obstruction above. The longitudinal muscular fibers of the large bowel are accentuated in three portions; these accentuations constitute the three longitudinal bands which begin at the cecum and terminate at the end of the sigmoid flexure of the colon. Each band is composed of a number of shorter bands, the shortness of these constituent bands permitting the sacculation of the large intestine. Longitudinal bands and sacculation are not met with in the small gut, their presence or absence being a means of identification in many cases; but when the colon is much distended the bands cannot be seen distinctly and the sacculation disappears. From the large intestine only spring the appendices epiploicæ (small overgrowths of fat in pouches of peritoneum), but they are sometimes not well marked except upon the transverse colon, and when emaciation exists they may almost entirely disappear. The relatively fixed position of the large intestine and the free mobility of the small bowel are important points of distinction. The foregoing indicates that it is not always easy to distinguish between colon and small gut, and that, according to old rules, it may be often necessary to make large incisions, to see as well as feel, and to handle a large extent of the bowel. Any scrap of knowledge that will shorten an abdominal operation, that will permit of as certain work through a smaller incision, and that will diminish handling of intraperitoneal structures tends to increase the chances of recovery. For these reasons the writer suggests a method of bowel identification which rests upon the facts that each bowel has a posterior attachment, that the origin of the attachment differs according to the bowel it supports, that a single finger can detect the origin of the peritoneal support of any section of the bowel, and, this origin being known, the portion of the bowel it supports is with certainty deducible. In an exploratory operation, for instance, the finger comes in contact with the bowel: to determine whether it is a large or a small bowel, note first if the structure is movable or is firmly fixed; next, pass the finger over the bowel and let it find its way posteriorly. If dealing with a small bowel, the finger will reach the origin of the mesentery between the left side of the second lumbar vertebra and the right sacro-iliac joint; if dealing with the large bowel, the finger will reach the origin of the mesocolon, or the point where the colon is fixed posteriorly and to the side."[1]

Location of a Loop of Small Intestine (Figs. 684–687).—Monks points out a plan by which, in most instances, we can learn with approximate accuracy what portion of the small intestine we may have hold of ("Annals of

[1] "The author, in "Medical News," June 9, 1894.

Surg.," Oct., 1903). He learns first by observation of the mesenteric vessels. Opposite the upper portion of the bowel there are primary vascular loops only with perhaps an occasional small secondary loop. As we descend

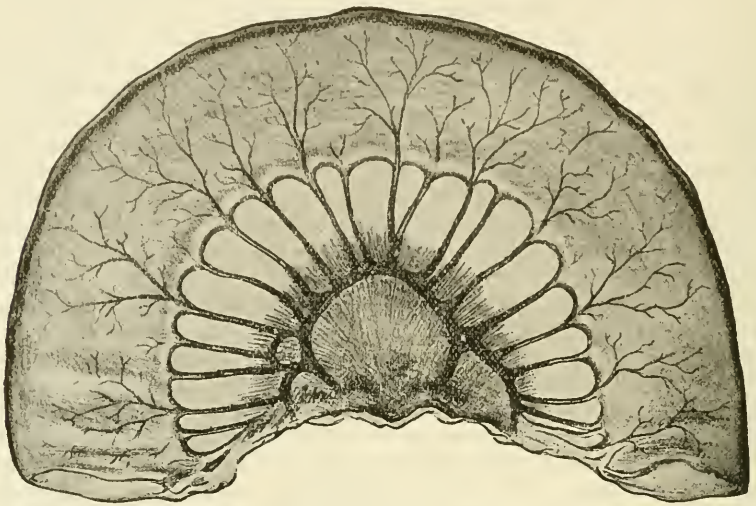

FIG. 684.—A loop of intestine, the middle of which is exactly 3 feet from the end of the duodenum. The gut is of large size. The mesenteric loops are primary, and the vasa recta large, long, and regular in distribution. The translucent spaces (lunettes) between the vessels are extensive. Below, the mesentery is streaked with fat. The veins, which had a distribution similar to the arteries, are for simplicity omitted from this and from the subsequent drawings. The subject from which the specimen was taken was a male of forty years, with rather less than the usual amount of fat. The entire length of the intestine was 23 feet (Monks).

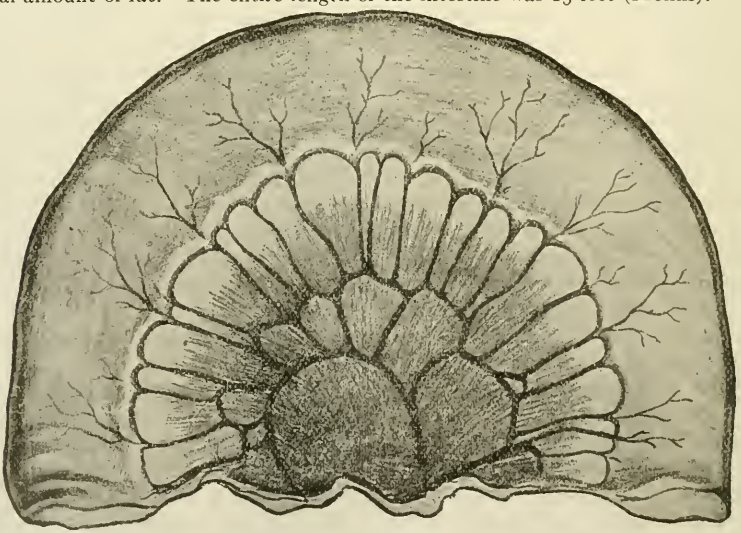

FIG. 685.—A loop of intestine at 6 feet. As compared with Fig. 684 the gut is somewhat smaller. The vascularity of the intestine and mesentery is less. Secondary loops are a prominent feature. The vasa recta are smaller. The lunettes are also present, but are not so large as in Fig. 684. The subject was a male of about thirty-five years, with an average amount of fat. The entire length of the intestine was 20 feet (Monks).

"secondary loops become more numerous, larger, and approach nearer to the bowel than the primary loops in the upper part," and about the fourth foot these secondary loops first become a "prominent feature." As we descend

primary loops become smaller, secondary loops become more numerous and nearer the bowel, and possibly tertiary loops appear. Opposite the lower portion of the ileum the loops are not definite in arrangement, but are simply a

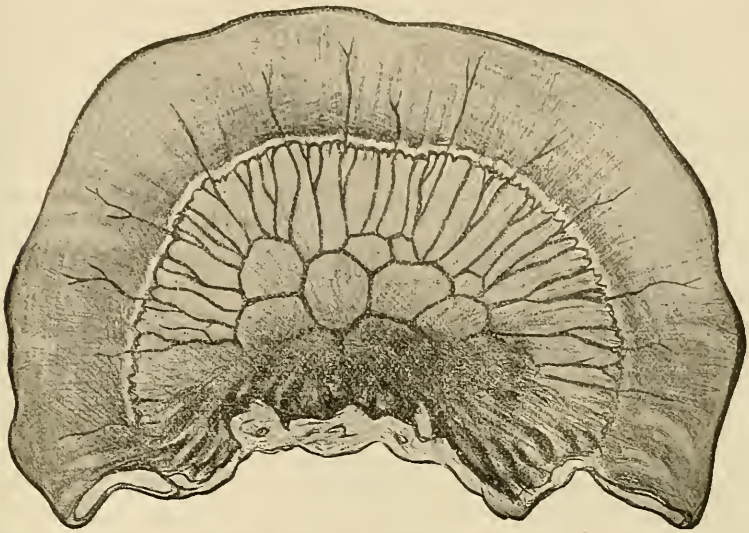

FIG. 686.—A loop of intestine at 12 feet. The vessels are smaller. The primary loops are lost in the fat, but secondary and even tertiary loops are visible. The vasa recta are shorter, more irregular, and branching. The specimen came from the same subject which furnished Figs. 684 and 685 (Monks).

FIG. 687.—A loop of intestine at 20 feet. The gut appears to be thick and large. The mesentery is quite fat and opaque, and large and numerous fat tabs are present. The vessels, which are complicated, are seen with difficulty, and are represented by mere grooves in the fat. The subject was a stout woman, and the entire length of the gut was 21 feet (Monks).

network. Monks points out that opposite the upper bowel the vasa recta, when put gently on the stretch, "are straight, large, and regular, and rarely give off branches to the mesentery," and are about 5 cm. long. In the lower

third they are usually less than 1 cm. long, are smaller, are not quite so straight, are not so regular, and give off numerous mesenteric branches. Monks further shows that fat impairs the translucency of the mesentery. The thinnest mesentery is that connected with the upper gut. As we descend the mesentery becomes thicker and thicker because of fibrous tissue, unstriated muscle, and fat. Translucency varies greatly. If a loop of upper intestine is raised against the light, one notices close to the gut and between the vasa recta transparent lunettes. The lunettes become smaller and fatty as we descend, and disappear at the eighth foot. In an incision in the median line, if the loop of intestine is pulled downward, we can determine if "the line of resistance from above is from the median line of the body or from the left or right of it." This resistance of the mesentery indicates to which point the loop is attached, and hence what portion of bowel the loop comprises. I have used these observations of Monks repeatedly to great advantage.

Rupture of the Liver.—(See page 1170.)

Rupture of the gall-bladder and the bile-ducts (see page 1170) is most apt to happen from injury when gall-stones exist. Peritonitis, general or local, is almost certain to follow such a rupture. Besides those symptoms common to all severe abdominal injuries there may be intense jaundice.

Treatment.—Suture the laceration or make a biliary fistula.

Rupture of the Pancreas.—(See page 1192.)

Rupture of the Spleen.—(See page 1201.)

Rupture of Mesenteric Arteries.—The symptoms are those of hemorrhage. The superior mesenteric artery, the inferior mesenteric artery, or branches of either or both may be damaged. If branches of the superior mesenteric artery are divided near the bowel, gangrene of the bowel will result, but wound of a branch far from the intestine does not cause gangrene. The branches near the gut are terminal arteries, hence the gangrene. The branches of the artery divide and form arcades arranged concentrically and the terminal arteries come from the peripheral arcades. In wounds of the vessels far removed from the gut anastomosis prevents gangrene (Labastie, in "Archives Générales de Chirurgie," Jan. 25, 1908). In most cases in which there has been rupture of mesenteric arteries death from hemorrhage rapidly occurs If the victim should not die of hemorrhage he is in danger of gangrene and peritonitis. Aldrich[1] reported a case in which death was deferred until the seventh day. The treatment is immediate laparotomy. If the wound is found close to the gut, the portion of gut supplied by the cut vessel should be resected. If well removd from the gut, simply ligate the vessel (Labastie, Ibid.). In a wound near the root of the mesentery perform extensive resection of the gut and remove also a portion of the mesentery.

Rupture of the Kidney.—(See page 1424.)

Rupture of the Ureter.—(See page 1426.)

Wounds of the Abdominal Wall.—**Non-penetrating wounds** are to be treated on general principles. They are sutured with great care and are firmly supported externally. Ventral hernia may follow a large wound.

Penetrating Wounds.—The *symptoms* of penetrating wounds of the abdominal wall are usually those of shock and hemorrhage, and later of septic peritonitis. Emphysema is apt to occur and viscera may protrude, and often do in the case of a large incised or lacerated wound. Extravasation of contents of intra-abdominal viscera is very apt to occur, and is sure to occur if the viscus was distended when injured. Normal urine and normal bile may do little harm, but if either excretion is septic, disastrous consequences are certain to ensue. If intestinal contents escape, septic peritonitis is sure to arise. Bleeding is usually profuse and prolonged, because spontaneous arrest of hemor-

[1] "Annals of Surgery," March, 1902.

rhage from any vessel of considerable size will seldom take place unless the abdomen be opened.

Treatment.—The surgeon endeavors to discover promptly if a wound of the abdominal wall is or is not penetrating in character. This fact may be proved by protrusion of viscera, by the appearance of stomach contents in the wound, or by a flow of bile, urine, or feces from the wound. If none of the above indications exists, and if there are no signs of serious hemorrhage, the wound should be irrigated with hot salt solution, and should be dressed with gauze, and every effort should be made to bring about reaction; otherwise opertion should be immediate.

When reaction is obtained, the wound should be enlarged layer by layer until it becomes obvious whether or not the peritoneum is open. Madelung,[1] of Strassburg, points out that incision layer by layer will be of no use in settling the question of penetration if the wound is in the chest, the buttock, the perineum, or the back of a fat individual. If after incision layer by layer it becomes evident that penetration has not occurred, the wound should be closed and treated on general principles. If it becomes evident that it has occurred, the abdomen should be opened at the point of penetration, and a thorough exploration of intra-abdominal structures should be made in order to locate injury and be able to treat it properly.

In a case still doubtful after incision by layers, do an exploratory laparotomy in the middle line. It is impossible from the appearance of the wound and it may be impossible from the symptoms to affirm that visceral injury has not occurred; hence in every case in civil practice in which it is evident that penetration has occurred, laparotomy is necessary in order to detect and correct intra-abdominal injury, and to clean the peritoneum by flushing with hot salt solution. If viscera protrude, they must be washed off with hot salt solution and covered with hot sterile pads, and after the patient has reacted the wound should be enlarged, the condition of the contents of the abdomen investigated, hemorrhage arrested, wounds properly treated, and the viscera returned.

It is customary to flush the belly with hot salt solution, some of the fluid being allowed to remain. This procedure mechanically cleanses the peritoneum, removes blood-clots, strongly combats shock, and antagonizes infection. It is not absolutely necessary to flush out the belly unless a considerable hemorrhage has occurred or feces or stomach contents have been extravasated. If extravasation of stomach contents or feces has occurred, not only should flushing be practised, but evisceration should be carried out; the fouled intestine should be wiped off with gauze pads wet with hot salt solution, and while extruded should be kept wrapped in hot moist towels; the peritoneal fossæ should be rubbed with gauze pads and the space between the liver and the diaphragm should be carefully wiped.

A wound of the stomach should be sutured; a wound of the bowel may be sutured, or resection and anastomosis or resection and end-to-end suturing may be required. Visceral injuries are treated by appropriate means. In a punctured wound or a gunshot-wound of the intestine rectal insufflation of hydrogen gas when the abdomen is open may disclose the situation of the injury, but evisceration is usually practised instead and is preferable.

After the completion of intra-abdominal manipulations the surgeon restores any protruding bowel.

Drainage is required if the contents of the stomach or the intestines escaped, if hemorrhage was severe, or if the liver, pancreas, kidney, or spleen were found to have been damaged. The peritoneum may be sutured with a continuous suture of catgut; the muscles and fascia, with continuous or inter-

[1] "Annals of Surgery," Sept., 1897.

rupted sutures of catgut, and the skin, with interrupted sutures of fine silk or of silkworm-gut. If there is need of haste, through-and-through sutures of silkworm-gut may be used. Active stimulation and artificial heat are needed immediately after the operation to combat shock. In many cases intravenous infusion of hot normal salt solution is given. It is of great value. It may be given both during and after operation. Enteroclysis, or high rectal injection of hot saline fluid, is useful. So is hypodermoclysis, or the subcutaneous injection of hot salt solution. The usual after-treatment consists of the semierect position, continuous proctoclysis of salt solution, avoidance of food by the stomach for forty-eight hours, and the administration of brandy and water from time to time. For two days the patient should be fed by the rectum. On the appearance of flatulent distention, forty-eight hours or more after the operation, give a saline cathartic. It is not wise to purge during the first forty-eight hours after the operation unless a Murphy button has been used. When there is no sign of peritonitis a purge should not be given until the fourth day. After forty-eight hours liquid food can usually be given by the stomach. Solid food may be given after seven or eight days, but the patient must not leave his bed until the abdominal wound is firmly united because of the danger of ventral hernia. A support should be worn for a long time. E. D. Fenner[1] reports 39 stab-wounds of the abdomen operated upon in the Charity Hospital of New Orleans. There were 9 deaths (23.07 per cent.).

Gunshot Wounds of the Abdomen.—The bullet may penetrate from the front, the side, the back, the chest, or the perineum. If a bullet has penetrated, it may or it may not have produced visceral damage; a pistol-bullet or the bullet of a sporting-rifle almost invariably does. A projectile of a modern military rifle may not or may produce wounds which can be recovered from without operation. A urinary examination should be made promptly to see if blood is present.

In gunshot wounds of the belly shock is usually greatly added to by hemorrhage, and in civil practice prompt operation is certainly indicated. The incision is made through the belly even when the shot entered the back. In some cases the opening is made through the wound; in others it is not; but in every case the wound made by the bullet is explored and disinfected. The incision should be long enough to permit of thorough work. After opening the abdomen our first duty is to arrest hemorrhage, our next is to look for perforations of the viscera and mesentery and close them. If the anterior wall of the stomach is perforated, close the opening and examine the posterior wall through an opening made in the gastrocolic omentum. If a posterior perforation is found, close it, and insert posterior drainage into the lesser peritoneal cavity. As a rule, an intestinal perforation can be closed, but occasionally a portion of the intestine requires resection. If the bullet is encountered it is removed, but a prolonged search for it should never be made. Finally, the abdominal cavity is cleansed, drainage is provided for, and the abdominal wound is closed. In one of my fatal cases the bullet entered the rectum low down and was not found. In a case of mine with 6 perforations of the small intestine recovery followed operation.

E. D. Fenner[2] reports 113 gunshot wounds of the abdomen operated upon in the Charity Hospital of New Orleans; there were 78 deaths (69 per cent.). In a series of 14 cases operated upon by Vaughan the mortality was 64 per cent. ("Am. Jour. Med. Sciences," Feb., 1906).

Military surgeons have taught that wounds inflicted by the modern hard-jacketed projectile are not so apt to involve fatal hemorrhage and disastrous complications; in fact, such wounds are often recovered from without operation, and sometimes with an entire absence of serious symptoms. Again, it is

[1] "Annals of Surgery," January, 1902.
[2] Ibid., January, 1902.

difficult or impossible to treat such cases as in civil practice, even were it desirable. The belief has been until recently that in military practice the results are slightly better from expectant treatment, whereas in civil practice expectant treatment is a dismal failure. Still, even in war, if conditions permit, operation should be performed if there is hemorrhage or obvious visceral injury, or if septic peritonitis develops. Treves says that in the Boer War only 40 per cent. of cases of gunshot wounds of the abdomen not operated upon died, but, as pointed out by Hildebrandt, many cases die on the battlefield and while being taken to the hospital, hence the real mortality of these injuries is much more than 40 per cent. In the war between China and Japan the mortality from gunshot wounds of the abdomen is said to have been about 77 per cent.

Abdominal Wounds in War.—In the beginning of this war surgeons were imbued with the conviction of Sir Frederick Treves that in gunshot wounds of the abdomen abstention from operation is the safer course. They were dominated by the axiom Sir William MaCormac put forth after the Boer War, viz., "those shot through the abdomen will live if let alone and will die if operated upon." After four years of violent war most surgeons have concluded that the policy of abstention is a ghastly failure. It is true that the mortality has been fearful even after operation, but, weighing up everything I believe that the balance tips strongly in favor of early operation.

Early operation is often impossible. Any operation may be out of the question because of lack of time, assistants, and materials—because of close adjacency to the line of battle—or because of military necessity demanding evacuation. As yet figures are not conclusive. Claims are made for both sides of the controversy. The advocate of one view is certain to dispute conclusions and perhaps statements of the advocate of the other view. Distinguished surgeons are found in opposition. The published facts lead us to side with Tuffier when he says that if the surgeon has the necessary time, assistants and equipment operation gives a better prognosis than abstention. Reports demonstrate the following truths: Shell fragments cause the worst, rifle bullets the least serious injuries. The least serious wounds are those above the level of the pylorus.

A wound from side to side is extremely grave. So is a vertical wound. Anteroposterior wounds in the midline are usually rapidly fatal because the spine, aorta or the vena cava is very apt to be struck (Wallace, in "Lancet," 1915, clxxxix). Rifle-bullet wounds of the liver, if anteroposterior, and through-and-through may be recovered from without operation. Oblique wounds, tangential injuries, and shell wounds give a far worse prognosis. The kidney is apt to be injured. Midline anteroposterior wounds are more fatal in the hypogastric than in the epigastric region. A wound of the buttock, thigh or perineum may enter the peritoneal cavity.

Exploratory operations have proved that a bullet can cross the peritoneal cavity without opening a hollow viscus. In such cases the peritoneal coat of the stomach or intestine may be bruised or torn. Hence it is possible for a rifle bullet to push a hollow viscus out of the way and not perforate it (Wallace, Ibid). This can only occur when the bullet is traveling with great velocity and the viscus contains very little fluid. Only in such cases is spontaneous recovery possible. Wounds of the large intestine are usually associated with pelvic fracture, wound of the bladder, or damage to nerve trunks. They are more fatal than wounds of the small gut. Wounds of the small gut are often multiple.

In wounds of the liver, spleen and pelvis, hemorrhage is the imminent danger. In wounds of the hollow viscera infection is the great peril.

There may be no rigidity of the abdomen. It is especially prone to be absent when there is hemorrhage. Early operation is the indicated treatment if circumstances admit of it, even if the surgeon must operate without an assist-

ant. As Keen says: "Every hour diminishes such a patient's chance of recovery" ("Treatment of War Wounds").

Wallace, Hughes, and Rees show that operations done within six hours are followed by 62.8 per cent. of recovery; those done between six and twelve hours, only 36.3 per cent.—those done between twelve and sixteen hours, 16.6 per cent. The earlier operations were of course upon the most dangerous cases (see Wallace, in "Brit. Jour. of Surgery," iv; Hughes and Rees, in "Lancet," April 28, 1917; Walters, Robinson, Jordan and Blacksmith, in "Lancet," Feb. 10, 1917). Certain it is that intestinal operations are peculiarly fatal if seen late. Bowlby will not operate on such a case if it is seen later than thirty-six hours after the injury because operation offers scarcely the shadow of a chance ("Lancet," Feb. 10, 1917).

Bowlby does not operate on a through-and-through wound of the liver believing that if the hemorrhage is not rapidly fatal recovery may follow. Liek saw 17 gunshot wounds of the liver recover without operation ("Arch. f. klin Chir.," 1916, cvii). If there is no evidence of severe bleeding he secures rest and gives morphia. If there are signs of continued hemorrhage he operates and finds the mortality to be 29 per cent. If a patient wounded in the abdomen is suffering from hemorrhage immediate operation is imperative. If there is severe shock but no progressive hemorrhage many surgeons endeavor to establish reaction before operating. Lockwood and his associates consider the pulse a valuable guide. If the pulse is above 120 operation they postpone until reaction occurs ("Brit. Med. Jour.," March 10, 1917). Walters and his associates also regard the pulse as a valuable guide ("Brit. Jour. of Surgery," iv). Webb and Milligan ("Brit. Jour. of Surgery," iv) says that a pulse above 110 gives a bad prognosis for operation, a pulse of under 85 gives a good prognosis. As a rule the incision should be median and should not include or cross the wound (see Fraser, in "Brit Med. Jour.," 1916, i). The situation of the wound or wounds determines where the incision is to be placed. An escape of feces, bile, or urine from the wound gives us valuable information. Foreign bodies, especially bits of clothing, must be removed. If they are allowed to remain fatal sepsis is almost inevitable.

In intestinal wounds suture is preferred to resection unless there "is extensive damage to the mesentery or extravasation between the two layers of the mesentery at its attachment to the bowel" (Views of Fraser and Drummon as set forth by Keen, in "Treatment of War Wounds). A kidney damaged by a gunshot wound may recover. If nephrectomy is demanded it should not be done immediately, except for hemorrhage (Fullerton, in "Brit. Jour. of Surgery," v).

Many cases are closed without drainage. Many others are drained. All are placed in the Fowler position and are given salt by the plan of Murphy. In some cases suprapubic drainage is used. The wound inflicted by the missile should be excised; sometimes it is sutured; sometimes it is drained.

Bowlby ("Brit. Med. Jour.," June 2, 1917) published the following statistical table:

	Cases
Considered with view to operation	1038
No operation advised	73
Number of operations	965
	Per Cent.
Total operative mortality	53.9
Total hollow viscera mortality	64.7
Mortality from uncomplicated stomach wounds	52.7
Mortality from uncomplicated wounds of the small gut	65.8
Mortality from uncomplicated wounds of the colon	58.7

Gunshot Wounds of the Pregnant Uterus.—It is rarely that both walls are perforated by a pistol bullet, as the force of the bullet is greatly lessened by the uterine contents. A rifle bullet usually passes through the organ.

Wounds by shell fragments are extremely grave. There are severe shock and hemorrhage, and occasionally amniotic fluid flows from the wound of entrance. Blood may flow from the vagina. The intestine may also be injured. As a rule, labor-pains come on soon after the injury. In Albarran's case the fetus was expelled forty-eight hours after operation. Open the abdomen in all cases and empty the uterus. If the patient is late in pregnancy empty by Cesarean section. Hysterectomy is indicated if the uterus is seriously torn. All cases should be drained (Smead) in "Trans. of Assoc., Obstetrics and Gynecology," 1916. Gellhorn[1] has collected 18 cases. In this series there were 12 recoveries. Smead cites 30 cases. Russel Fowler reports a case of a patient eight months pregnant who was shot twice in the abdomen. There were two wounds in the uterus. Fowler did a Cesarean operation. The incision in the uterus was made by enlarging one of the bullet wounds. The other bullet wound was sutured. The baby was wounded on the fingers of the right hand. Both mother and baby recovered ("New York State Jour. of Med.," Nov., 1911). In Judge's case ("Jour. Am. Med. Assoc.," vol. i, 1912), a girl of sixteen, nearly at full term, was shot with a Winchester rifle. The child was in the abdominal cavity and dead. The mother recovered. Tucker, of Shanghai, did a Cesarean operation for gunshot wound of the uterus. The mother died and the child survived.

Omental Cysts.—Cysts may spring from the outer surface of the omentum (escaped ovarian cysts, lymphatic cysts, dermoids).

True omental cysts arise within the cavity of the great omentum. In 50 per cent. of cases the patient is an adult, but in half of the reported cases the patients have been under ten years of age. Some of the cysts are probably of embryonic origin. Dowd is inclined to think that the cyst he removed resulted from omental hematoma ("Annals of Surgery," Nov., 1911). In this case there was torsion of the pedicle of the cyst. Dowd (Ibid.) reports 1 case of omental cyst and collected 37 from literature. Hasbrouck ("Annals of Surgery," August, 1908) points out that the condition is much more common in females than in males, that there are no characteristic symptoms, that the condition begins as omental endothelioma between the two surfaces of omentum which fuse because of inflammation and form a closed sac, that hemorrhages are apt to occur into the cyst, and that operation shows a mortality of 6 per cent. The operation performed is extirpation.

Mesenteric Cysts.—These rare cysts are divided into (1) embryonic, (2) hydatid, (3) cystic malignant disease (Dowd, "Annals of Surgery," 1910). A great majority of mesenteric cysts are embryonic. Moynihan believes that embryonic cysts arise in "rests" from "the Müllerian or Wolfflan organs or ducts, or from the ovary," which are included between the folds of mesentery. These rests undergo cystic degeneration. Miller ("Bull. Johns Hopkins Hosp.," 1913, xxiv) classifies mesenteric cysts as follows:

1. Cysts of intestinal origin:

(*a*) By sequestration occurring during development of the bowel.

(*b*) From Meckel's diverticulum when it arises from the concave side of the intestine (intramesenteric diverticulum).

2. Dermoids.

3. Cysts springing from retroperitoneal organs (duct of Müller, body of Wolff, ovary or germinal epithelium). Mesenteric cysts grow and pass along between the layers of mesentery until they reach the gut and then compress the gut and push its wall ahead of them. A cyst may cause intestinal obstruction. Volvulus is one of its results.

Such a cyst may contain embryonal material, bloody fluid, serous fluid, chylous fluid, or lymph. In Harry C. Deaver's report of a case ("Annals of Surgery," May, 1909) it is shown that in 40 cases there were 25 females and

[1] "St. Louis Med. Review," Dec. 2 and 9, 1901.

15 males; that the size varies from that of a split pea to enormous dimensions; that there may be a pedicle form in front of the vertebral column or from the intestinal wall; that the sac wall may be exceedingly thin or as much as 1 cm. in thickness; that in some cases large veins are present on the surface of the cyst; that adhesions to the abdominal viscera are common; that intestinal obstruction may occur (kinks, volvulus, intussusception); that cysts are most commonly found in relation with the lower end of the ileum; and that there are no characteristic symptoms except perhaps the rapid body wasting mentioned by Moynihan. Moynihan also points out that the cyst fluctuates and is most prominent toward the navel, that it is very mobile, especially transversely (we should add if not anchored by adhesions), and that the cyst is surrounded by a resonant zone and crossed by a resonant band.

Treatment.—Incision and drainage if there are numerous and firm adhesions. Enucleation whenever possible. Resection of the involved portion of gut with the cyst in some cases of multiple cyst (Harry C. Deaver, Ibid.).

Torsion of the great omentum is usually caused by a fall or strain or attempts to reduce a hernia. In nearly all cases a hernia is present. Hedley ("Brit. Med. Jour.," Nov. 11, 1911) studied records of 73 cases. In 60 there was or had been a hernia. In 5 cases without a hernia there were adhesions. In 48 of the hernia cases the omentum was attached in the sac, in 4 it was anchored near the sac, in 3 to the bowel, and in 1 to the Fallopian tube.

Symptoms are like those of a strangulated omental hernia or of appendicitis.

The **treatment** is by laparotomy.

Stomach and Intestines

Foreign Bodies in the Stomach and Intestines.—Foreign bodies of considerable size are rarely taken into the alimentary canal except by children, insane people, or drunkards. Small bodies (bits of straw, fragments of bone, etc.) are frequently swallowed. Most foreign bodies swallowed are passed with the feces, but some lodge in the stomach or intestine. Any body which can pass the esophagus is not too large to pass through the intestines. Lodgment is an accident, not an inevitable consequence—an accident which is due to the shape and size of the body. A foreign body may lodge in the stomach. In some cases there are no symptoms or slight symptoms. In other cases symptoms are violent. The severity of the symptoms depends upon the shape and character of the body. Some nervous women have a tendency to chew and swallow bits of their own hair. If a person continues doing so for years a *hair-ball* (*trichobezoar*) may form. It consists of a tangled mass of hairs agglutinated together by mucus and food remains. It grows slowly. When small it acts like a ball-valve at the pylorus ("Dyspepsia," by W. S. Fenwick), when large it fills the stomach and is moulded to the shape of the organ. Matas reported an interesting case of hair-ball ("Tr. Southern Surgical and Gynecological Assoc.," 1914). A hair-ball gives rise to dyspeptic symptoms. If the ball is large it causes pain and can be palpated. The *x*-rays make the diagnosis.

In some cases it is possible to feel the body from without. A metal body in the stomach will deflect a magnetic needle held over the viscus (Polaillon). Many foreign materials can be skiagraphed. A body of small size may pass through the entire canal and emerge without having done any harm, but it may lodge and may cause perforation. If perforation occurs, the foreign matter may become encysted, for instance, in the mesentery; may cause an abscess or may cause general peritonitis. A fish-bone may cause an anal abscess. An epiploic appendix may cause sacculation of the bowel, perforation by a foreign body may take place in this sac, an *epiploic abscess* resulting, which may attain considerable size and may be mistaken for carcinoma (Sir J. Bland-Sutton, in "Lancet," Oct. 24, 1903). It is not wise to attempt to recover a foreign

body from the stomach by inducing vomiting. In some cases gastrotomy is necessary. When a small or sharp foreign body has been swallowed and has not caused perforation, abscess, or obstruction, the usual treatment is as follows: a purgative should *never* be given to expedite the passage of a foreign body, because increased peristalsis increases the danger of impaction or of perforation. Endeavor to encrust the foreign body, and thus lessen the danger of perforation, by feeding with bread and milk only for several days, and at the end of this period give a mild laxative. An exclusive diet of mush or of mashed potatoes has been suggested. Suet dumplings may be given. Pain is relieved by opium. A foreign body rarely lodges in the duodenum, but may lodge lower down, and may cause ulceration, perforation, abscess, or intestinal obstruction. Operation is necessary in such cases.

Volvulus of the Stomach.—This condition is very unusual. According to T. Kocher 28 cases were on record five years ago and of these 18 were operated upon ("Internat. Abstract of Surgery," Dec., 1914). The condition may be inaugurated by vomiting, peristalsis after vomiting, by body movements or abdominal trauma when the stomach is prolapsed and dilated or by a tumor. One-third of the cases are associated with diaphragmatic hernia and one-fourth with hour-glass stomach. The symptoms come on suddenly. There is violent abdominal pain. Distention and collapse are early. There is nausea, but the patient can neither vomit nor belch. In the upper left abdomen there is a tender, tense, and tympanitic area. The rotation of the stomach may be on its vertical or on its longitudinal axis. An hour-glass stomach may undergo twisting on its vertical or longitudinal axis. Berg operated successfully for volvulus of the stomach. He opened the abdomen, relieved distention by tapping the stomach with a trocar, and then easily corrected the twist. The gastrohepatic omentum should be shortened by Beyea's operation (see page 1243). Kocher had a case in which an hour-glass stomach twisted. At the first operation he untwisted the organ. At a second operation gastro-enterostomy was performed upon the larger sac. The patient was cured ("Internat. Abstract of Surgery," Dec., 1914).

Fibromatosis of the Stomach.—This condition was long ago described by Brinton as cirrhosis of the stomach. Alexis Thomson has recently published an admirable description containing many new things ("Annals of Surgery," July, 1913). He shows that ulceration of some form is the cause (simple ulceration or cancerous ulceration). The condition may be and commonly is localized, but it may involve the entire stomach ("leather-bottle stomach"). There may be glandular enlargement. The local form starts at the pylorus and resembles cancer, but is not nodular. There may or may not be adhesions. There is no "cicatricial stenosis of the pylorus," but the canal of the pylorus is narrowed by submucous thickening. The thickening is not scar-tissue, but is more like a fibroma (Ibid.). It is probably a reaction against infection. Thomson proves that there is an innocent form of fibromatosis, and thinks it probable that there may even be an innocent form of leather-bottle stomach (Ibid.).

The **symptoms** suggest ulcer, cancer, or some sequel of ulcer. It is often possible to be mistaken as to the nature of the mass even when it is exposed by exploratory incision. The cases of "pyloric cancer" which have recovered after gastro-enterostomy and some of the cures of gastric cancer by gastrectomy are explained when we know how easy it is to mistake innocent fibromatosis for cancer.

Treatment.—Thomson always insists on an immediate microscopical examination of a portion of the tumor or, better, of an enlarged lymph-gland. He advocates resection for local fibromatosis because he believes cancer is liable to arise. In some cases gastro-enterostomy is performed; in some, jejunostomy.

Carcinoma of the Stomach.—Innocent tumors and sarcomata occasionally attack the stomach, but they are infinitely rare in comparison with primary cancer. In only 1 per cent. of cases is cancer secondary (Friedenwald, "Am. Jour. Med. Sciences," 1914, cxlviii). Cancer is a common disease, in fact "30 per cent. of all cancers in civilized man are in the stomach" (Wm. J. Mayo, in "Surgery, Gynecology, and Obstetrics," 1918, xxvi). The reason for this great gastric liability to cancer is unknown. Mayo (Ibid.) thinks it may be caused by hot drinks. This disease is unusual before the age of forty, and is very seldom seen before the age of thirty. The period of greatest liability is between the ages of forty and sixty. I operated upon a man of twenty-three for gastric cancer. It is more common in men than in women, the proportion being as 5 to 4. Beyond question, in some cases cancer arises from the margins of an ulcer. We used to regard such an origin as rare. We now look upon it as common. In the Mayo clinic it is thought that 70 per cent. of cases thus originate. Friedenwald from a study of 1000 cases decided that 7 per cent. exhibit a definite history of ulcer but in only 23 per cent. of the cases could the cancer have arisen from an ulcer ("Am. Jour. Med. Sciences," 1914, cxlviii). In over half the cases there is a history of overeating or overdrinking. The forms of cancer which may arise in the stomach are the spheroidal cell growth (either the hard form known as scirrhus or the soft form known as medullary or encephaloid), the cylindrical cell growth or adenocarcinoma, and colloid (due to the myxomatous degeneration of either a spheroidal cell or a cylindrical cell carcinoma). Scirrhus more than any other form produces constriction of the pylorus and less often than any other produces hemorrhage. It may spread for a considerable distance along the submucous coat, muscular coat, and subserous coat without apparent involvement of the mucous membrane wide of the primary focus of disease. Fibromatosis may develop about it. In some cases scirrhus is limited to the pyloric region, in others it is a limited tumor of some other part of the wall of the stomach. In the condition known as malignant "leather-bottle stomach" a scirrhus has invaded the entire stomach wall, or fibromatosis has developed with the cancer and the wall of the viscus is thick and rigid.

Medullary cancer and adenocarcinoma produce hemorrhage. Both of these forms most often arise in the pyloric region. Medullary cancer may remain limited, but, as a rule, a cauliflower growth arises and eventually fills the stomach and portions of the mass may slough away.

Adenocarcinoma is apt to spread along the mucous membrane instead of "infiltrating the deeper layers," as other forms are prone to do ("Cancer and Tumors of the Stomach," by Samuel Fenwick and W. Soltau Fenwick). Spheroidal celled carcinomata are twice as common as cylindrical celled, and medullary cancer is about as common as scirrhus. Any cancer may be accompanied by fibromatosis.

Cancer may be limited to the body of the stomach (either curvature or either wall), the pyloric end or the cardiac end, but it may involve two of these regions or almost the entire stomach, or, being multiple, may be found in many parts. Sometimes there is a primary cancer on one wall, and another growth, due to contact, on a corresponding point of the opposite wall (*contact cancer*). All forms of carcinoma most frequently begin in the region of the pylorus. In many cases of gastric carcinoma adhesions form between the stomach and the liver, colon, or diaphragm. Even in cancer of the pylorus the duodenum is seldom invaded. Medullary cancer not unusually passes into the esophagus. Gastric cancer is usually fatal in from four months to two years, and most patients die within one year. In 60 per cent. of cases the pylorus is involved. In 80 per cent. of cases the lesser curvature is diseased. In over half of the cases of cancer of the pylorus there is no important lymphatic involvement (McArdle). In investigating any gastric disorder follow the advice of the Mayo brothers

and study the history of the case, the size and situation of the stomach, the existence and situation of pain and tenderness, the presence of a tumor, and whether or not the passage of food is unhampered.

Symptoms.—Examine with care a patient in whom cancer is suspected. In unusual cases (1 per cent. of all cases) it produces no symptoms until it has lasted for some time and has attained a large size (latent cancer). In nearly all cases it does produce symptoms. The disease comes on gradually, usually with indigestion and physical weakness. In over nine-tenths of the cases the patient has persistent dragging pain, which usually is increased by eating and pressure, and attacks of vomiting are frequent. In seven-tenths of the cases there is definite tenderness. After a short time the victim of cancer becomes very weak and exceedingly anemic, and it is often possible to feel a tumor in his stomach. Blood examination shows diminution of red corpuscles and hemoglobin and perhaps absence of any increase of leukocytes after a full meal. There is rapid loss of weight and strength. The general tendency is downward but now and then there may be temporary gain in weight and strength. Cachexia is not deferred long. The vomiting of a patient with gastric cancer is at first occasional only, but as the case progresses it becomes more and more frequent. Vomiting soon after eating occurs when the cardiac region is involved; vomiting an hour or so after eating occurs when the pyloric end is involved. When the body of the organ is the seat of disease, vomiting may be absent. The vomited matter in nine-tenths of cases is mixed with a small amount of altered blood (*coffee-ground vomit*). In one-fourth of the cases there is definite melena and in most cases occult blood is found in the feces, especially if hydrochloric acid be absent from the stomach contents. These symptoms above cited associated with "coffee-ground vomit" and lactic acid in the stomach contents are strongly indicative of cancer (Wm. J. Mayo, in "Surg., Gynec., and Obstet.," May, 1908). A *test-meal* is given, and important conclusions are sometimes derived from the presence or absence of hydrochloric acid and lactic acid. It is my custom to have the stomach washed out and then have Ewald's test-breakfast given. This consists of one roll of white bread (35 gm.), 400 gm. of H_2O, and 400 gm. of tea without milk or sugar. In one hour the stomach is emptied by means of a tube and a pump or a tube and abdominal compression, and the material is examined. If the result of the test seems out of accord with the other symptoms, repeat the process (L. Boas, in "Berlin. klin. Woch.," No. 440, 1905). In most cases free hydrochloric acid is not found in the stomach contents, but lactic acid is found and Oppler's bacillus can often be detected. There may be red blood-corpuscles in the fluid. If the cancer is not ulcerated, free hydrochloric acid will probably be found; if it is ulcerated, it will usually be absent.[1] Free hydrochloric acid may be absent from the stomach because of atrophy of glands, cessation of secretion, or neutralization by the products of the cancerous area. Friedenwald (Ibid.) says that 89 per cent. of cases exhibit anacidity, 3 per cent. normal acidity, 4 per cent. hyperacidity, 3 per cent. subacidity. Lactic acid is present in 81 per cent. of the cases, Oppler's bacillus in 79 per cent., sarcinæ in 32 per cent., coffee-ground matter in 71 per cent. I believe that a cancer arising from an ulcer is apt for a time to be accompanied by hyperacidity, and that the advent of anacidity is delayed. Free hydrochloric acid may be absent in individuals in whom cancer does not exist. I have noted its absence in several cases of cicatricial stenosis of the pylorus.

It may be absent in cancer of the esophagus, advanced Bright's disease, cancer of the duodenum, distant cancer, febrile conditions, and amyloid disease. The constant presence of considerable quantities of hydrochloric acid is strong evidence against the existence of cancer of the stomach. If cancer arises from ulcer, free hydrochloric acid is apt to be present for a considerable time after the cancer has begun.

[1] Reissner, in "München. med. Woch.," Dec. 3, 1901.

Distend the stomach with gas or fluid and map out its outlines. Feel for a tumor. A tumor can usually be felt if it involves the greater curvature or anterior wall, and a large tumor of the pylorus can be palpated, but in other regions the tumor can rarely be felt. In Friedenwald's 1000 cases a tumor was palpable in 72 per cent. but in only 30 per cent. within the first six months after the appearance of symptoms (Ibid.).

Cancer of the cardiac end interferes with the entrance of food into the stomach, and in such a case the stomach is shrunken and the esophagus is dilated immediately above the growth. In cancer of the pylorus the food is partially or completely arrested as it is being urged on to pass the pylorus, and the stomach becomes much dilated. Dilatation occurs in nearly half the cases. The vomited matter in a case of cancer rarely contains recognizable fragments of the growth, but fluid with which the stomach has been irrigated may contain pieces which can be identified as cancer (Rosenbach).

In cancer of the stomach the general course of the temperature is normal, but there are occasional deviations to below or above normal. Febrile seizures occur in nearly half the cases. In many cases the urine contains albumin, indican, acetone, and casts. Occasionally cancer of the stomach produces spasm of the esophagus. I have seen this in several cases. Cancer of the stomach is apt to involve secondarily adjacent lymph-glands, or other structures, especially the liver; in fact, the liver is involved in 30 per cent. of the cases (Welch). Occasionally there is enlargement of the supraclavicular glands of the left side. Metastases are usual and early, but in cancer of the pylorus over half of the cases show no distinct lymphatic involvement. In many doubtful cases exploratory incision is required imperatively. Friedenwald (Ibid.) shows that the average expectation of life is less than one year in 66 per cent. of cases, between one and two years in 22 per cent., and over two years in 11 per cent.

Treatment.—The *medical* treatment consists in milk-diet, the use of morphin, and of *lavage* if the pylorus or body of the stomach be diseased. Perform lavage as follows: The tube for lavage should be long enough to extend about 3 feet out of the mouth when the other end is in the stomach, it should be flexible, should have an opening in the stomach end and another opening on the side about 1 inch above the stomach end. The tube should be greased with glycerin or the end of it chilled in a bowl of cracked ice. The patient sits down, throws the head back, opens the mouth widely, and is directed to take deep breaths, at regular intervals. The tube is carried into the pharynx, the patient is ordered to make efforts to swallow it, and the tube is thus taken into the stomach. About 1 quart of fluid is poured into the funnel-like end of the tube, and just before the tube empties itself of the last of the water the funnel is lowered and the fluid runs out. This proceeding is repeated until the fluid becomes clear. The best fluid to use is a solution of bicarbonate of sodium, a teaspoonful of the salt to a quart of warm water. Lavage should be practised before breakfast, and sometimes also at bed-time.

The *indications for operation* are well set forth by Macdonald[1]: They are progressive aggravation of symptoms in spite of a rigid diet and medical treatment, loss of gastric mobility, progressive diminution of gastric peristalsis, progressive diminution of free hydrochloric acid, emaciation even under forced feeding, progressive reduction of hemoglobin to 65 per cent. or under, and moderate leukocytosis.

Surgical treatment aims to remove the growth or to obviate the effect of obstruction at one of the orifices of the stomach.

In cancer of the body of the stomach, if the growth is not extensive, excision of the growth may be performed; if it is extensive, it is useless to attempt it unless the growth is absolutely non-adherent. Conner, of Cincinnati, attempted total excision of the stomach in 1883, but the patient died on the

[1] John B. Murphy, in "Chicago Med. Recorder," June 15, 1902.

table. In 1897 Schlatter, of Zurich, successfully removed the entire stomach. Brigham, Richardson, Macdonald, Boeckel, De Carvalho, Bardeleben, Haine, Gallet, Dollinger, Ferry, Ribera, and others have successfully removed the entire stomach and attached the esophagus to the small intestine (*complete* or *total gastrectomy*). In the successful cases digestion was satisfactorily performed after removal of the stomach. Very rarely will cases be found suitable for such a radical proceeding. The case suitable for this treatment is one in which the entire stomach is involved in the growth, in which there is no obvious glandular involvement, and in which the stomach is not adherent, but is feely movable. Herbert J. Paterson ("The Hunterian Lectures for 1906") collected 27 cases of total gastrectomy for cancer: 10 died and 17 recovered. If a small portion of the fundus is left the operation is called *subtotal gastrectomy*. H. J. Paterson (Ibid.) collected 20 cases of subtotal gastrectomy for cancer with 6 deaths. In limited cancer of the body of the stomach perform *partial gastrectomy*. In cancer of the cardiac orifice of the stomach the surgeon usually keeps the passage open as long as possible by the frequent passage of a tube, and through this tube introduces liquid food. Sometimes a small tube is introduced and permanently retained. When it becomes difficult to introduce a tube, *gastrostomy*, *duodenostomy*, or *jejunostomy* may be performed. As a matter of fact, in most cases gastrostomy is done as a last resort, and it is scarcely worth doing in cancer of the cardiac end of the stomach. It is far more useful in cancer of the esophagus. Arch, Kümmel, Sauerbruch, Voelcker, and Zaaijer succeeded in removing cancer of the cardia. In cancer of the pylorus, limited in extent and without lymphatic involvement, *pylorectomy* may be performed; but in cancer which has widely infiltrated the coats of the stomach and has involved the lymphatic glands, *gastro-enterostomy* is performed as a palliative measure, the patient during the rest of his life subsisting upon liquid or semiliquid foods and submitting to frequent irrigation of the stomach to remove food residue. In cases of irremovable and far-advanced cancer it is often best to refuse to operate and to create deliberately the opium-habit in the patient, although, in some cases, duodenostomy or jejunostomy may be performed.

The most successful of all the above operations are pylorectomy and partial gastrectomy. The mortality used to be large but has been greatly reduced during recent years. In the Mayo clinic over 38 per cent. pass the three-year limit and may be called cures (page 1222). There are in literature many cases which have survived three years or over. In the Mayo clinic gastro-enterostomy for cancer has a mortality of 8 per cent. It seldom prolongs life more than a few months although in some cases it does prolong it a year or more.

Sarcoma of the Stomach.—Of recent years it has been proved that sarcoma of this region is more common than was once supposed. There are over 60 cases on record. I have had one case, for which I performed jejunostomy. It can occur at any age, but is more usual in early life than carcinoma. It has been estimated by Wm. T. Howard[1] that 37.7 per cent. of cases are under the age of forty, and 11.44 per cent. are under the age of twenty. The pylorus is involved in about one-fourth of the cases. In most cases the posterior wall and greater curvature are involved. Howard says there is a diffuse growth in 21.31 per cent. of cases and that the cardiac end is involved in only 4.9 per cent. of cases. Sarcoma arises in the submucous coat. Any form of sarcoma may arise. It causes stenosis in less than one-tenth of the cases. There is no sex predisposition in sarcoma. The growth may attain a great size.

Symptoms.—A tumor forms, grows rapidly and often attains a large size, and not unusually actually causes a projection of the abdominal wall. If it ulcerate there will be hematemesis, but it often does not ulcerate, and bleeding is much rarer than in carcinoma. Not unusually this growth arises in a person under forty, and sometimes in one of less than twenty years of age.

[1] "Jour. Am. Med. Assoc.," Feb. 8, 1902.

Stenosis is uncommon. The liver is involved secondarily in only 11.47 per cent. of cases (Howard), metastases are more rare than in carcinoma, free hydrochloric acid is usually absent from the gastric contents, and microscopical examination of washings from the stomach may detect fragments of sarcoma. Certain diagnosis is impossible without exploratory incision. Howard estimates the average duration of life to be from nine to ten months.

Treatment.—If the liver is free and if there are no metastases, partial gastrectomy or complete gastrectomy may be advisable. If pyloric stenosis should arise, gastro-enterostomy may be performed. Scudder ("Annals of Surgery," August, 1913) reports a case. He performed jejunostomy. Six weeks later he removed the tumor by partial gastrectomy, closed the jejunal opening, and did anterior gastro-enterostomy. A year later the man remained well.

Ulcer of the Stomach (Peptic Ulcer of the Stomach).[1]—Ulcer of the stomach is a condition due to digestion of a portion of the stomach wall by very acid gastric juice, the destroyed portion having been the seat of lowered vitality. The reason for the lowered vitality of the gastric mucous membrane is uncertain. Thrombosis has been suggested as a cause, but it is rare in gastric ulcer. Embolism is assigned by some as a cause, but emboli are seldom found on pathological examination. It has been asserted that menstrual disorders may be responsible for ulcer, that tight lacing may be, and that habitually bending over (as in making shoes) may be a cause. The Mayos are of the opinion that the grinding action of the pyloric portion of the stomach may be a traumatic exciting cause of ulcer of that region. Some assert that mental anxiety, alcoholism, and syphilis may be causal (Alderson). Thirty-two per cent. of the cases in the Mayo Clinic used alcohol. Ulcers due to syphilis and tuberculosis are not peptic ulcers.

Robson believes that gastric ulcer is septic in origin, and that oral sepsis is responsible for its origin in most cases. "Mild sepsis leads to gastritis and hyperchlorhydria, which in its turn provokes and keeps up ulceration" (A. W. Mayo Robson, in "Keen's Surgery," vol. iii). In 140 cases studied by Smithies in the Mayo clinic ("Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912) 26 had had enteric fever, 6 pneumonia, 5 syphilis, 8 malaria, and 27 some other general infection. Twelve had previously been operated upon for appendicitis and 2 for gall-stones. Some observers blame direct damage to the mucous membrane by traumatism or the swallowing of corrosive liquid. The question of cause is involved in uncertainty. What does seem to be certain is that anemia predisposes to the formation of very acid gastric juice (*hyperchlorhydria*) and to ulceration. In some cases chlorosis is associated with ulcer. According to Wm. J. Mayo there are three known causal factors of the first importance, viz., anemia, hyperchlorhydria, and traumatism (April 16, 1904).

It used to be stated that ulcers are far more common in females than in males. This statement is not correct. It applies to acute ulcers, but not to chronic ulcers. Up to July 1, 1912, the Mayos had operated on 404 proved ulcers of the stomach, and over 70 per cent. of these patients were males (Smithies, in "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912). The acute round ulcer is vastly more common in women, and in young women rather than in those of middle or advanced age. The chronic indurated ulcer is most frequent in men. Men about forty, and women between twenty and thirty are particularly liable. Between thirty and forty is the period of greatest liability. I have only once found ulcer in a person under twenty, but ulcers do occur in children and even in infants. There is usually a single ulcer, but in one-fifth of all cases there are two or more, and when there is

[1] There is an admirable collective Review of Gastric and Duodenal Ulcer, by R. C. Coffey, in the "Internat. Abstract of Surgery," March, 1917.

an ulcer on the anterior wall, it is not uncommon to find one exactly opposite on the posterior wall (*a kissing ulcer* Moynihan calls it). The Mayos divide ulcers into two clinical forms—the *indurated* and the *non-indurated*. In the indurated ulcer all the coats of the stomach are involved, and the mass of scar-tissue indicates an effort at repair. The most common situation for this form of ulcer is the region of the pylorus (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905). The non-indurated ulcer involves the mucous coat only and may be of microscopical size, and even a microscopical ulcer may cause death from hemorrhage. These non-indurated ulcers exhibit no sign, or almost no sign, on the outer surface of the stomach, and may not be detected even when the stomach is opened by the surgeon. The non-indurated ulcers are divided into the *mucous erosions* of Dieulafoy (*exulceratio simplex*), in which the superficial epithelium only is involved, and the true round fissured *peptic ulcers* (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905). Both conditions are rare. Ulcers are also divided into *acute ulcers*, which progress rapidly and produce definite symptoms, and *chronic ulcers*, which are usually chronic from the beginning, but which may exhibit acute exacerbations, and may have periods of great relief or apparent cure (Wm. J. Mayo, in "Med. Record," August 6, 1904). The most common seats of ulcers are the posterior wall and lesser curvature, especially in the pyloric region; in fact, 80 per cent. occur in the pyloric region. An ulcer may heal or may perforate. Only 1 or 2 per cent. of ulcers on the posterior wall perforate, as they tend to form adhesions to adjacent structures. Ulcers on the anterior wall are unusual, do not tend to form adhesions, and are apt to perforate. It is not uncommon to have ulcer of the first portion of the duodenum associated with gastric ulcer. An ulcer may be accompanied or followed by fibromatosis which gives a deceptive likeness of cancer (see page 1089). Gastric ulcer is at least four times as frequent in England as in the United States. In 2830 autopsies made in the Philadelphia Hospital there were 40 gastric ulcers, and in 3763 autopsies made in four Philadelphia institutions there were 51 gastric ulcers—a percentage of 1.35. (See A. P. Francine, in "Proceedings Phila. County Med. Soc.," March 31, 1905.)

Ulcer is a frequent cause of cancer (page 1090).

Symptoms.—In an acute ulcer the symptoms are often typical; there are pain, tenderness on pressure, slight or distinct unilateral muscular rigidity, vomiting, hemorrhage, and hyperchlorhydria. In a chronic ulcer the symptoms may be clear, may be misleading, may be variable, and in some cases even absent (*latent ulcer*). In ulcer dyspepsia usually exists. It is usually but not always acid dyspepsia, and is associated with much flatulence. In most cases, though not in all, food promptly causes pain. There is a gnawing sensation (*hunger-pain*) when the stomach is empty, and there may be actual pain. The taking of food may *temporarily* relieve pain, but as gastric peristalsis arises and perhaps as quantities of gastric juice are poured out to digest the food the pain increases. A small quantity of bland food may relieve pain and a larger quantity or coarser food may cause pain. If hyperchlorhydria disappear (as it may do from chronic gastritis and does from gastric dilatation following pyloric obstruction), pain may not be increased during digestion. In ulcers of the cardiac end and lesser curvature gnawing uneasiness is but briefly or not at all relieved by taking food and pain develops immediately or almost at once after eating. In ulcer of the pyloric region the gnawing uneasiness may be distinctly relieved by taking food, but within an hour or two pain is apt to become severe. The time after eating when pain occurs may not be constant in a case. In ulcer the pain is paroxysmal. It is at times very violent in the epigastric region, and may pass to the back, being located between the eighth and ninth dorsal vertebræ to one side of the back (the right most often), into the esophagus, into the chest, to the left side of the abdomen, or to the top of the ensiform process.

In gastric ulcer it is usual to find distinct or severe tenderness developed by epigastric pressure, and tenderness is associated with more or less rigidity. In ulcer of the lesser curvature pain and tenderness are in the neighborhood of the left costal margin. In ulcer of the pylorus they are above the umbilicus in or to the right of the midline. Vomiting usually relieves the pain, so does lavage, so does the administration of an alkali. In ulcers of the anterior wall tenderness is most acute. In many of these patients vomiting occurs about two hours after eating. The vomited matter, as a rule, contains much hydrochloric acid and the vomiting usually relieves the pain. Examination of the gastric contents after the administration of a test-meal shows in about 80 per cent. of the cases hyperacidity. Obvious hemorrhage from the stomach occurs in less than one-half of the cases, and from 3 to 8 per cent. of cases actually die of hemorrhage. Wm. J. Mayo states that "more than 90 per cent. of hemorrhages from the stomach are from chronic ulcers with a well-marked ulcer history" ("Surg., Gynec., and Obstet.," May, 1908). The blood may be brought up with food, and is then black and clotted, or may be vomited clear and in large amount. Blood may be present in vomited matter or stools in such small amount that its presence is observed by the microscope only. The demonstration in the feces of minute quantities of blood (occult blood) is important diagnostically. It may be demonstrated by the guaiacum test or the aloin test. For two days before this test the patient must not eat rare meat, sausages, or fish. Blood in the stools does not prove the existence of gastric ulcer. The blood may have come from any spot from the mouth to the anus. As Wm. J. Mayo ("Surg. Gynec., and Obstet.," May, 1908) says: "Visible or occult blood in the stool affords proof as to the fact that there is blood, but it should never be lost sight of that it bears with it no evidence as to its exact gastrointestinal origin. The patient may have bleeding gums or hemorrhage from some slight abrasion in any part of the many feet of mucous membrane which exist between the lips and the anus. If occult blood is found by one chemical test, it must be corroborated by others, as some unsuspected food or drug may give rise to the reaction.

"As a matter of fact, hemorrhage from ulcer is by no means of frequent occurrence. The base of the ulcer is clean and free from granulation tissue, so that bleeding may be infrequent. Careful examination of the stools for many days may be necessary to detect its presence."

In hemorrhage from an acute ulcer a pint or two may be ejected in a few minutes, and such a patient presents all the general symptoms of dangerous hemorrhage. When an ulcer bleeds the blood is far more apt to be vomited than passed by the bowels, but in some cases blood from the stomach is passed by the bowels in part or wholly. A very large hemorrhage may occur, and yet the bleeding never be repeated, or a large hemorrhage may be followed by another or be the first of three or of a series. In a great many cases after a large hemorrhage there is no further bleeding or there are subsequently a few small hemorrhages. Small hemorrhages may occur indefinitely, and may after a time eventuate in a large hemorrhage. In chronic ulcer in which small hemorrhages recur over a long period the condition is due to bleeding from congested mucosa, dilated veins, or to the erosion of small vessels which cannot contract or retract because they are embedded in fibrous tissue. A large hemorrhage may be due to the erosion of a large vessel, but is often produced by the existence of a great number of erosions of the mucous membrane, erosions perhaps so numerous that blood seems to pour from every portion of the mucous surface. We speak of such erosions as the *erosions of Dieulaföy* or *exulceratio simplex*. It is usually stated that in a sudden acute violent hemorrhage there will probably be no history of antecedent stomach trouble, but Wm. J. Mayo is of the opinion that "a single hemorrhage from a patient who has not had previous gastric symptoms is probably not due to ulcer" (Ibid.). It may arise from

rupture of veins about the cardia or from blood from hemoptysis having been swallowed.

In a chronic ulcer it is sometimes, though seldom, possible to palpate the indurated area.

Constipation exists in at least 90 per cent. of cases. There is often very marked anemia, aggravated and, some think, occasionally cause by continued loss of blood. Indigestion aggravates anemia and also may cause it. Most cases complain of prolonged indigestion. There is often a tender area in the back a little to the side of the eighth and ninth dorsal spines (usually the right side). A triangular area of hyperesthesia may be found in the left epigastric region (Head).

If the ulcer does not cicatrize, but progresses, causing pain and hemorrhage, the patient usually becomes thinner, more anemic, weaker, and even exhausted. In 140 cases in the Mayo clinic studied by Smithies ("Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912) 107 showed loss of weight. The average loss of weight was 20 pounds. The maximum loss observed was 65 pounds in six months. The average hemoglobin finding was 72 per cent.

It is certain that many cases of gastric ulcer are unrecognized; in fact, as Habershon says, diagnosis is rarely made unless hemorrhage exists, and in certain latent cases both vomiting and bleeding are absent. It is believed by some that latent ulcers are even more common than are ulcers causing symptoms. Hall ("Am. Jour. of Med. Sciences," May, 1909) says: "Rather than look too narrowly for exactly this or that evidence, we should take the broader ground that ulcer probably exists in most patients complaining of persistent indigestion, even though not of an acid character, if pain, tenderness, vomiting and rigidity, or two or three of these phenomena be present, and even though hyperacidity be not proved." A bleeding ulcer with palpable thickening of the pylorus, especially if there be anemia and loss of weight, is frequently mistaken for cancer. *Fibromatosis* of the stomach with or without ulcer is usually diagnosticated as cancer. This condition was fully described by Alexis Thomson at the 1913 meeting of the American Surgical Association. The entire stomach may be indurated. It is cases like the above that may get well after gastroenterostomy and thus furnish the first proof that the condition was not cancerous (see page 1089). The diagnosis of ulcer is far less difficult when there is food retention than when there is not.

The fluoroscope may aid in the diagnosis. Skiagraphs after a bismuth or barium meal give highly important information as to the existence of scars, contraction of the pylorus, dilated stomach, and hour-glass stomach. In many cases it is impossible to make a differential diagnosis between pyloric ulcer and duodenal ulcer. In duodenal ulcer the pain and tenderness are above the umbilicus and in the midline or to the right, and if the duodenal ulcer bleeds the blood is most apt to pass by the bowel, but vomiting of blood is not unusual. A small percentage of duodenal ulcers also involve the pylorus.

A gastric ulcer may cicatrize and thus be cured, but the cure of the ulcer may prove the ruin of the stomach by producing stenosis of one of the stomach orifices or hour-glass contraction of the body of the stomach. An ulcer may perforate. Perforation occurs in about 15 per cent. of cases (Robson). A *perforation* may be *acute;* that is, the ulcer suddenly breaks open when the stomach contains food or liquid, and the contents of the stomach are poured into the free peritoneal cavity. A *subacute* perforation occurs when the stomach is empty or nearly empty. The opening is small in size, there is no escape of stomach contents or the escape of only a small amount, and the opening may be quickly closed by adhesion to an adjacent surface of peritoneum or to a piece of omentum. If a certain amount of stomach contents is extravasated, it is usually surrounded by adhesions or tracks slowly toward the pelvis. In what is known as a *chronic* perforation the break takes place usually in the

posterior wall into a box of preformed adhesions, the extruded gastric contents are circumscribed by these adhesions, the general peritoneal cavity is not invaded, but circumscribed suppuration is inaugurated.[1] This condition is known as *perigastric abscess*, and the subphrenic form is the commonest. In such a case the abscess may break into the pleural cavity or even into the lung. I operated on a girl of sixteen and found a perigastric abscess and a perforation of the anterior wall near the pylorus, and this condition was tuberculous. A fistula persisted for months, but finally healed.

Perforation is generally preceded by a history of indigestion, but it may come on without a suggestion of antecedent stomach trouble, is usually brought about by muscular effort, and is most common after a full meal, but it may occur when the patient is perfectly quiet and has not eaten for some tine. The real cause is spasm of the pylorus which causes tension of the stomach walls and keeps the viscus from emptying. Pyloric spasm is very common in sufferers from ulcers. In acute perforation food is the most active cause; in chronic perforation, muscular effort. "The severity of the symptoms depends upon several conditions: the previous state of health, the size and number of the perforations, the condition of the stomach, whether full or almost empty, the bacterial virulence of its contents, and the occurrence of vomiting."[2] The situation of the ulcer has some influence on the symptoms. "If in the fundus, at the cardiac end, or in the body of the stomach, an acute infection of the whole peritoneal cavity rapidly follows; if the ulcer be at the pylorus or in the first portion of the duodenum, the fluid is directed down the right side of the abdomen, owing to the hillock formed by the transverse mesocolon at the pyloric end of the stomach."[3] In such a case the fluid may gravitate toward the right iliac region and the condition may be mistaken for appendicitis. In a case of subacute perforation I operated, believing that appendicitis existed. Alderson calls attention to the fact that the sudden perforation of an ulcer may be mistaken for poisoning, and he cites the death of Henrietta, Duchess of Orleans, in 1670.

Acute perforation can be certainly diagnosticated if the case is seen early. Such an emergency has usually, but not invariably, been preceded by positive and prolonged symptoms of gastric disorder. It causes sudden and intensely violent epigastric pain, greatly increased by swallowing fluids, by vomiting, by turning the body, by cough, by inspiration, and by pressure. This pain may radiate throughout the abdomen, but the chief tenderness is in the region of the stomach. The seat of the pain after perforation does not, of necessity, correspond to the seat of perforation. Vomiting occurs in about half the cases after rupture. When it does occur it comes on soon after the pain, may recur again and again, and does much harm by increasing shock and by ejecting gastric contents into the peritoneal cavity. Vomiting of blood is very unusual. In many cases there is, singularly, little shock. Even when severe shock exists its duration is usually temporary. This important fact is insisted on by Eliot ("Annals of Surgery" May, 1912). Board-like rigidity exists, and it is most marked in the upper portion of the abdomen. The area of liver dulness is in some cases diminished and in exceptional cases obliterated. This symptom is due to gas passing into the peritoneal cavity and getting between the liver and the parietal peritoneum. It is seldom present after pyloric perforation or when the stomach at the time of the perforation contained very little food. It is when perforation is far from the pylorus and when the stomach contains fermenting food that enough gas escapes to diminish liver dulness (Eliot, Ibid.). The sign is most significant when the abdomen is flat. There may be dulness in one flank or both flanks due to fluid. Eliot (Ibid.) lauds

[1] See paper by B. G. A. Moynihan, "Brit. Med. Jour.," Jan. 31, 1903.

auscultation as an aid to detecting small amounts of fluid, and calls attention to *Shoemaker's symptom*, that is, a dull note on light percussion giving way to a tympanitic note when the percussed finger is pressed firmly against the abdominal wall, thus coming nearer to the intestine by pushing fluid away. The pulse may be very rapid, but often shows curiously little disturbance. Some few cases die rapidly in shock, but, as a rule, reaction occurs and, if operation be delayed, peritonitis arises. Acute perforation of the stomach may be in certain cases mistaken for appendicitis, cholecystitis, or hemorrhagic pancreatitis. If a patient with acute perforation be not promptly operated upon, he will soon exhibit the symptoms of general peritonitis. Subacute perforation causes less violent symptoms and they come on more gradually. There is in the beginning severe but not agonizing pain, which gradually abates. Moynihan points out that there is gastric uneasiness for several days before the perforation. Peritonitis develops slowly and the chief symptoms are often pelvic. *Chronic perforation* gives the signs and symptoms of perigastric abscess.

Treatment.—*Medical Treatment of Non-perforated Ulcer.*—Rest in bed. It is necessary to abandon stomach feeding for a time. For seven to ten days give nothing whatever by the mouth and give an enema of 10 oz. of normal salt solution every sixth hour. This is preferable to a nutritive enema because every time a nutritive enema is given a flow of gastric juice takes place into the stomach. (See W. Pasteur, in "Lancet," May 21, 1904; Seymour J. Sharkey, in "Lancet," Nov. 10, 1906.) During this treatment the patient is usually comfortable and is not unbearably disturbed by hunger and thirst. At the end of a week or ten days pancreatinized or peptonized milk is cautiously given by the mouth. According to some, nutritive enemata should now be substituted for saline enemata and be given for a few days before stomach feeding is instituted. After rectal enemata (saline and nutritive) have been abandoned the patient is placed on a very bland diet, preferably pancreatinized milk, and lavage is given twice a day. The value of introducing food into the rectum is, to say the least, doubtful. Saline fluid and certain drugs are absorbed from the rectum, but little if any protein matter is absorbed. Investigators are now seeking for some form of digested protein matter that will be absorbed. Protein material when in the rectum is not acted upon by the enzymes necessary for its absorption, it undergoes putrefaction, causes irritation, and sets free toxic alkaloids which are absorbed. It is suggested that digested albumin and fat and grape-sugar may be absorbed. In some cases of ulcer Carlsbad salts are given by the mouth (Ziemssen); in others, silver nitrate with extract of belladonna, bismuth subnitrate, or oxalate of cerium. If pain is severe, opium may be required. Many cases are apparently cured by medical treatment. Russel's statistics show that 40 per cent. of cases were reported cured under medical treatment, but no one knows how many of those reported cured again gave evidence of the disease or later perished because of hemorrhage or perforation. Further, 18 per cent. of the 500 London Hospital cases under medical treatment died and 42 per cent. were not cured when discharged. Out of the supposed 40 per cent. of cures many later undoubtedly developed or will develop renewed symptoms and perhaps fatal conditions.

Medical Treatment for Gastrorrhagia (*Hemorrhage from the Stomach*).—Some claim that surgical treatment is not to be employed in gastric hemorrhage and that statistics are decidedly against it. I believe this statement to be correct. Kraft's table, which was published in 1910, gives 83 cases operated upon with 30 deaths, a mortality of 37 per cent. (Lindenberg, see "Lancet," Dec. 5, 1914). Lindenberg (Ibid.) looked up the records of 68 cases of acute hemorrhage treated medically in the clinic of Faber of Copenhagen. There were five deaths (a mortality of 7.3 per cent.) and he does not believe operation could have saved one of the five. Some treat stomach bleeding by morphia, and adrenalin by the mouth. Serum may be useful. Transfusion of blood may save life.

I believe Lindenberg's plan to be valuable ("Lancet," Ibid.). I have employed it with apparent success. It is as follows: Raise the foot of the bed. Give no salt solution intravenously and give no stimulants, because each would raise blood pressure and retard clotting. Give no morphia. It arrests the spasm of the gastric muscle which helps to stop the bleeding. No food is to be given by stomach for several days. Put into the stomach daily with a small tube 100 c.c. of a 1 per cent. solution of ferric chlorid; let the patient lie first supine and then prone and remove the fluid by aspiration (Bourget's plan).

Once a day give subcutaneously 40 c.c. of a 10 per cent. solution of gelatin the fluid being at a temperature of 40° C.

Surgical.—The exact curative value of operation is not settled. Kronlein's clinic claims 85 per cent. cures, Von Eiselsberg's clinic but 52 per cent. of cures and 15 per cent. of improvements. The nearer the ulcer is to the pylorus, the better the chance of cure. Following the Mayos, we would not advise surgical treatment in acute ulcer unless complicated by hemorrhage, perforation, or obstruction; or in chronic ulcer, until careful medical treatment has failed. Operation is indicated for chronic ulcer when a mechanical cause is responsible for retention and stagnation of stomach contents, and in certain cases of hemorrhage. Operation is also indicated in chronic ulcer with frequent exacerbations, but the surgeon should be very chary of operating upon neurotic women with gastroptosis unless, of course, there be a positive indication (Wm. J. Mayo, in "Jour. Am. Med. Assoc.," Oct. 21, 1905).

In a chronic ulcer if the patient grows worse in spite of careful dietetic and medical treatment, if hemorrhage has been profuse or if there have been frequent distinct hemorrhages, if the pain is violent, or if tenderness is marked, open the abdomen and inspect the stomach. An ulcer with indurated edges is easily found. The form, called by the Mayos the non-indurated ulcer, gives no evidence or little evidence of its existence when the outer coat of the stomach is felt and inspected (Wm. J. Mayo, Ibid.). Even when the stomach is opened, no ulcer may be found. According to Mikulicz, in some mucous ulcers there is a very little thickening, and, according to Moynihan, the mucous coat may be a little adherent to the muscular coat, so that it does not slide easily. An enlarged gland in a portion of the omentum may be a sign of ulcer (Lund). An indurated ulcer may be removed by an elliptical incision in the long axis of the stomach, the coats being sutured by the usual method, and gastro-enterostomy being also performed. Balfour uses the cautery to effect excision. It leaves a smaller opening than the knife and the wound heals well. In ulcer of the pylorus with great thickening we may excise the pylorus, close both the duodenal and stomach openings, and perform posterior gastro-enterostomy. In some cases gastro-enterostomy alone leads to the cure of chronic ulcer. The Heineke-Mikulicz operation is not satisfactory in ulcer. Finney's gastroduodenostomy is not advisable if there be an unhealed ulcer, because food will continue to pass over the ulcer after the performance of this operation.

Wm. J. Mayo ("Annals of Surgery," 1910) has described a transgastric method for excising ulcers of the posterior wall which are adherent to the pancreas. The excision passes through pancreatic tissue. Bleeding is arrested by suture-ligatures. The wound in the pancreas is not sutured, but is closed by a mobilized portion of gastrohepatic or of gastrocolic omentum.

A strong argument in favor of excision of ulcers instead of gastro-enterostomy alone is the frequency with which ulcer gives origin to cancer. Instead of excising an ulcer it may be destroyed, as Balfour suggested, by the actual cautery ("Surgery, Gynecology, and Obstetrics," 1914, xix). This plan is especially valuable on the lesser curvature and the posterior wall.

Operation for Gastrorrhagia.—Rydygier proposed in 1882 to operate for hemorrhage. The first operation was done by Mikulicz in 1887, and the first successful operation was reported by Roux in 1893. It may be wise to transfuse blood before operating.

In acute and violent hemorrhage threatening life the proper course to pursue is somewhat uncertain. It is not proper to operate if there has been but one hemorrhage, because the chances are that the bleeding will not be repeated. Again, the chance of arresting such a hemorrhage by operation is, on the whole, poor. The danger of waiting after one hemorrhage is not so great as the danger of immediately operating, because collapse antagonizes renewed hemorrhage, but adds enormously to the risk of an operation. In over 90 per cent. of cases the hemorrhage ceases spontaneously. In over 18 per cent. of those dying of hemorrhage death is so rapid that operation is impossible (Savariaud). If the bleeding is from a distinct ulcer, we may succeed in excising the ulcer or in ligating the bleeding-point. Roux, of Lausanne, saved a patient by excising an ulcer and ligating the bleeding coronary artery on each side of it. As a rule, however, the bleeding is not from a distinct point, but from a multitude of excoriations. In the light of our present knowledge we may lay down the following rule: Do not operate for one acute hemorrhage. Simply bring about reaction by gentle means, let the patient take bits of ice, and give suprarenal extract by the stomach. If the bleeding recurs once or twice in comparatively trivial amounts, do not operate; but if it recurs violently, we should advise operation. I have been shaken in my faith that we must operate after a second severe hemorrhage by two of my cases. In one case a man had two tremendous hemorrhages. He was transfused, was treated by Lindenberg's plan (page 1100) and recovered.

I was associated with my colleague, Professor Hare, in the case of a young woman. She had two immense hemorrhages, refused operation and recovered. In cases of ulcer in which bleeding in small amounts persists, operation is indicated. In operating for a severe hemorrhage the surgeon opens the abdomen while hot salt solution is being thrown into a vein. The stomach is opened, the clots washed out, and a search made for the source of the blood. If it be found that the blood comes from an area of ulceration, this area may be extirpated, ligated, or cauterized with the thermocautery. Some advise surrounding it with a purse-string suture. Others, notably Moynihan, simply perform gastro-enterostomy, which is of service by draining and giving rest to the dilated stomach, the hemorrhage being perhaps arrested by contraction of the gastric walls and the rest secured preventing the detachment of hemostatic clot. Gastro-enterostomy is of most service in ulcer near the pylorus and in duodenal ulcer. If the ulcer is well above the pylorus it should be excised if possible. As a rule, it will be found that the vessels entering the ulcer are varicose. Excision is indicated because of this varicosity. If excision is impossible "the main blood-vessels leading into the ulcer should be ligated and the peritoneum and muscular coats drawn over it" (Wm. J. Mayo, in "Surg. Gynec., and Obstet.," May, 1908). If it be found that the bleeding comes from a multitude of excoriations and that the stomach is, as Moynihan expresses it, "weeping blood," we can do nothing but gastro-enterostomy, which in such a condition is of uncertain value.

Operation for Perforation.—In acute and subacute perforation operate at once, having all proper means taken to bring about reaction from shock, while the abdomen is being sterilized and while ether is being administered (hot saline enemata, external heat, atropin hypodermatically, etc.). As a matter of fact, shock is seldom so profound as to cause us to hesitate about operating. I formerly advised to wait until reaction was established before operating. I now believe such advice erroneous. To delay after an acute perforation is to wait for what may never come. Open the abdomen at the point of greatest tenderness, or, if there be no such point, open it in the epigastric region, a little to the right of the midline. When the abdomen is opened there may be an escape of odorless gas, and food or fluid may be discovered in the peritoneal cavity. The perforation is sought for and is usually found in the

anterior wall. When found, it should be buried and overlaid by stomach wall, a portion of which must be inverted by two layers of Halsted sutures. I do not believe that excision or paring the edges is necessary or desirable in a case of perforated ulcer. If it be too large to close, stitch a plug of omentum into the opening or insert a tube and create a temporary gastrostomy. If no perforation is found on the anterior wall, make an opening into the lesser peritoneal cavity through the gastrohepatic omentum, the transverse mesocolon or the gastrocolic omentum, explore the posterior wall, and close and cover any perforation found. In order to reach the posterior wall of the stomach Lardennois and Okinczyc suggested the epiplo-enterocolic method (see B. Sherwood Dunn, in "Am. Jour. of Surgery," Oct., 1916). The great omentum and its mesentery are separated from the colon. When this is done the duodenum, pancreas and posterior wall of the stomach can be quickly exposed. In addition to closing the perforation, gastroenterostomy is indicated theoretically in order to drain the viscus, give it rest, and lessen the tendency to recurrence of ulceration. But, as a matter of fact, such ulcers seldom return. By the time the perforation has been closed the patient is perhaps too severely shocked to render such an additional operation justifiable, and I agree with Gibbon that such an operation should be performed only when there are multiple ulcers or when there is pyloric constriction (John H. Gibbon, in paper before the Tri-State Med. Assoc. of Virginia and the Carolinas, Feb. 23, 24, 1904). If Balfour excises an ulcer he prefers to do so with the cautery. After closing the perforation the abdominal cavity is irrigated with hot salt solution, and the space between the liver and diaphragm is sponged out with a gauze pad wet with hot salt solution. If the case is operated on many hours after the perforation, or if the peritoneum has been badly soiled, drainage *must* be used, but even in other cases it is safest to use it. Drainage is obtained by means of a cigarette drain or a piece of gauze passed to the suture line in the stomach. In cases with much extravasation, especially if the extravasation has reached the pelvis, a suprapubic opening is made and a tube inserted. After the patient has reacted from the shock of the operation he should be placed in a semi-erect position to direct the flow of infective material to the pelvis, and continuous proctoclysis should be employed as in peritonitis (see page 1162). The treatment of chronic perforation is the treatment of perigastric abscess, and consists of incision and drainage. Of late, a number of cases of acute and subacute perforation have been successfully operated upon. Moynihan estimates that 35–40 per cent. of acute perforations recover after operation. T. Crisp English ("Lancet," Nov. 28, 1903) reported 42 consecutive gastric perforations operated on in St. George's Hospital; 22 recovered.

Cicatricial stenosis of the orifices of the stomach results from the healing of an ulcer, the swallowing of a corrosive substance, or traumatism from a foreign body. Constriction of the *cardiac orifice* is indicated by gradually increasing difficulty in swallowing. After a time the esophagus above the stricture dilates or pouches; the fluid food passes into the stomach, but the solid food lodges in the esophageal pouch and is soon regurgitated. The site of the stricture is located by a bougie, and by having the patient swallow while auscultating over the esophagus and cardiac end of the stomach. If the constriction be malignant, the patient will be found to be beyond middle life, the vomit is occasionally bloody, emaciation is rapid and decided, and occasionally the supraclavicular glands are enlarged. A tumor of the cardiac end of the stomach can seldom be palpated. If the constriction be cicatricial, the history will indicate the cause. Constriction of the *pyloric orifice* causes retention of food and dilatation of the stomach. Dyspeptic symptoms will be found to have been long present. A tube passed into the stomach permits of the injection of fluid so as to fill the stomach. When the fluid runs out it contains portions of undigested food, which was perhaps eaten days before, and measurement of the liquid shows that the capacity of the stomach is enormously in-

creased. If hydrogen be forced through the tube, the outline of the distended stomach is at once made clear. The usual method of distending the stomach is by a Seidlitz powder: two solutions are made; the bicarbonate solution is swallowed at once, and the tartaric solution is taken afterward in small amounts at a time. Percussion over the distended stomach indicates the size of the viscus. It is well to remember that when gastric ulcer exists dilatation of the stomach can occur without cicatricial stenosis. The cause in such a case is pyloric spasm, or perhaps the atonic condition which may result from anemia and neurasthenia.

In malignant disease of the pylorus a tumor may often be palpated; there are tenderness and considerable persistent pain, great cachexia and emaciation, absence of free hydrochloric acid from the gastric juice, diminution of red corpuscles and hemoglobin, and perhaps no increase of white corpuscles after a full meal. There is sometimes enlargement of the supraclavicular glands. Vomiting of bloody fluid occurs in 40 per cent. of the malignant cases. The use of the *x*-rays after a bismuth or barium meal is a valuable aid in diagnosticating pyloric constriction. The diagnosis of cardiac constriction is discussed in the section on Stricture of the Esophagus. In cicatricial stenosis of the pylorus there may be paroxysms of pain, there is no tenderness, emaciation is not so early in onset or so rapid in progress, and the supraclavicular glands are never enlarged. Vomiting occurs, but the ejected matter is not bloody.

Treatment.—Cicatricial cardiac stenosis requires dilatation with bougies and the maintenance of the restored caliber. If dilatation from above is unsatisfactory, perform gastrotomy, push a small bougie from the mouth into the stomach, tie a string to the bougie, draw the string through the stricture, use the string as a saw to cut the fibrous bands, pass a full-sized bougie, close the wound in the stomach, and maintain the caliber of the cardiac orifice by the repeated passage of dilating instruments. If no instrument can be passed through the stricture from above, perform a gastrotomy, introduce an instrument from below and pass it into the mouth, tie a string to it, draw the string into the stomach, and use Abbe's string-saw (see page 1066). If no instrument can be passed from below, convert the gastrotomy into a gastrostomy. In malignant stenosis of the cardia, gastrostomy, if performed at all, should be performed early. Jejunostomy is a better operation. Cicatricial pyloric stenosis was formerly treated by gastrotomy and digital divulsion of the stricture (*Loreta's opertion*); but this operation is obsolete, experience having shown that recontraction is inevitable. Pyloroplasty was until recently advocated by many surgeons. This is known as the Heineke-Mikulicz operation. In 30 per cent. of the cases the symptoms are not relieved by pyloroplasty, a condition which renders gastro-enterostomy necessary. Mayo points out that in such cases pyloroplasty fails because the pylorus is on a higher level than the gastric pouch, the degenerated muscle of the stomach is unable to lift the food from the pouch to the pylorus, and the symptoms of gastric dilatation and retardation of the passage of food into the duodenum are not relieved. The operation has been generally abandoned. Finney's method of gastroduodenostomy (Figs. 731–734) is a great improvement on pyloroplasty. The opening is large and in a proper position to afford satisfactory drainage. Gastro-enterostomy is the most satisfactory operation in most cases and usually effects a cure. Malignant stenosis is treated by pylorectomy or gastro-enterostomy. (See under these heads respectively.)

Congenital or Infantile Hypertrophic Stenosis of the Pylorus or Pyloric Stenosis of Infancy (Warbasse, "Surgical Treatment").—Osler tells us that the first case was published by an American, Hezekiah Beardsley, in 1778. Hirschsprung, of Denmark, in 1887 published the first modern case (Bunts, "Am. Jour. Med. Sciences," Jan., 1912). Stenosis in adults is almost invariably due to cancer or to ulcer, but in very young children one occasionally meets with a form that is congenital. The victims of hypertrophic stenosis not unusually have club-foot or imperforate anus.

The condition exists at birth and about ten days later the region becomes edematous because of increased activity of the stomach (W. A. Downes, in "Surgery, Gynecology, and Obstetrics," 1916, xxii). The history of such a case is that during the first two or three days after birth the child seems in every way normal, but that after several or a number of days or perhaps weeks projectile vomiting suddenly begins—vomiting for which no dietary cause seems responsible, and which persists irrespective of medication. After the stomach has been emptied by vomiting the child seems much relieved, but when, after a time, food is administered, vomiting will begin again, either in a very short time or after an hour or so. It has been noted that the vomited matter in congenital stenosis of the pylorus never contains any bile whatever, for obvious reasons—the pylorus is shut and the bile cannot enter the stomach. A child in this condition receives little or no nourishment, becomes quickly emaciated, and soon dies. Some of these children die in a month; others, in several months, and a few may live for five or six months. It may be possible, in these cases, to palpate a thickened pylorus, and the outlines of the dilated stomach may be made out. Regurgitant vomiting by keeping the stomach empty may prevent dilatation. The most common symptom is gastric peristalsis. In Bunts's table gastric peristalsis was present in 84 per cent., and a palpable tumor in 69 per cent. of cases. In true congenital stenosis there is hypertrophy. The circular muscular fiber undergoes great increase from hypertrophy, perhaps with some fibrosis. The mucous membrane is hypertrophied and thrown into folds. The opening into the duodenum may be no larger in diameter than a pin and may be totally blocked by folds of mucous membrane. Even when there is comparatively little or no hypertrophy the lumen of the pylorus may be closed by spasm. It is these latter cases which are benefited by medical treatment. Such cases are not to be regarded as instances of congenital hypertrophy and should be classified as pyloric spasm. In congenital hypertrophic stenosis the intestines are very much collapsed, and the child is, of course, much constipated. Cases of pyloric closure have recovered after lavage carried out daily for some weeks and careful breast feeding. Such cases are probably instances of spasm. This plan is only permissible if there be no palpable thickening at the pylorus. A trial should be given this method unless the condition of the patient demands immediate relief. If there be palpable thickening of the pylorus, operation is called for imperatively. The delay in employing surgery in hopes of lavage succeeding must never be so long as to cause emaciation in the patient. If the condition does not soon show signs of improvement operation is indicated. Cases reported cured by medical means may have been instances of pyloric spasm. The operation for this condition is usually posterior gastro-enterostomy. The mortality after the operation has been set at over 50 per cent. though in Downes's 31 cases of gastro-enterostomy it was 35 per cent. (Ibid.) and in Scudder's recent cases it was 13.8 per cent. ("Annals of Surgery," 1914, lix). It is superior to pyloroplasty because it enables us to feed the exhausted child at once. In 19 posterior gastro-enterostomies Richter had two deaths, a mortality of 10.5 per cent. ("Jour. Am. Med. Assoc.," 1914, lxii). Downes (Ibid.) prefers partial pyloroplasty in cases where great haste is necessary. He cuts to but not through the mucous membrane. He operated on 35 cases with 8 deaths, a mortality of 23 per cent. Gastro-enterostomy saves the child from starvation and restores the function of the intestinal canal, but the pyloric tumor remains permanently (Scudder, in "Surg., Gynec., and Obstet.," Sept., 1910).

Perigastric Adhesions.—That perigastric adhesions are frequently responsible for stomach pain and digestive difficulty is undoubted. Such adhesions often arise in cases of protracted ulceration of the stomach or duodenum. A common cause of perigastric adhesions is gall-stone disease. Tuberculous peritonitis causes dense adhesions. In some cases adhesions are traumatic, in some are due to syphilis, in many the cause is uncertain (Fred. D.

Bird, "Intercolonial Med. Jour. of Australia," Dec. 20, 1900). Adhesions may cause blocking or kinking of the pylorus, or may glue the stomach to the parietal peritoneum or to some adjacent viscus. In Fenwick's table of 123 cases he finds that the adhesions usually cause the stomach to adhere to the pancreas or to the liver. The formation of adhesions in cases of gastric ulcer is, in many instances, conservative, serving to prevent perforation or to limit extravasation if perforation of the stomach wall occurs.

The **symptoms** are variable. In some cases the adhesions produce little or no trouble; but in the majority of cases they cause definite symptoms, and sometimes the condition becomes one of absolute disablement. The symptoms may be due to blocking of the pylorus, a condition that is followed by gastric dilatation. They may be due to dragging upon the adhesions when the stomach contracts during digestion, or when peristalsis occurs in an adherent piece of intestine.

The usual symptom is pain, frequently of a violent character. The pain comes on in paroxysms, and recurs over and over again, it may be during years. H. Hale White[1] points out that in these cases there is usually some pain persisting, which is now and then increased into violent paroxysms; and that the only other condition that produces persistent pain with violent exacerbations is cancer. In *adhesion-dyspepsia*, however, there is no distinct loss of weight; the condition may exist in youth, as well as in middle age or old age; it is not always increased by taking food, and it very rarely causes death. If there be a history of antecedent gall-stone disease or of ulcer of the stomach, it is possible to make the diagnosis without exploratory operation. Even in other cases the condition may sometimes be diagnosticated, because, although there are these attacks of violent pain, there is no tenderness. In rare cases the matting together of inflammatory exudate produces a palpable mass. In doubtful cases of chronic and disabling stomach disease an exploratory operation should be performed; if adhesions exist, they will then become manifest.

Treatment.—In some cases simply dividing an adhesion effects a cure; in other cases it is necessary to make extensive separation of adherent structures, covering the raw surfaces with omental grafts. In serious adhesions about the pylorus gastro-enterostomy is usually the proper operation.

Bilocular Stomach (Hour-glass Stomach).—It is usually stated that some cases are congenital, but the writings of Mayo Robson, Moynihan, and H. L. Paterson cause us to doubt if the condition is ever congenital. Even in the so-called congenital cases ulcers are found, or ulcer scars exist, or ulcer adhesions are demonstrable. The advocates of a congenital origin say that the ulcers are secondary to the narrowing, and that ulceration tends to occur, particularly at the seat of constriction. Beyond doubt, a very great majority, at least, of cases of bilocular stomach result from adhesions produced by the healing of ulcers. In hour-glass stomach with a large opening between the two sacs there may be no symptoms. When the opening is small the symptoms resemble those of pyloric stenosis. The sac toward the cardia is frequently much dilated.

Symptoms.—The diagnosis of cancer is often made. The protracted gastritis may have caused free hydrochloric acid to disappear and acids of fermentation are usually found. The patient vomits from time to time, bringing up food which was eaten a day or two before, proof that food has been retained in the stomach and not digested. Occasionally, perhaps, blood is vomited. There is pain and the patient is harassed by foul-smelling eructations. Emaciation becomes pronounced. Cumstom[2] points out that in a thin belly distention of the stomach may make the condition evident; further, that if water is thrown into the stomach, only a part returns, and when the stomach is emptied as

[1] "Lancet," Nov. 30, 1901.
[2] "Med. News," Dec., 1901.

much as possible by a tube, a splashing sound can still be elicited in the stomach because the pyloric pouch is not empty. One cause of death is torsion on the axis. A skiagraph taken after a bismuth or barium meal gives diagnostic information of the first importance.

Treatment.—The diagnosis becomes certain after exploratory operation, and exploration also enables the surgeon to decide with certainty what operation should be performed. Cumstom[1] gives us the following suggestions:

1. In rare cases resect the stricture and suture the pouches.
2. If there is trivial ulceration or a slight scar, do gastroplasty, an operation upon the constriction exactly similar to pyloroplasty.
3. The best operation in most cases is gastrogastrostomy—that is, anastomosis of the cardiac pouch to the pyloric pouch; but this cannot be done if the pyloric pouch is small. Then do gastro-enterostomy.

Other operations are:

4. Gastroduodenostomy.
5. Gastrojejunostomy.
6. Gastrolysis.

In malignant disease resection (partial gastrectomy) is indicated. After gastroplasty recontraction is common, and I do not believe in the operation. Gastro-enterostomy is unsatisfactory. The ordinary operation drains but one pouch. Weir and Foote advised a double gastro-enterostomy, tapping each sac. In most cases gastrogastrostomy followed by gastro-enterostomy is the best procedure.

Chronic Dilatation of the Stomach.—A dilated stomach, roughly speaking, is one which can contain more than 1.5 quarts (Ewald). Some few cases of dilatation result directly from atrophy of the muscular coat brought about by drinking quantities of liquid, especially beer; chronic catarrh of the stomach; and conditions such as cancer, tuberculosis, diabetes, etc. The common cause of dilatation is constriction of the pylorus. In order to force food through the pyloric narrowing more force is necessary than is required normally, hence the stomach muscle hypertrophies. This muscular hypertrophy is compensatory, and dilatation does not occur so long as the muscle is efficient. But finally the pyloric opening becomes so narrow that compensation fails, the stomach contents accumulate, and the stomach dilates.

Symptoms of Dilated Stomach.—There is annoying hunger unless cancer exists. Thirst is complained of. At intervals of a day or two the patient vomits enormous quantities, and portions of food may be identified which were eaten one or more days before. The vomited matter is sour and foul smelling, contains numbers of yeasts, and much fermentative acid. Free hydrochloric acid is often absent. In some cases vomiting occurs two or three hours after each meal. The patient suffers from foul gaseous eructations. There are progressive emaciation, constipation, scantiness of urine; sometimes cramp in the legs, belly, and arms; tetany may occur (see Parathyroid Tetany, page 1386); insomnia is the rule; cardiac palpitation occurs, and there is dyspnea, particularly at night.

Physical Signs of Dilated Stomach.—The epigastric region is hollow and the left side of the abdomen is more prominent than the right. The outline of the greater curvature of the stomach can be distinguished. If the stomach contains air, percussion gives a tympanitic note; if it contains fluid, a dull note. When it is partly full of fluid, by altering the position of the patient we can show by percussion that the fluid changes its position. In a doubtful case give a light meal in the evening, and in the morning, before the patient has eaten, introduce a tube and remove any material contained in the stomach. The presence of undigested food points to dilatation.

[1] "Med. News," Dec. 7, 1902.

To Test the Motor Power of the Stomach. *Klemperer's Test.*—Wash out the stomach. Introduce 100 c.c. of olive oil by means of the tube. After two hours withdraw the oil. The stomach cannot absorb oil, and if the amount withdrawn is subtracted from the amount introduced the difference is the amount which passed the pylorus. If the condition is normal, not more than from 20 to 40 c.c. should be found in the stomach after two hours.

The Salol Test of Ewald.—Salol is not decomposed in the stomach, but in the intestine is broken up into phenol and salicylic acid. Salicylic acid is absorbed and salicyluric acid soon appears in the urine. If salol cannot reach the intestine, salicyluric acid will not appear in the urine. If salol reaches the intestine more slowly than normal, salicyluric acid will appear after a longer interval than when there is no pyloric block to retard the emptying of the stomach. In a normal person salicyluric acid is found in the urine in from three-fourths of an hour to an hour after swallowing a dose of salol. In stenosis of the pylorus it appears much later. The test is made as follows: The bladder is emptied and the patient is given three capsules, each containing 5 gr. of salol. The patient is directed to pass water every half-hour until he has done so four times. Each sample voided is examined for salicyluric acid by adding neutral chlorid of iron. If salicyluric acid is present, a violet color is noted.

To Test the Absorptive Power of the Stomach.—The absorptive power of the stomach can be tested by giving the patient a capsule containing 1½ gr. of iodid of potassium. Normally the drug should be found in the saliva in from ten to fifteen minutes. When absorption is deficient, it may not appear for an hour or longer. In order to test for it, moisten starch paper with the saliva and touch the moist paper with a drop of fuming nitric acid. If iodin is present, a blue color develops.

While the diagnosis of dilatation of the stomach can be certainly made, the determination of the cause may require an exploratory operation.

Treatment.—Cases not due to pyloric obstruction are much improved by lavage, regulated diet, use of an abdominal belt, electricity, aperients, and other agents called for by symptoms.

In all cases in which there is pyloric obstruction, in many doubtful cases, and in cases in which medical treatment fails, exploratory operation is indicated. In dilatation without pyloric obstruction some surgeons advocate gastroplication. If pyloric obstruction exists, the surgeon may elect to do pylorectomy, pyloroplasty or gastro-enterostomy, the method selected depending on the condition discovered. If gastroptosis exists, gastropexy or Beyea's operation may be performed.

Acute Dilatation of the Stomach.[1]—This condition may arise suddenly in the course of chronic dilatation or when no previous dilatation existed. Its clinical features were described by Brinton in 1859. Hilton Fagge in 1873 furnished us with the first comprehensive description of the signs and symptoms. It can occur in association with intestinal paralysis and if it does do so it constitutes but part of the picture of postoperative paralytic intestinal obstruction. We are considering only acute dilatation of the stomach. The cause is uncertain, and is a subject of active investigation at the present time. It is said to be due to degeneration of the gastric muscle in the course of specific fevers, to paresis arising in the course of chronic gastritis, or to the drinking of a quantity of effervescing liquid. It is occasionally a fatal sequence of abdominal operations, particularly operations upon the gall-bladder and bile-ducts. The surgeon sees it in the course of sepsis and during shock from operations in which a general anesthetic was used, and occasionally in cases of spinal curvature.

One set of observers maintains that the condition is brought about by actual

[1] See Kelling, in "Archiv. f. klin. Chir.," 1901, lxiv; Albrecht, in "Virchow's Archiv.," 1899, clvi; Conner, in "Am. Jour. Med. Sciences," March, 1907.

constriction of the duodenum, the duodenum dropping because of relaxation of its supporting structures, the constricting cause being the root of the mesentery and the superior mesenteric artery and the duodenum being squeezed against the vertebral column (Rokitansky, Albrecht, Robinson, and Kundrat). Codman believes that normally in man there is more or less tendency to such constriction on standing erect or lying supine, and that a trivial increase of the constriction, which may be brought about by various causes, may completely obstruct the duodenum ("Boston Med. and Surg. Jour.," 1908). Lewis A. Conner collected 18 fatal cases shown apparently by necropsy to be due to mesenteric obstruction ("Am. Jour. Med. Sciences," March, 1907).

Another set of observers asserts that acute dilatation is due to lesion of the nerve-trunks or nerve-centers, resulting in paresis of the muscle of the stomach wall and perhaps in spasm of the pylorus, putting the stomach in such a condition that it cannot empty itself. The cause of the nerve lesion is variously held to be hyperacidity of gastric secretion, the absorption of the toxins of fermentation, the secretion of chloroform into the stomach, the overdistention of the viscus with ether vapor, or an enormously great secretion of fluid into the stomach. Those who hold this view claim that the abdominal organs are not supported by ligaments (if they were, the supposed supporting structures would contain ligamentous fibers), but are supported by the organs beneath them and these by the floor of the pelvis, and that all are sustained by intra-abdominal pressure. Furthermore, they are of the opinion, that traction on the mesentery sufficient to cause duodenal occlusion would lead inevitably to thrombosis and gangrene, and that the dilatation of the stomach and upper portion of the duodenum when contrasted with the collapse of the lower part of the duodenum leads to the mistaken view that a constriction exists between the two portions.

Conner (Ibid.) says that the theory of pyloric spasm being causative is untenable because in most cases vomited matter contains bile, and in two-thirds of the cases the duodenum is involved in dilatation. The constriction is regarded as secondary to the dilatation. Some think that acute dilatation occurs only in those with atonic stomachs. Others regard it as due to lack of adrenalin or to toxic influence upon muscular fiber. We do know that neurotics and the victims of gastric disease are predisposed, that the anesthetic is a danger (chloroform being more dangerous than ether), that early feeding or giving of much liquid during the first few hours after operation may be an exciting cause, that a person who is predisposed is insatiably thirsty and hence that great thirst is a sign of danger, that the condition never occurs unless the stomach is full of fluid or gas and that slight conditions of dilatation are very common but pass away in from twelve to twenty-four hours.

It seems probable that some cases of gastric dilatation are associated with mesenteric constriction of the duodenum, brought about by the intestines descending into the pelvis. The constriction inaugurates the dilatation and is aggravated by the dilatation. Conner points out that the intestines enter the pelvis as a result of dorsal decubitus, a long mesentery, and a gut nearly empty of gas and feces, and that this condition is favored by relaxation of the belly wall ("Jour. Am. Med. Assoc.," March, 1907).

Symptoms.—Violent, profuse, gushing vomiting is most frequent and the most prominent symptom; it inaugurates the attack and continues throughout the illness, although occasionally it ceases for some time before death. The amounts vomited are always large and often enormous. The vomitus is thin and of a green or black hue, usually contains bile and sometimes a little blood, but very seldom feces.

In most cases, but not in all, there is epigastric or umbilical pain and tenderness. Distention is the rule. Rigidity is rare. In many cases there is no passage of gas or feces, but in some diarrhea exists. There is great thirst, there may be hiccup, and delirium may arise before death. The temperature

is nearly always normal or below normal. There is seldom visible gastric peristalsis (Conner, Ibid.), and splashing sounds are obtainable over the stomach.

Collapse arises early and quickly becomes profound. Tetany occasionally occurs. A case of my own died of acute gastric dilatation after an operation for stone in the kidney. He suddenly developed attacks of violent and profuse vomiting, rapidly went into collapse, lividity developed and hiccup arose, and he died in forty-eight hours.

A case may die in less than twenty-four hours or may die after ten days or more. Conner's group of cases shows a mortality of 72.5 per cent. Fluid cannot reach the small intestine, and as none is absorbed from the stomach and little from the duodenum, the tissues starve for the want of it (Laffer, in "Annals of Surgery," April, 1908). The condition is frequently diagnosticated acute intestinal obstruction or peritonitis from perforation.

Treatment.—When the stomach has dilated greatly and when collapse is profound, treatment is usually of no avail. When an early diagnosis is made treatment is often of the greatest value. The stomach must be at once emptied by the use of a tube and the treatment be repeated at intervals of a few hours. Neither food nor drink should be given by the mouth. Saline enemata and perhaps nutritive and stimulating enemata should be given. The patient should at once be placed upon the belly and kept there with occasional changes to the knee-chest or left lateral prone position until the condition abates, in the hope that this posture will relieve duodenal constriction.

Gastro-enterostomy has been employed, and is advocated by Mayo Robson. Byron Robinson had a recovery after operation. In a number of cases the stomach has been opened and washed out without benefit. Petit opened the abdomen and discovered a kink at the junction of the duodenum and jejunum; he raised the jejunum and sutured it to the transverse colon and the patient recovered (Conner, "Jour. Amer. Med. Assoc.," March, 1907). I cannot see how gastro-enterostomy can drain an acutely dilated stomach. The atonic muscles must be helpless in forcing stomach contents through the new exit.

Not until we know definitely the cause or causes of acute dilatation of the stomach will we be able to lay down with precision and accuracy the treatment which is indicated. There is much difference of opinion as to the causation of the condition, and widely different methods of treatment are advocated by various surgeons.
